More rapid methods of detection of drug resistance are now available. The WHO recommends that rapid methods of drug susceptibility testing for INH and rifampin or rifampin alone be used over conventional testing. The Xpert MTB/RIF test described previously correctly identified 98% of rifampin resistance. Since rifampin resistance rarely occurs in isolation and is generally accompanied with INH resistance, rifampin resistance frequently indicates MDR TB. Thus, Xpert MTB/RIF can provide a presumptive diagnosis of MDR TB within 2 hours. Unlike the Xpert MTB/RIF, other molecular methods are able to identify mutations in the *M. tuberculosis* genome that confer resistance to multiple agents. Line-probe assays like the Genotype MTBDR*plus* (Hain Lifesciences, Nehren, Germany) can detect mutations that confer resistance to rifampin and INH whereas the MTBDRsi test also can identify resistance to fluoroquinolones, aminoglycosides, and ethambutol. In the United States, the Molecular Detection of Drug Resistance program at the Centers for Disease Control and Prevention (CDC) uses DNA sequencing to identify mutations that confer resistance to rifampin, INH, fluoroquinolones, kanamycin, amikacin, and capreomycin. With previous authorization, this service accepts and tests isolates from patients at particularly high risk for MDR or XDR TB.

TREATMENT

Identifying and treating patients with TB is the most effective way of preventing transmission in the community. TB must be treated with at least two drugs to which the organism is susceptible, to prevent the emergence of drug resistance. Dosages

Table 31-2 First-Line Antituberculosis Drug Regimens for Adults and Children

		Doses			
Drug	**Preparation**	**Daily**	**1×/wk**	**2×/wk**	**3×/wk**
Isoniazid	Tablets (50 mg, 100 mg, 300 mg); elixir (50 mg/5 mL); aqueous solution (100 mg/mL) for intravenous or intramuscular injection	*Adults* (max.):			
		5 mg/kg (300 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)
		Children (max.):			
		10-15 mg/kg (300 mg)	—	20-30 mg/kg (900 mg)	—
Rifampin	Capsule (150 mg, 300 mg); powder may be suspended for oral administration; aqueous solution for intravenous injection	*Adults* (max.):			
		10 mg/kg (600 mg)	—	10 mg/kg (600 mg)	10 mg/kg (600 mg)
		Children (max.):			
		10-20 mg/kg (600 mg)	—	10-20 mg/kg (600 mg)	—
Rifabutin	Capsule (150 mg)	*Adults* (max.):			
		5 mg/kg (300 mg)	—	5 mg/kg (300 mg)	5 mg/kg (300 mg)
		Children (max.):			
		Appropriate dosing for children unknown	Appropriate dosing for children unknown	Appropriate dosing for children unknown	Appropriate dosing for children unknown
Rifapentine	Tablet (150 mg, film-coated)	*Adults*:			
		—	10 mg/kg (continuation phase) (600-900 mg)	—	—
		Children:			
		Drug not approved for children	Drug not approved for children	Drug not approved for children	Drug not approved for children
Pyrazinamide	Tablet (500 mg, scored)	*Adults*:			
		20-25 mg/kg (2 g)	—	35-50 mg/kg (4 g)	30-40 mg/kg (3 g)
		Children:			
		15-30 mg/kg (2 g)	—	50 mg/kg (4 g)	—
Ethambutol	Tablet (100 mg, 400 mg)	*Adults*:			
		15-20 mg/kg (1.6 g)	—	35-50 mg/kg (4 g)	20-35 mg/kg (2.5)
		Children:			
		15-20 mg/kg (1 g)	—	50 mg/kg (4 g)	—

of commonly used first-line and second-line drugs are shown in Tables 31-2 and Table 31-3, respectively. In the United States, a regimen consisting of INH and rifampin given for 6 months, plus pyrazinamide for the initial 2 months, is considered standard short-course therapy. Ethambutol should be added to the treatment regimen for the first 2 months of therapy, but once a drug-susceptible isolate has been demonstrated, ethambutol can be stopped (Table 31-4). After the first 2 months of treatment, one of several regimens can be chosen for the continuation phase of treatment. For HIV-negative patients who have a documented negative AFB smear after 2 months of therapy and have no evidence of cavitation on the initial chest radiograph, a once-weekly regimen consisting of rifapentine and INH is effective. The total duration of therapy should be 6 months, but in patients whose 2-month culture remains positive and whose chest radiograph shows evidence of cavitation, the continuation phase should be extended by 3 months, to complete a 9-month treatment course (Figure 31-10).

Some patients may be intolerant of a first-line drug or have underlying drug-resistant disease. In such cases, addition of a second-line drug may be necessary (see Table 31-3). These medications include the fluoroquinolones, PAS, ethionamide, cycloserine, clofazimine, and injectables such as kanamycin, capreomycin, and amikacin. The duration of treatment for drug-resistant TB will be determined by the drugs used, the site, and the extent of the disease. Expert consultation should be obtained for treating drug-resistant TB.

To prevent acquired drug resistance, clinicians must prescribe an adequate regimen and ensure that patients adhere to therapy. Directly observed therapy (DOT) should be used whenever possible. If DOT is not available, combination

		Doses			
Drug	**Preparation**	**Daily**	**1×/wk**	**2×/wk**	**3×/wk**
Cycloserine	Capsule (250 mg)	*Adults* (max.): 10-15 mg/kg/d (1.0 g in two doses), usually 500-750 mg/d in two doses *Children* (max.): 10-15 mg/kg (1 g)	*	*	*
Ethionamide	Tablet (250 mg)	*Adults* (max.): 15-20 mg/kg/d (10 g/d), usually 500-750 mg/d in a single daily dose or two divided doses *Children* (max.): 10-20 mg/kg (1 g)	*	*	*
Streptomycin	Aqueous solution (1-g vials) for intravenous or intramuscular administration	*Adults* (max.):			
		15 mg/kg (1 g)	—	15-20 mg/kg (1.5)	15-20 mg/kg (1.5)
		Children (max.):			
		20-40 mg/kg (1 g)	—	20 mg/kg	—
Amikacin/ kanamycin	Aqueous solution (500-mg and 1-g vials) for intravenous or intramuscular administration	*Adults* (max.):			
		15 mg/kg (1 g)	—	15-20 mg/kg (1.5)	15-20 mg/kg (1.5)
		Children (max.):			
		15-30 mg/kg (1 g)	—	15-30 mg/kg	—
Capreomycin	Aqueous solution (1-g vials) for intravenous or intramuscular administration	*Adults* (max.):			
		15 mg/kg (1 g)	—	15-20 mg/kg (1.5)	15-20 mg/kg (1.5)
		Children (max.):			
		15-30 mg/kg (1 g)	—	15-30 mg/kg	—
Paraaminosalicylic acid (PAS)	Granules (4-g packets) can be mixed with food; tablets (500 mg) are still available in some countries, but not U.S.; a solution for intravenous administration is available in Europe	*Adults* (max.): 8-12 g/d in two or three doses *Children* (max.): 200-300 mg/kg in two to four divided doses	*	*	*
Levofloxacin	Tablets (250, 500, 750 mg); aqueous solution (500-mg vials) for intravenous injection	*Adults/children* (max.): 500-1000 mg daily Optimal dose not known	*	*	*
Moxifloxacin	Tablets (400 mg); aqueous solution (400 mg/250 mL) for intravenous injection	*Adults/children* (max.): 400 mg daily Optimal dose not known	*	*	*

*There are no data to support intermittent administration.

preparations that include INH and rifampin, or INH, rifampin, and pyrazinamide, should be used.

Persons with active untreated pulmonary TB are infectious, particularly those for whom AFB are identified in a sputum specimen. Treatment of TB rapidly renders these patients noninfectious. According to the CDC, patients are not considered infectious if they are on adequate therapy for 2 or more weeks, have a favorable clinical response to therapy, and have three consecutive negative sputum smear results from sputum collected on different days.

SPECIAL CIRCUMSTANCES

Human Immunodeficiency Virus Co-infection

Despite being immunocompromised, HIV-infected patients with TB respond well to regimens containing INH and rifampin. Thus, the current recommendations are to begin the same antituberculosis regimens as used in HIV-seronegative cases. A recent study from San Francisco, however, noted that the relapse rate among HIV-infected patients was 9.3 per 100 person-years versus 1.0 in HIV-uninfected patients or those with unknown

Months

Figure 31-10 Treatment of pulmonary tuberculosis. Patients suspected to have tuberculosis whose chest radiograph (*CXR*) shows no evidence of cavitation and who have negative acid-fast bacilli (*AFB*) sputum smears after 2 months of therapy can be treated in the continuation phase with isoniazid (*INH*) and rifampin (*RIF*) to complete a 6-month duration of therapy. Alternately, they may be treated with INH and rifapentine (*RPT*) administered once weekly. If cultures remain positive after 2 months of therapy, treatment duration should be extended by 3 months. TB suspects who have evidence of cavitation on the chest radiograph or who have a positive AFB smear after 2 months of therapy should be treated with INH and RIF. If the 2-month culture is negative, they can be treated for a total of 6 months. If the 2-month culture is positive and there is no evidence of cavitation on the CXR, they can be treated for 6 months. However, if cavitation is present, the continuation phase should be lengthened by 3 months. *EMB*, ethambutol; *PZA*, pyrazinamide. *(From American Thoracic Society; CDC; Infectious Diseases Society of America: Treatment of tuberculosis,* MMWR Recomm Rep *52[RR-11]:1–80, 2003.)*

serostatus. In addition, HIV-infected patients treated with a 6-month regimen were four times as likely to relapse as those treated longer. Studies have demonstrated that intermittent therapy is also associated with a higher rate of relapse and acquired rifampin resistance. Therefore, HIV-infected patients should not be treated with highly intermittent treatment regimens, particularly if they have advanced HIV disease.

The treatment of TB in HIV-infected patients is more complicated because of the potential for drug interactions between the rifamycins and antiretroviral agents, such as the protease inhibitors and non-nucleoside reverse transcriptase inhibitors (NNRTIs), the risk of an immune reconstitution syndrome, and the propensity to develop acquired drug resistance. The rifamycins are inducers of the cytochrome P-450 pathway (rifampin > rifapentine > rifabutin) and thus can increase the metabolism of some antiretroviral drugs. Some combinations of these drugs are contraindicated, and for other combinations, dosages must be adjusted. Therefore, consultation with an expert in the field is necessary to determine the best treatment regimens for HIV-infected patients with TB.

Antiretroviral treatment should be started for all HIV-infected patients with TB, regardless of $CD4^+$ count. For patients who are antiretroviral-naive, the timing of antiretroviral initiation has been controversial because of the concern for interactions with TB medications and immune reconstitution syndrome. A recent trial in South Africa demonstrated that “integrated” therapy (in which antiretrovirals are started during TB therapy) was associated with a 56% reduction in mortality relative to “sequential” therapy (in which antiretrovirals are started at the completion of TB therapy). A trial in Cambodia compared initiation of antiretrovirals 2 weeks or 8 weeks after starting TB therapy in patients with $CD4^+$ count less than 200 cells/μL. Earlier initiation of antiretrovirals was associated with a 34% reduction in mortality.

Extrapulmonary Tuberculosis

In general, treatment of extrapulmonary TB follows the same principles as those for pulmonary disease. However, both surgery and the use of corticosteroids may be needed more often in extrapulmonary TB. Corticosteroids should be considered in patients with confirmed CNS or pericardial TB. Corticosteroids have been demonstrated to improve the outcomes of tuberculous pericarditis in both acute and later phase disease. In neither setting, however, is there a significant decrease in progression to constriction or need for pericardiectomy. In CNS TB, use of corticosteroids has been shown to decrease the frequency of neurologic sequelae in children. Treatment duration should be prolonged in patients with bone and joint disease to 6 to 9 months and for CNS disease to 9 to 12 months.

Children

Children should be treated with the same regimens as those recommended for adults, but doses should be adjusted appropriately. Although some experts do not recommend the use of ethambutol in children, it seems to be safe and should be used whenever underlying drug resistance is suspected. In addition, some experts recommend increasing the duration of therapy to 9 to 12 months in children with disseminated or meningeal disease. HIV-infected children should receive at least 9 months of therapy.

Pregnancy and Breastfeeding

Pregnant and breastfeeding women with active TB must be treated, because the potential for untreated TB in the fetus or infant is always of greater concern than any small risks associated with therapy. Pyrazinamide currently is not recommended in the United States in pregnant women because of a lack of data regarding teratogenicity, but the drug is recommended by the WHO and the International Union Against Tuberculosis and Lung Disease (IUATLD).

Drug-Resistant Tuberculosis

New guidelines for the programmatic management of drug-resistant TB were recently published by the WHO. The recommendations were formulated on the basis of the results of several large systematic reviews commissioned by the WHO. In patients with MDR TB, four second-line drugs that are likely to be effective, as well as pyrazinamide, should be used in the intensive phase of therapy. Regimens should include pyrazinamide, a later-generation fluoroquinolone, an injectable agent, ethionamide (or prothionamide), and either cycloserine or PAS if cycloserine cannot be used. No second-line parenteral agent was found to be superior to another. Because of its low cost, kanamycin was favored, although amikacin could be used in place of kanamycin. Streptomycin is not recommended. An intensive phase (injectable phase) of at least 8 months’ duration is recommended, with a total duration of at least 20 months. Cure rates for treatment of MDR TB have averaged around 60% to 70% (range of 30% to 95%) in programmatic settings. XDR TB is associated with a high mortality rate and cure rates ranging from 30% to 60%. In view of the complexity of therapy and possible need for surgical resection, experts in the management of drug-resistant TB should be consulted early in the course of therapy.

CLINICAL COURSE AND PREVENTION

MONITORING FOR ADVERSE REACTIONS AND RESPONSE TO THERAPY

All patients receiving antituberculosis therapy must be educated about possible drug-related adverse reactions. The patients should be warned about insignificant side effects, such as the orange discoloration of urine from rifampin, as well as the symptoms of potentially serious side effects. Baseline measurements of hepatic enzymes, bilirubin, serum creatinine, and blood urea nitrogen, as well as a complete blood cell count including platelets, are obtained before initiation of drug therapy. A serum uric acid level is obtained if pyrazinamide is included in the drug regimen. Visual acuity and red-green color discrimination are monitored in patients receiving ethambutol. Although routine laboratory monitoring for drug toxicity may not be necessary, many centers repeat liver function tests after 1 month of therapy and thereafter if symptoms develop or the liver function tests are elevated significantly.

Sputum examinations at monthly intervals are important to monitor response to therapy. Smears and cultures should be negative after 2 to 3 months of therapy. If the sputum smear remains positive after 3 months, the patient must be reevaluated; special attention is given to monitoring adherence and ruling out acquired drug resistance. Drug susceptibility tests are repeated, and the appropriateness of the drug regimen is reassessed.

PREVENTION

The best method of preventing TB is to identify active cases and treat them to cure, thus preventing transmission to others.

Unfortunately, most transmission has occurred before diagnosis and initiation of therapy, so other methods are needed to prevent the development of TB. Two methods are used to do this. The first is to vaccinate patients with the only available TB vaccine, bacillus Calmette-Guérin (BCG). Although BCG is the most widely used vaccine in the world, serious shortcomings with this approach are recognized (as discussed later on). The second is to diagnose LTBI and treat affected patients with antituberculosis drugs to prevent progression to active disease.

DIAGNOSIS OF LATENT TUBERCULOSIS INFECTION

Most people who are infected with *M. tuberculosis* are able to arrest the development of active disease with adequate cell-mediated immunity. As noted previously, however, approximately 10% of infected people have TB develop during their lifetime. Treatment of LTBI is a pillar of TB prevention in lower incidence countries like the United States because treatment can reduce the risk of progression to TB by up to 92%. Testing for LTBI should be targeted at people with clinical and epidemiologic risks for TB (**Figure 31-11**). Until recently, the only method to detect LTBI was the TST. Recently, blood-based assays have been developed that provide an alternative to the TST.

Tuberculin Skin Test

The traditional test to diagnose LTBI for more than 100 years has been the TST. The reaction to intradermally injected tuberculin is a classic example of a delayed-type hypersensitivity reaction, characterized by a peak reaction at 48 to 72 hours marked by induration and, rarely, vesiculation and necrosis. The standard tuberculin test consists of intradermal administration of 0.1 mL (5 tuberculin units) of PPD, usually given in the volar surface of the forearm. Sensitization is induced by infection with *M. tuberculosis* or other cross-reacting mycobacteria antigens. The TST reaction should be read by trained readers 48 to 72 hours after injection. The basis of the reading is the degree of induration present, not erythema.

Symptoms (e.g., fever, cough, weight loss) or abnormal chest x-ray
Evaluate for active TB

Figure 31-11 Flow diagram for screening for latent tuberculosis infection (LTBI). In persons with clinical or epidemiologic risk factors for tuberculosis (TB), a tuberculin skin test (TST) or interferon-γ release assay (IGRA) should be performed. A positive test result warrants clinical evaluation and chest radiograph. If either yields abnormal findings, the patient should be evaluated for the possibility of active TB. If the chest radiograph is normal in appearance, the patient is a candidate for LTBI treatment. If the initial TST reaction or IGRA result is negative but the patient has had contact with infectious cases of TB, treatment may still be indicated.

Over time, delayed-type hypersensitivity resulting from mycobacterial infection may wane in some people, resulting in a nonreactive TST despite the fact that they are truly infected. The stimulus of this initial negative TST reaction in these persons may “boost” or increase the size of the reaction to a second test administered later, resulting in a positive TST reaction and incorrectly suggesting tuberculin conversion. This ability of the TST to recall the waned reactivity is known as the booster phenomenon.

Because of the difficulty in distinguishing boosting (indicating previous infection many years ago) from tuberculin conversion (indicating recent infection), two-step testing is recommended in persons who require annual TSTs and persons older than 55 years of age.

TST is not entirely specific for the diagnosis of infection with *M. tuberculosis* and false-positive tests can occur from either infection with NTM or BCG vaccination. In a patient who has received BCG, the likelihood that a positive TST reaction represents a false-positive result due to BCG rather than LTBI depends on the age at vaccination. In 24 studies that involved almost 250,000 subjects vaccinated in infancy with BCG, only 1% had a positive TST attributable after 10 years. BCG vaccination after infancy had a more significant and lasting impact on the TST reaction. In practice, most clinicians ignore previous BCG vaccination when interpreting the results of TSTs if at least several years have elapsed since the time of vaccination.

Three different thresholds—5, 10, and 15 mm—have been set for defining a positive tuberculin reaction, depending on the individual or population being tested (see Table 31-1). For persons at highest risk for development of TB, a cutoff of 5 mm or more is recommended. This group includes persons known or suspected of being HIV-infected, close contacts of active TB cases, persons with an abnormal-appearing chest radiograph showing fibrosis consistent with previous TB (**Figure 31-12**), and other immunosuppressed patients. A cutoff of 10 mm of induration or greater is classified as positive for people at intermediate risk for TB. The remaining group consists of persons at low risk for TB who have no risk factors. In these persons, TST reactions are classified as positive if the induration is 15 mm or more across; in general, such patients should not be screened.

Recent TST converters also are at high risk for development of TB and have therefore been identified as a high-priority group for treatment of LTBI. In the United States, conversion is defined as an increase in induration of at least 10 mm within a 2-year period.

Interferon-γ Release Assays

As noted previously, there are three new T cell–based tests for the diagnosis of LTBI: QFT-TB Gold, QFT-GIT, and T-Spot.*TB* test. The QFT-TB Gold assays use an ELISA method to measure antigen-specific production of IFN-γ, whereas the T-Spot.*TB* test uses ELISPOT to measure the number of cells that produce IFN-γ. The CDC has recommended that these assays be used in any situation in which the TST is used, whereas the U.K.

National Institute for Clinical Excellence has suggested that the IGRAs be used as confirmatory tests to the TST.

Numerous studies have assessed the test characteristics of these assays by use of different versions of the tests, in different populations, and under different laboratory conditions. Overall, the specificity rates for QFT-GIT, T-Spot.*TB*, and TST are approximately 99.8%, 97.8%, and 88.7%, respectively. Of note, however, a "gold standard" test for LTBI is lacking, so the true test characteristics of these assays are unknown. In studies assessing the correlation with degree of exposure, both IGRAs correlated with exposure better than the TST, and neither was affected by previous BCG vaccination.

The advantages of IGRAs compared with the standard TST are several: These blood-based tests have less cross-reactivity from vaccination with BCG and NTM, are less susceptible to reader variability that occurs with TST interpretation, require only one patient visit to obtain results, and may be more specific for identifying *M. tuberculosis* infection. Additionally, IGRAs may be more predictive of the development of active disease than the TST. The rate of progression to active disease among patients who tested positive for LTBI and who refused preventive therapy has ranged from 2.3% to 3.3% for TST, 2.8% to 14.3% for QFT-GIT, and 3.3% to 10.0% for T-Spot.*TB*.

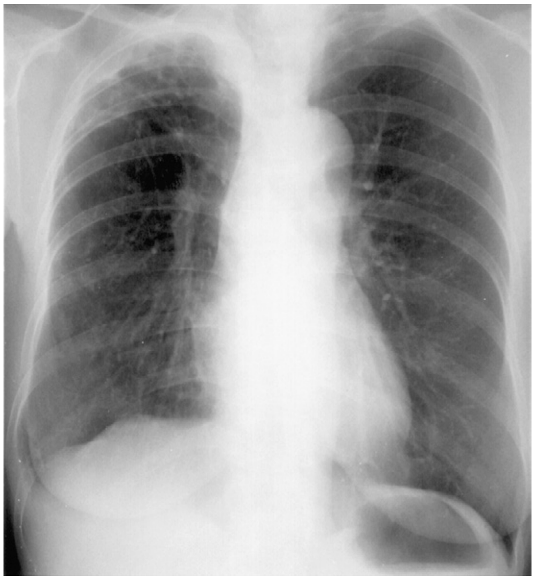

Figure 31-12 Chest radiograph obtained in a patient with previous tuberculosis. Changes include right upper lobe linear and nodular opacities with pleural thickening. In addition, note the elevation of the right hemidiaphragm and superior retraction of the right hilum secondary to volume loss.

TREATMENT OF LATENT TUBERCULOSIS INFECTION

Treatment is not recommended for all persons with LTBI. Instead, therapy should be provided to those persons at higher risk for TB infection and/or TB. For persons who are at increased risk of progressing to disease, treatment of latent infection is indicated, regardless of age. It is critical that patients being considered for LTBI therapy receive a clinical and radiographic evaluation to exclude the possibility of active disease. The two most commonly used drugs for the treatment of LTBI are INH and rifampin (Table 31-5).

INH was evaluated in randomized controlled trials conducted by the United States Public Health Service that included more than 70,000 participants encompassing a variety of populations. In these studies, the effectiveness of the drug compared with placebo in reducing the incidence of active TB averaged approximately 60%, with a range of 25% to 92%, the higher values being associated with better adherence to the drug. On the basis of these studies, the American Thoracic Society (ATS) and the CDC recommend that INH be administered as a single daily dose or twice weekly. Completion of treatment is based on the total number of doses administered and not on duration of therapy alone.

Hepatitis is the most important adverse reaction related to INH. Although liver enzyme abnormalities are relatively common in persons taking INH, symptomatic hepatitis is uncommon. The rate of INH-related hepatitis is estimated to be 1 per 1000 persons and increases with age. The most important cofactor for the development of INH hepatitis is alcohol consumption, so patients should be advised not to drink alcohol when they are taking INH. In addition, all persons taking INH should be educated about the signs and symptoms of hepatitis, including nausea, vomiting, extreme fatigue, abdominal pain, dark urine, and jaundice, so that they can be evaluated before the hepatitis becomes severe.

The other potential side effect of INH is peripheral neuropathy that is caused by interference with the metabolism of pyridoxine. In persons predisposed to neuropathy (such as patients with diabetes, uremia, malnutrition, and HIV infection), in pregnant women, and persons with seizure disorders, pyridoxine (at a dose of 25 or 50 mg/day) should be given concurrently with INH.

Rifampin alone for 4 months is an alternative option for treatment of LTBI although only one large randomized trial has evaluated the efficacy of rifampin monotherapy for LTBI. This trial, conducted among patients with silicosis at extremely high risk for LTBI, found that 3 months of daily rifampin was as efficacious as 6 months of daily INH. Nonetheless, approximately 10% of the patients in each treatment group progressed

Table 31-5 Recommended Drug Regimens for Treatment of Latent Tuberculosis Infection in Adults

Drug	Duration (months)	Dosing Interval	Minimum No. of Doses	Comments
Isoniazid	9	Daily	270	*Preferred*: 9 months of isoniazid *Acceptable alternative*: 6 months of isoniazid OR 4 months of rifampin
		Twice weekly	76	
Isoniazid	6	Daily	180	Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiograph, or children
		Twice weekly	52	
Rifampin	4	Daily	120	For persons who are contacts of patients with isoniazid-resistant, rifampin-susceptible tuberculosis
Rifapentine/ isoniazid	3	Once weekly	12	Newly recommended regimen using directly observed therapy

HIV, human immunodeficiency virus.

to active TB. Subsequent nonefficacy trials indicate that 4 months of daily rifampin monotherapy is associated with fewer serious adverse effects and better rates of treatment completion than 9 months of daily INH. Rifampin alone has a very low rate of hepatotoxicity. Rifampin should be used for patients who are intolerant of INH or who are presumed to have infection with INH-resistant strains of *M. tuberculosis*.

Weekly rifapentine plus INH for 3 months is a third option for treatment of LTBI in low-incidence settings. In 2011, the CDC released results of the PREVENT TB trial, a 10-year multinational study in which more than 8000 patients with LTBI at high risk for progression to active disease were randomized to receive once-weekly, directly observed rifapentine plus INH for 3 months or standard daily self-administered INH for 9 months. The once-weekly rifapentine plus INH group had equivalent efficacy (7 TB cases versus 15 in the INH-only group), was safe and tolerable, and was associated with better adherence (82% completion versus 69% completion in the INH group). A critical point to emphasize is that the PREVENT-TB trial evaluated directly observed rifapentine plus INH, and the effectiveness of this regimen in practice if self-administered is unknown.

CLINICAL MONITORING

Baseline laboratory testing of liver enzymes is not routinely indicated but is recommended in the following patient groups: HIV-infected persons, pregnant women and those within 3 months post partum, patients with a history of liver disease, and persons who use alcohol regularly. Follow-up laboratory testing of liver enzymes is indicated only if baseline liver enzyme tests are abnormal or when symptoms of hepatitis occur. Drugs should be withheld if a patient's serum transaminase level is greater than three times normal if associated with symptoms and five times normal if asymptomatic.

SPECIAL CIRCUMSTANCES

CO-INFECTION WITH HUMAN IMMUNODEFICIENCY VIRUS

All HIV-infected persons should be screened for TB and LTBI. HIV-infected persons with LTBI should receive 9 months of INH once active TB has been ruled out. Rifampin should be used with caution in HIV-infected persons taking PIs or NNRTIs because of drug interactions described previously. In HIV-infected persons taking these antiretroviral drugs who have LTBI, rifabutin (often at an adjusted dose) can be substituted for rifampin in some circumstances.

ABNORMAL-APPEARING CHEST RADIOGRAPHS

In patients with evidence of LTBI who have an abnormal-appearing chest radiograph with parenchymal fibrotic lesions (see Figure 31-12) who have not been previously treated, sputum should be collected to exclude active TB. Once active TB has been excluded, treatment options for LTBI include INH for 9 months and rifampin for 4 months.

PREGNANCY AND LACTATING WOMEN

Although INH can be given safely during pregnancy, most clinicians wait until after delivery to begin treatment for LTBI, unless the woman has HIV infection or has been in known contact with an infectious case.

Infants and Children

Once infected, infants and children younger than 5 years of age are at high risk for progression of the initial infection to active TB and should receive INH for 9 months.

Contacts with Drug-Resistant Cases

Contacts of patients with INH-resistant, rifampin-susceptible TB should be treated with rifampin for 4 months. The treatment of persons in recent contact with an MDR TB case is challenging, however, and needs to be individualized on the basis of the susceptibility pattern of the source patient's organism, the probability that infection has occurred, and risk factors for progression to active TB. Treatment of contacts of patients with MDR TB often entails the administration of two drugs (to which the source case's isolate is susceptible) for 9 to 12 months.

VACCINATION WITH BACILLUS CALMETTE-GUÉRIN

BCG is a live attenuated vaccine derived from a strain of *M. bovis*. BCG is used to vaccinate children and, in some cases, adolescents and adults throughout much of the world. Although the vaccine seems to be protective in children, it confers little protection in adults, who are the ones who usually transmit disease. Data suggest that BCG vaccination decreases the risk of disseminated disease in young children—the primary reason for its use today. In countries in which BCG vaccination was suspended, TB rates did not increase significantly.

As noted previously, BCG vaccination can influence the results of tuberculin skin testing because of cross-reaction with PPD. The effects of BCG vaccination on tuberculin reactivity vary, depending on the specific vaccine used, age at vaccination, and interval between vaccination and skin testing. Despite widespread use of BCG vaccination, it has been difficult to demonstrate significant impact on TB control globally. New vaccines are urgently needed.

DISEASES CAUSED BY NONTUBERCULOUS MYCOBACTERIA

NTM comprise more than 135 different species that are widely distributed throughout the environment. The list of mycobacterial species has grown dramatically over recent years because of the availability of DNA sequencing, and because organisms that differ in sequence by 1% or more from all known species are defined as new species.

The NTM were not widely recognized as a cause of human disease until the late 1950s. In 1959, Runyon reported a classification system that organized NTM organisms into four groups on the basis of microbiologic characteristics, including the formation of pigment and the speed of growth. This system has become less useful with the development of rapid molecular methods of diagnosis, but differentiating NTM species on the basis of their rate of growth is still used today. NTM typically are divided into rapidly and slowly growing species (Table 31-6).

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

EPIDEMIOLOGY

NTM have been isolated from soil and water, including both natural and treated water sources, from throughout the world.

Table 31-6 Clinically Significant Nontuberculous Examples of Mycobacteria by Rate of Growth

Slowly Growing (>7 days of incubation for mature growth)	Rapidly Growing (≤7 days of incubation for mature growth)
Mycobacterium avium	*Mycobacterium fortuitum*
Mycobacterium intracellulare	*Mycobacterium peregrinum*
Mycobacterium kansasii	*Mycobacterium abscessus*
Mycobacterium xenopi	*Mycobacterium massiliense*
Mycobacterium simiae	*Mycobacterium bolletii*
Mycobacterium szulgai	*Mycobacterium chelonae*
Mycobacterium scrofulaceum	*Mycobacterium mucogenicum*
Mycobacterium malmoense	
Mycobacterium haemophilum	
Mycobacterium genavense	
*Mycobacterium marinum**	

*This organism often grows within 7 to 10 days.

Because these organisms do not seem to be transmitted from human to human, the source of human infection is thought to be through environmental exposures. Skin test surveys of U.S. Navy recruits in the 1960s demonstrated higher rates of reactivity in those from the southeastern United States than from the northern states, suggesting higher rates of infection. Studies evaluating antibody to lipoarabinomannin (LAM) have demonstrated anti-LAM antibodies beginning early in life and rapidly rising through age 12.

Epidemiologic data on NTM infections are largely lacking, because unlike TB, NTM infections are not routinely considered reportable to public health authorities. The median rates of pulmonary NTM isolation have been estimated to be approximately 6.2 per 100,000 population in North America, 8.3 per 100,000 in Europe, 15 per 100,000 in Asia, and 7.2 per 100,000 in Australia. Studies from Oregon have reported that the prevalence of NTM infections was higher in females than males (6.4 per 100,000 versus 4.7 per 100,000) and was highest in persons aged more than 50 years (15.5 per 100,000). Among four integrated health care systems in the United States, the annualized prevalence ranged from 1.4 to 6.6 per 100,000 and among persons aged 60 years or more, the annualized prevalence was 26.7 per 100,000.

Recent data support the view that the incidence of NTM infections is increasing. Studies from Canada, Australia, Taiwan, the Netherlands, and the United States have reported increases in the incidence or prevalence of NTM. In a retrospective cohort review from 1997 to 2003 in Ontario, Canada, 222,247 pulmonary isolates from 10,231 patients were identified. The prevalence was 9.1 per 100,000 in 1997 and increased to 14.1 per 100,000 by 2003 ($P < .0001$), with an average annual increase of 8.4%. Increases were noted among *Mycobacterium avium* complex (MAC), *Mycobacterium xenopi*, rapidly growing mycobacteria, and *Mycobacterium kansasii*. Of note, the rate of TB declined 4.0% over the study period. Of 200 patients who were evaluated in more detail, 33% fulfilled the clinical, radiologic, and bacteriologic ATS criteria. In the United States, pulmonary hospitalizations for NTM infections increased significantly among both males and females between 1998 and 2005.

The most common pathogenic NTM vary geographically. MAC is the most common cause of NTM-related pulmonary disease in almost all studies. The next most common NTM species depends on the origin of reported data. For example, in the United States, *M. kansasii* is the second most common cause of pulmonary disease, followed by *Mycobacterium abscessus*. In Canada, and some parts of Europe, *M. xenopi* is the second most common, whereas in northern Europe and Scandinavia, *Mycobacterium malmoense* is second.

RISK FACTORS

Skin test reactivity to mycobacterial antigens has ranged in prevalence from 11% to 33% in the United States. Predictors of skin test reactivity have included residence in the southeastern region of the country, male gender, black race, birth outside of the United States, and degree of soil exposure. Of note, however, many of the patients who develop pulmonary disease related to NTM do not have these characteristics. For example, patients with the nodular-bronchiectatic form of pulmonary disease (see "Pulmonary Disease" further on) frequently are white, postmenopausal women who were born in the United States.

Patients who have pulmonary infections caused by NTM often have structural lung disease such as chronic obstructive pulmonary disease, bronchiectasis, cystic fibrosis, pneumoconiosis, previous TB, alveolar proteinosis, and chronic aspiration. A study from France noted that more than 50% of the patients who met ATS disease criteria (except for those with *M. kansasii*) had underlying predisposing factors such as preexisting pulmonary or immune deficiency. HIV-infected patients and those with abnormalities in the IFN-γ or interleukin-12 (IL-12) pathways are predisposed to severe NTM infections.

PATHOGENESIS

Although little is known about the pathogenesis of NTM infections, several observations have provided some insight into this disease. First, in HIV-infected patients, disseminated NTM infections typically occur only after the $CD4^+$ lymphocyte count falls below 50 cells/μL, suggesting that specific T cell products or activities are required for mycobacterial resistance. Second, in HIV-uninfected patients, certain genetic syndromes have been identified that are associated with disseminated NTM infections. These syndromes have been traced to mutations in IFN-γ and IL-12 synthesis and response pathways. Third, a striking association has been noted among bronchiectasis, nodular pulmonary NTM infections, and a particular body habitus, predominantly in postmenopausal women. In the last instance, it remains to be seen whether or not these women have some sort of subtle immune deficiency that predisposes them to NTM pulmonary infections, or whether their predisposition is related to ineffective mucociliary clearance or poor tracheobronchial secretion drainage. Investigators have hypothesized that decreased leptin, increased adiponectin, and/or decreased estrogen may account for the increased susceptibility in these latter patients. In addition, in those with the distinctive morphotype, abnormalities in fibrillin have been hypothesized to further increase the susceptibility to NTM infections through expression of the immunosuppressive cytokine tumor growth factor-β.

NTM do not seem to live in a state of dormancy like that for *M. tuberculosis*. Moreover, unlike with TB, simply isolating an NTM from a respiratory specimen does not mean that the patient has NTM-related disease. For years the term *colonization* has been used to describe the infective status of patients who have a single or small number of positive cultures over time and in whom progressive disease cannot be demonstrated. With longer follow-up, however, many of these patients do, in fact, demonstrate clinical and/or radiographic progression of disease, so it may be more appropriate to think of these patients as having indolent infection.

GENETICS

The genetics of NTM infection are not well understood. Studies from Japan and South Korea have not found an association of such infections with mutations in genes encoding IFN-γ, IL-12, or HLA. However, associations with NTM pulmonary disease and mutations in the major histocompatibility complex class I chain–related A (MICA) gene and natural resistance-associated macrophage protein 1 gene (*Nramp1*) have been reported. The role of Toll-like receptor-2 remains controversial.

CLINICAL FEATURES

The most common clinical manifestation of NTM infection is chronic lung disease. However, lymphatic, skin or soft tissue, and bone or joint involvement, as well as disseminated disease, also is important. The propensity for a specific manifestation varies with the NTM species and certain host factors. For example, HIV-infected patients typically are seen with disseminated disease caused by *Mycobacterium avium*, whereas elderly white women often have pulmonary disease caused by *Mycobacterium intracellulare*.

PULMONARY DISEASE

Chronic pulmonary disease is the most common clinical presentation of NTM disease, and patients usually present with chronic cough, fatigue, malaise, dyspnea, fever, hemoptysis, chest pain, and weight loss. Patients should be evaluated for possible gastroesophageal disorders that lead to aspiration, lipoid pneumonia, cystic fibrosis, and α_1-antitrypsin anomalies. Physical examination may identify certain morphologic characteristics in postmenopausal women, and occasionally men, that include thin body habitus, scoliosis, pectus excavatum, and mitral valve prolapse.

NTM pulmonary infections manifest with two prototypical radiographic patterns: fibrocavitary disease, consisting of upper lobe opacities with cavities and volume loss, and nodular bronchiectatic disease, consisting of nodules and bronchiectasis. Classically, *fibrocavitary disease* was recognized in older men with underlying lung disease (**Figure 31-13**). This radiographic pattern mimics that of TB, and NTM infection frequently is identified in the course of evaluation for TB. By contrast, *nodular bronchiectatic disease* typically occurs among women without known structural lung disease. Chest radiographs reveal opacities in the middle and lower lung fields. High-resolution CT scans demonstrate bronchiectasis often in the middle lobe and lingula, with evidence of small noncavitating nodules, centrilobular in location (**Figure 31-14**). It is important to recognize that there is a great deal of overlap between the two classic radiographic presentations and between the patterns of disease produced by the various NTM species.

Patients with *M. kansasii* infection usually present with upper lobe cavitary opacities, and the cavities typically are thin-walled (**Figure 31-15**). The chest radiograph in patients with rapidly growing mycobacterial infections usually shows multilobar, patchy, reticulonodular or mixed interstitial alveolar opacities, with an upper lobe predominance (**Figure 31-16**). Cavitation is reported to occur in 15% to 40%. High-resolution CT scans will show bronchiectasis and small nodules, similar to those in MAC infection.

LYMPHADENITIS

In children, the most common form of NTM disease is cervical lymphadenitis. *M. avium* is the most common etiologic agent, accounting for 80% of culture-proven cases. *Mycobacterium scrofulaceum* is the second most common cause of lymphadenitis in the United States and Australia, whereas *M. malmoense* and *Mycobacterium haemophilum* are in Scandinavia, the United Kingdom, and other areas of northern Europe. *M. tuberculosis* is isolated in only 10% of cases of culture-proven mycobacterial cervical lymphadenitis in the United States, but in adults, 90% are due to TB.

Infection usually involves the submandibular, submaxillary, cervical, and preauricular lymph nodes in children between 1 and 5 years of age. The disease is of insidious onset and is rarely associated with systemic symptoms. Involvement of the lymph nodes usually is unilateral, and affected tissue is nontender. The lymph nodes may enlarge and eventually rupture, producing sinus tracts just as in tuberculous lymphadenitis. Diagnosis

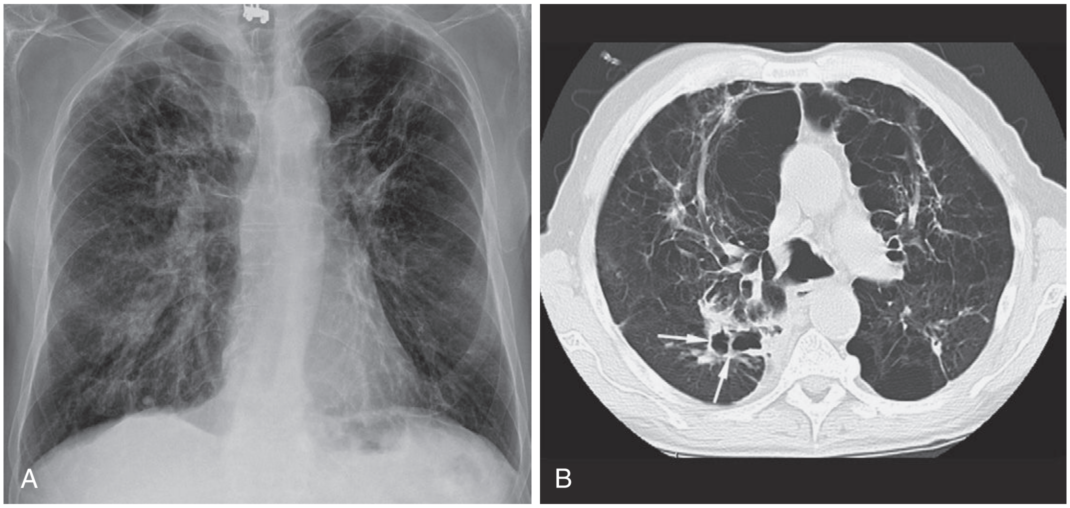

Figure 31-13 **A,** Chest radiograph obtained in a patient with upper lobe emphysema and severe lung disease caused by *Mycobacterium avium* complex. **B,** Chest computed tomography from the same patient demonstrates severe emphysema with cavitation posteriorly (*arrows*) in the right lower lobe.

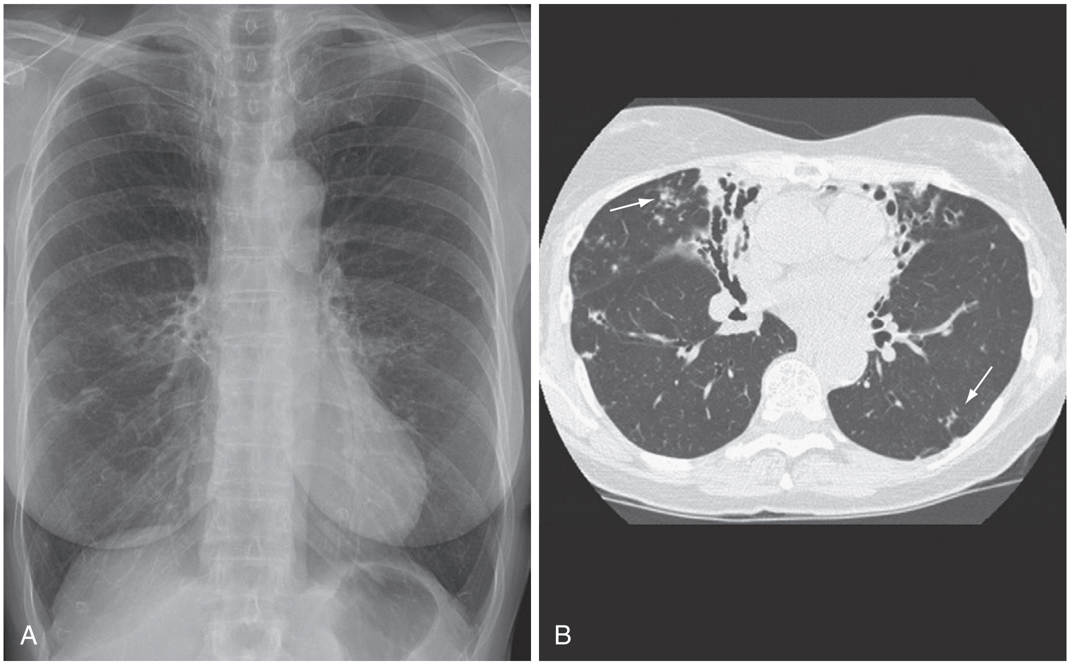

Figure 31-14 **A,** Chest radiograph showing right middle lobe and lingular bronchiectasis in a patient with *Mycobacterium avium* complex and *Mycobacterium simiae* infection. **B,** Chest computed tomography from the same patient demonstrating bronchiectasis in the right middle lobe and lingula. Note also the nodular opacities and tree-in-bud opacities (*arrows*).

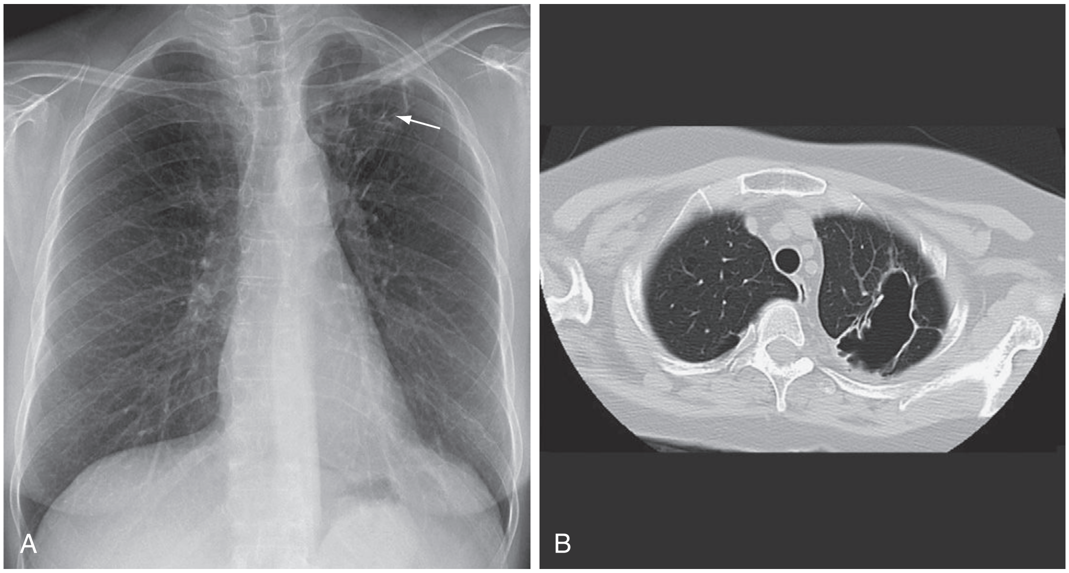

Figure 31-15 **A,** Chest radiograph showing a thin-walled cavity (*arrow*) in the left upper lobe caused by infection with *Mycobacterium kansasii.* **B,** Chest computed tomography from the same patient demonstrating a thin-walled cavity in the left upper lobe.

usually is made by fine needle aspiration or surgical excision of the involved lymph nodes. Only 50% to 82% of excised nodes will be culture positive. Treatment for most cases of NTM-related cervical lymphadenitis is surgical excision.

SOFT TISSUE, SKIN, AND BONE INFECTIONS

Although virtually any NTM can cause skin, soft tissue, and bone infections, the most common species to do so are the rapid growers *Mycobacterium marinum* and *Mycobacterium ulcerans.* Rapid growers often produce infections at the site of punctures or surgery. Joint and bone infections have occurred after surgery and traumatic injuries. Tissue biopsy is the most sensitive way to diagnose these infections.

DISSEMINATED INFECTIONS

Disseminated infections are most commonly associated with HIV infection and other forms of severe immunosuppression. More than 90% of reported cases of disseminated infection in HIV-infected patients are due to MAC, and almost all of these are due to *M. avium*. The next most common cause of disseminated NTM disease in HIV-infected patients is *M. kansasii*, but a number of other species also have been implicated. Most patients have advanced HIV disease at clinical presentation and complain of fever, night sweats, and weight loss. Abdominal pain and diarrhea also may be reported. In non–HIV-infected patients, fever of unknown origin is a common presentation. Diagnosis usually is through detection of the causative

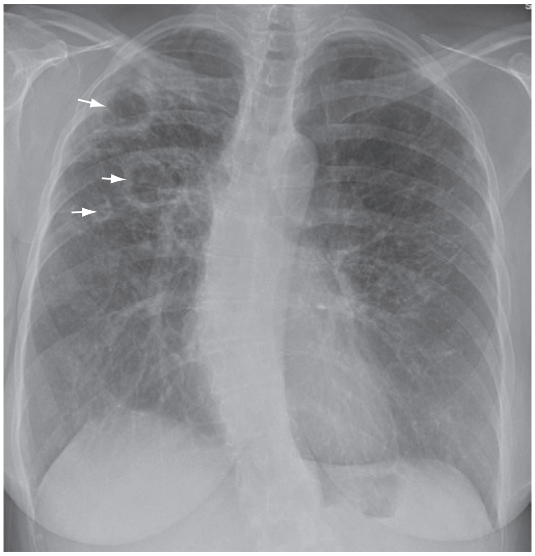

Figure 31-16 Chest radiograph obtained in a patient with infection caused by *Mycobacterium abscessus*. Note the multiple cavities (*arrows*), diffuse nodular opacities, and kyphoscoliosis.

organism in the blood. In HIV-infected patients, *M. avium* can be isolated in more than 90% of cases.

DIAGNOSIS

INTEGRATION OF CLINICAL, MICROBIOLOGIC, AND RADIOGRAPHIC DATA

Patients suspected of having a NTM infection should be evaluated with a chest radiograph or high-resolution CT, or both, particularly in the absence of evidence of cavitation on the radiograph. If radiographic abnormalities are consistent with an NTM infection, at least three sputum specimens should be obtained for AFB examination and mycobacterial culture. TB, as well as other disorders, should be excluded.

To diagnose NTM infection, the clinician must weigh clinical, bacteriologic, and radiographic information (Box 31-1). NTM pulmonary infections should be suspected when a patient presents with a compatible clinical picture and nodular or cavitary opacities on the chest radiograph or multifocal bronchiectasis with multiple small nodules on a high-resolution CT scan. In addition to these clinical criteria, the patient should have at least two positive cultures from separate sputum specimens or a positive culture from at least one bronchial wash or lavage procedure. Additional diagnostic criteria include transbronchial or other lung biopsy specimens with mycobacterial histopathologic features and culture-positive for NTM, or a biopsy specimen showing mycobacterial histopathologic features and one or more sputum or bronchial washings that are culture-positive. In patients who do not meet the preceding definition for disease, close follow-up is indicated, because many will demonstrate progression over time.

Box 31-1 Clinical and Microbiologic Criteria for Diagnosis of Lung Disease Due to Nontuberculous Mycobacteria

Clinical*

1. Pulmonary symptoms, nodular or cavitary opacities on the chest radiograph, or multifocal bronchiectasis with multiple small nodules on a high-resolution computed tomography scan
   AND
2. Appropriate exclusion of other diagnoses

Microbiologic

1. Positive culture results from at least two separate expectorated sputum samples. If results are nondiagnostic, consider repeat sputum acid-fast bacilli (AFB) smears and cultures.
   OR
2. Positive culture result from at least one bronchial wash or lavage.
   OR
3. Transbronchial or other lung biopsy with mycobacterial histopathologic features (granulomatous inflammation or AFB) and positive culture for nontuberculous mycobacteria (NTM) or biopsy showing mycobacterial histopathologic features (granulomatous inflammation or AFB) and one or more sputum or bronchial washings that are culture-positive for NTM.

*Presence of both clinical criteria is required.

Modified from Griffith DE, Aksamit T, Brown-Elliott BA, et al; ATS Mycobacterial Diseases Subcommittee, American Thoracic Society; Infectious Diseases Society of America: An official ATS/IDSA statement: diagnosis, treatment, and prevention of nontuberculous mycobacterial diseases, *Am J Respir Crit Care Med* 175:367–416, 2007.

LABORATORY DIAGNOSIS

The same methods that are used to stain and grow *M. tuberculosis* are used for NTM. Both solid and liquid culture media support growth of the NTM, and both are recommended for use in the clinical laboratory. Although cultures in broth media have a higher yield and provide a more rapid result, they do not allow for observation of colony morphology, growth rates, and recognition of mixed cultures, as do solid media. For most mycobacteria, the optimum temperature for growth is 28° to 37° C, and most clinically significant NTM organisms grow at 35° to 37° C. However, some NTM species—*M. marinum*, *Mycobacterium chelonae*, *M. ulcerans*, and *M. haemophilum*—require lower temperatures for optimum growth. Others, such as *M. xenopi*, grow best at higher temperatures. Some species require special media, such as iron or heme for *M. haemophilum* and mycobactin J for *Mycobacterium genavense*. Most NTM organisms grow within 2 to 3 weeks on subculture, but it may take up to 8 to 12 weeks to grow *M. ulcerans* and *M. genavense*. Rapidly growing mycobacteria usually grow within 7 days on subculture.

Species identification can be performed biochemically or, more commonly, with high-performance liquid chromatography (HPLC), genetic probes, and/or 16S ribosomal DNA sequencing. Genetic probes are commercially available only for *M. tuberculosis*, *M. kansasii*, *M. avium*, *M. intracellulare*, and *Mycobacterium gordonae*. These probes have a sensitivity of between 85% and 100%, with a specificity of 100%. HPLC is a practical and rapid way to detect differences in mycolic acid content between NTM species, although this method cannot differentiate some species of NTM. DNA sequence analysis is able to differentiate strains on the basis of two hypervariable sequences.

An alternative approach to the clinical problems of rapidly distinguishing pulmonary MAC infection from TB and distinguishing MAC disease from MAC colonization has been proposed by Japanese investigators who have developed an enzyme immunoassay (EIA) for a MAC-specific glycopeptidolipid. This assay identified MAC pulmonary disease with 84% sensitivity and 100% sensitivity. Although promising, this assay is not widely available and awaits validation in additional clinical cohorts.

DRUG SUSCEPTIBILITY TESTING

The role of in vitro susceptibility in management of patients with NTM disease is controversial because, with the few specific exceptions mentioned further on, in vitro susceptibility results are not demonstrated to correlate with clinical response to therapy. This is in contrast with *M. tuberculosis*, for which susceptibility results have clear clinical implications.

Macrolide resistance in MAC infection is an important instance in which susceptibility results have prognostic and therapeutic implications. Development of macrolide resistance is associated with azithromycin or clarithromycin monotherapy and portends a poor prognosis. Macrolide resistance is an indication for aggressive therapy including the use of an aminoglycoside and surgical resection if feasible. Current ATS guidelines recommend clarithromycin testing for new, previously untreated MAC isolates, those who fail macrolide-based treatment regimens, or prophylaxis regimens.

Rifampin resistance among previously untreated *M. kansasii* isolates represents a second instance in which in vitro susceptibility informs management, because rifampin resistance has been correlated with poor outcomes. Isolates resistant to rifampin also should be tested against rifabutin, ethambutol, isoniazid, clarithromycin, fluoroquinolones, amikacin, and sulfonamides.

The role of testing for macrolide susceptibility with *M. abscessus* is unclear. *M. abscessus* isolates routinely appear to be macrolide-susceptible on in vitro testing but patients with *M. abscessus* infections are noted to have poor clinical responses to macrolides. This discrepancy may be explained with discovery of the *M. abscessus erm(41)* gene, which confers inducible macrolide resistance. A subset of isolates classified as *M. abscessus* on routine testing are shown with molecular methods to be *Mycobacterium massiliense. M. massiliense* has a deletion in the *erm(41)* gene that makes it nonfunctional, and a better clinical response to macrolide-based therapy was demonstrated in patients infected with *M. massiliense* than in those infected with *M. abscessus.*

In summary, because NTM susceptibility results do not always correlate with clinical response and interpretation differs for different organisms, results should be interpreted with caution and, if possible, in consultation with clinicians expert in the care of NTM infections.

TREATMENT

When the patient's culture specimen grows *M. tuberculosis*, treatment is always indicated, assuming that the isolate was not due to laboratory cross-contamination. With NTM infections, however, isolation should not always lead to treatment. The decision to treat is based on the potential risks and benefits for the individual patient. Thus, management of patients with NTM infections is complicated and requires a great deal of individualization of therapy. In addition, because in vitro susceptibility results for many NTM species do not correlate well with clinical response to antimicrobial therapy, clinicians should use such data with a clear understanding of the limitations.

PULMONARY INFECTIONS

***Mycobacterium avium* Complex**

Before the availability of the newer macrolides, the long-term cure rate for patients treated with antituberculosis regimens was approximately 50%. Small, noncomparative studies of azithromycin- and clarithromycin-containing regimens suggest higher bacteriologic response rates, but long-term follow-up data often are lacking. The ATS currently recommends that the treatment regimen be based on the presence or absence of cavitary disease and whether or not the patient has been treated previously (Table 31-7). For patients with noncavitary nodular bronchiectasis disease, a three-times-a-week regimen may be considered. For patients with cavitary or advanced disease and

Table 31-7 Nontuberculous Mycobacteria and Recommended Therapy

Common Etiologic Agents	Recommended Antimicrobial Therapy	Other Etiologic Mycobacterial Species
M. avium complex		*M. simiae* *M. szulgai* *M. celatum* *M. asiaticum* *M. haemophilum* *M. smegmatis* *M. chelonae* *M. fortuitum* *M. scrofulaceum* *M. shimodei*
Nodular bronchiectasis	Clarithromycin 1000 mg 3×/wk OR azithromycin 500-600 mg 3×/wk; rifampin 600 mg 3×/wk; ethambutol 25 mg/kg 3×/wk	
Cavitary disease	Clarithromycin 1000 mg daily OR azithromycin 250 mg daily; rifampin 450-600 mg daily; ethambutol 15 mg/kg daily Also consider amikacin 15 mg/kg (for the first 2-3 mo) 3×/wk	
Previously treated	Clarithromycin 1000 mg daily OR azithromycin 250 mg daily; rifampin 450-600 mg daily OR rifabutin 150-300 mg daily; amikacin 15 mg/kg (for the first 2-3 months) 3×/wk	
M. kansasii	Isoniazid 300 mg/day; rifampin 600 mg/day; ethambutol 15 mg/kg/day Can add aminoglycoside in severe disease	
M. abscessus	Clarithromycin 1000 mg/daily OR azithromycin 250 mg/daily; cefoxitin max. 12 g/d divided in 3-4 doses/day OR imipenem 500-1000 mg q8-12 h PLUS amikacin 15 mg/kg 3×/wk	
M. xenopi	Clarithromycin 1000 mg daily OR azithromycin 250 mg daily; rifampin 450-600 mg daily; ethambutol 15 mg/kg daily Also consider isoniazid and/or amikacin 15 mg/kg (for the first 2-3 mo) 3×/wk	
M. malmoense	Clarithromycin 1000 mg daily OR azithromycin 250 mg daily; rifampin 450-600 mg daily; ethambutol 15 mg/kg daily	

in those who have been treated previously, daily therapy is recommended. An aminoglycoside should be considered in patients, at least for the first 2 to 3 months of therapy, if they have cavitary disease or if previous treatment has failed. Surgery should be considered in patients in whom the infection is due to a macrolide-resistant strain of MAC, in whom treatment has failed, or in whom cavitary disease is localized and potentially resectable.

Mycobacterium kansasii

Patients with lung disease caused by *M. kansasii* should be treated with INH, rifampin, and ethambutol (see Table 31-7). Substitution of clarithromycin for INH has been associated with good short-term outcomes, and in one study, no relapses were seen at follow-up evaluation after 46 months. As with other NTM infections, the treatment duration should encompass 12 months of negative sputum cultures. For patients whose isolate is resistant to the rifamycins, a three-drug regimen is recommended on the basis of data for in vitro susceptibility to clarithromycin or azithromycin, moxifloxacin, ethambutol, sulfamethoxazole, or streptomycin. Surgical resection is almost never necessary in patients infected with *M. kansasii*.

Mycobacterium malmoense

Mycobacterium malmoense is the second most common cause of pulmonary NTM disease in some areas of northern Europe. The clinical relevance of *M. malmoense* seems to vary, because 70% to 80% of the European patients in whom *M. malmoense* is isolated meet ATS criteria for disease, whereas in the United States, this organism rarely causes pulmonary disease.

Current recommendations are to treat *M. malmoense* pulmonary disease with two to four drugs including ethambutol and rifampin. In a randomized clinical trial conducted by the British Thoracic Society, a regimen consisting of clarithromycin, ethambutol, and rifampin had a more favorable outcome than a regimen containing ciprofloxacin instead of the macrolide. However, overall mortality was not different between regimens.

Mycobacterium xenopi

M. xenopi is one of the most common causes of NTM lung disease in Canada, the United Kingdom, and some parts of Europe. Disease usually occurs in persons with underlying lung disease and often is cavitary at the time of clinical presentation. The optimal treatment is not known. In the British Thoracic Society clinical trial just described, the same two treatment regimens were evaluated in patients with *M. xenopi* pulmonary disease. No differences were noted in the treatment success, failure, or relapse rates. All-cause mortality was high and slightly greater in the ciprofloxacin-containing regimen. With use of various treatment regimens, 58% of patients with lung disease due to *M. xenopi* were cured in a report from the Netherlands. Current recommendations are to treat patients with ethambutol, rifampin, and a macrolide, with the possible addition of INH and an aminoglycoside for severe disease.

Rapidly Growing Mycobacteria

M. abscessus is the third most frequently encountered NTM respiratory pathogen in the United States and accounts for 80% of cases of lung disease due to rapidly growing mycobacteria. Treatment outcomes with *M. abscessus* generally are poor, in part because the organism is susceptible to only a few antimicrobials, including the macrolides, imipenem, cefoxitin, amikacin, tigecycline, clofazimine and occasionally linezolid. In vitro susceptibility testing is recommended for selection of a treatment regimen. As noted previously, although *M. abscessus* may be macrolide-susceptible in vitro, induction of the *erm(41)* gene may result in clinical resistance. The impact of such resistance on the efficacy of the treatment regimen is unknown, so macrolides are still recommended for treatment. Unfortunately, no antibiotic regimen has demonstrated predictable long-term sputum conversion in patients with pulmonary disease. Recent studies from South Korea and the United States reported culture conversion rates of at least 12 months in approximately 50% to 60% of patients. Current recommendations are to provide periodic drug administration of multidrug therapy, including a macrolide, and one or more parenteral agents such as amikacin, cefoxitin, or imipenem for 2 to 6 months to help control symptoms and prevent progression (see Table 31-7). For patients who are good candidates, surgical resection should be considered but only if done by an experienced surgeon and after a period of intensive antimicrobial therapy. In two studies, outcomes were better in patients who underwent surgical resection in addition to antimicrobial therapy.

M. chelonae typically is susceptible to tobramycin, macrolides, linezolid, imipenem, and amikacin and may demonstrate susceptibility to fluoroquinolones and doxycycline. Isolates usually are resistant to cefoxitin. Treatment should consist of at least two drugs to which in vitro drug susceptibility has been demonstrated. The duration should be for at least 12 months of culture negativity.

Mycobacterium fortuitum isolates typically are susceptible to newer macrolides, fluoroquinolones, doxycycline, minocycline, sulfonamides, cefoxitin, and imipenem. As with *M. abscessus*, however, *M. fortuitum* harbors an *erm* gene, so the clinical efficacy of macrolides is uncertain. Therapy should be with at least two agents with in vitro activity for at least 12 months of culture negativity.

LYMPHADENITIS

Cervical lymphadenitis usually is caused by MAC or *M. scrofulaceum* infection. Surgical excision of the involved lymph nodes without chemotherapy usually is curative, with success rates of approximately 95%. In patients who have surgical excision fail, a macrolide-based treatment regimen with or without repeat excision is usually successful.

SKIN, SOFT TISSUE, AND BONE/JOINT INFECTIONS

For most patients with MAC infection, a combination of surgical excision plus multidrug chemotherapy is usually successful. The optimal duration of therapy is not known but probably should be 6 to 12 months. For serious infections caused by rapidly growing mycobacteria, a newer macrolide should be combined with a parenteral medication (amikacin, cefoxitin, or imipenem) or perhaps another oral agent in the case of *M. fortuitum* infection. Therapy should continue for a minimum of 4 months for skin infections and at least 6 months for bone infections. Surgery generally is indicated for extensive disease, and removal of foreign objects such as breast implants, percutaneous catheters, and joint prostheses will be necessary.

DISSEMINATED INFECTIONS

Treatment of disseminated MAC infection in HIV-infected patients should include clarithromycin, 500 mg twice daily, and ethambutol, 15 mg/kg daily with or without rifabutin 300 mg, once daily. Azithromycin, 500 mg daily, could be used as an alternative to clarithromycin. Treatment should be considered to be lifelong, unless immune restoration is achieved by antiretroviral therapy. Anti-MAC treatment can be stopped for patients who are asymptomatic and have achieved a CD4$^+$ lymphocyte count of more than 100 cells/μL for at least 12 months. Prophylaxis should be reintroduced if the count falls below 100 cells/μL.

The treatment for disseminated disease caused by *M. kansasii* is the same as for pulmonary disease. Unlike with MAC infection, no effective prophylactic regimen is available.

CLINICAL COURSE AND PREVENTION

The clinical course will depend on the specific species of NTM causing disease, the severity and extent of disease, and the treatment regimen used. Untreated *M. kansasii* infection usually is progressive, much like TB. With appropriate treatment, however, almost all patients respond well, and both treatment failure and relapse are uncommon. Untreated MAC pulmonary disease is quite variable in its progression. In some patients, progression can be seen over a matter of months, and in others, it may take years to demonstrate progressive disease. Treatment responses in MAC infections also are variable, with cure rates ranging from 60% to 85%. Genotyping data suggest that reinfection is common in women with nodular bronchiectasis, so a patient in whom cure is achieved may become infected again. The clinical course of untreated *M. abscessus* infection generally is slow and progressive, but more rapidly progressive presentations have been described, particularly in patients with cystic fibrosis or esophageal disorders associated with aspiration. Treatment of *M. abscessus* disease is complicated, and cure is uncommon. The mortality rate with *M. xenopi* infection has been reported to be as high as 57%, but this probably reflects the organism's predilection for patients with severe underlying structural lung disease.

PREVENTION

Strategies for preventing NTM infections are difficult to formulate because of the current poor understanding of the transmission and pathogenesis of these infections. In at least two or three situations, methods to potentially prevent NTM disease have been recognized. The first is among patients with advanced HIV infection. Preventive therapy for disseminated MAC infection is recommended for HIV-infected patients with fewer than 50 CD4$^+$ lymphocytes/μL. Azithromycin given in a dose of 1200 mg once weekly is the preferred agent. An acceptable alternate regimen is clarithromycin, 500 mg, twice daily, or rifabutin, 300 mg daily. Primary prophylaxis should be discontinued when patients have responded to highly active antiretroviral therapy (HAART) with an increase in CD4$^+$ lymphocyte count to more than 100 cells/μL for more than 3 months. Prophylaxis should be reintroduced if the count falls to less than 50 to 100 cells/μL.

A second way to prevent NTM infections is through good clinical practices in health care settings, where contamination of water sources, biologicals, and multidose vials has been implicated in postsurgical infections. In these settings, tap water should not be used to wash wounds or equipment, and multidose vials should be avoided for injections.

Prevention of community-acquired pulmonary infections remains elusive. The organisms have been isolated in tap water and water distribution systems, survive well at water temperatures of 45° C, and are resistant to typical decontamination methods. Therefore, it is not clear how to best decrease environmental exposure.

CONTROVERSIES AND PITFALLS

TB remains one of the most important public health problems in the world. Despite effective treatment and preventive regimens, TB continues to spread, particularly in resource-poor countries, where both HIV co-infection and drug-resistant *M. tuberculosis* disease create additional barriers to control. Delays in the diagnosis and initiation of effective antituberculosis chemotherapy lead to higher morbidity and mortality in affected patients and continued transmission to others. The first step in preventing these scenarios is timely diagnosis and initiation of therapy, which begins with the recognition of TB as a potential cause of the patient's illness. Because of the increased frequency of drug-resistant TB, more rapid diagnostics are urgently needed, particularly in areas where HIV co-infection is common. Current treatment regimens require that multiple drugs be administered over a prolonged treatment course. Poor adherence to therapy, which has resulted in poor outcomes including the development of drug-resistant disease, remains a barrier to completion of therapy. New drugs that would allow for shorter treatment regimens, ideally administered intermittently, could improve our ability to treat patients to cure.

As the United States and other industrialized countries move toward the goal of TB elimination, improved diagnostics for detecting LTBI and ideally for identifying patients at increased risk for progression to active disease will be needed. It remains to be seen whether the new IGRAs will provide us with such tools. With 12 weekly doses of rifapentine plus INH, the PREVENT-TB has offered the long-awaited promise of a shorter course of therapy for LTBI, but the trial was performed with directly observed therapy. Implementation of this strategy in routine practice will require careful consideration of logistics and costs. Finally, BCG vaccination has failed as a significant TB control measure, because it does not prevent infection from occurring and it does not prevent the development of active TB in adults, thereby allowing continuation of the cycle of transmission. New vaccines are urgently needed if TB is to be eliminated on a global scale.

As the incidence of TB declines in many countries, NTM infections are increasing to fill the ecologic void. The reasons for this and just how much NTM exists are not really known because of the lack of epidemiologic and surveillance data. Much research effort should be directed at elucidation of the natural history of NTM infections and how and where people become infected. Because of the difficulty in distinguishing colonization from disease, it is important to develop better diagnostic tests and to develop new drugs and better treatment regimens for these resistant and difficult-to-treat infections. Current knowledge about the treatment of these infections is remarkably deficient. Which macrolide is superior? Which rifamycin is superior? Does addition of an aminoglycoside improve outcomes? What is the role of the fluoroquinonloes? Of importance as well, how can these infections be prevented? Only better epidemiologic data and clinical trials can answer these questions.

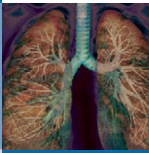
CRITICAL CARE RESPIRATORY MEDICINE



Chapter 32

Invasive Mechanical Ventilation

Lukas Brander • Arthur S. Slutsky

The ancient Greek physician and philosopher Claudius Galen (129 to 210 CE) was the first to describe artificial ventilation of an animal. With the exception of a few historical anecdotes, mechanical ventilation did not become a widely used therapeutic intervention in clinical medicine until the outbreak of the poliomyelitis epidemic in Europe and the United States in the 1940s and 1950s, during which negative-pressure ventilators were made available to many of the patients with polio-related breathing impairment. Since then, there have been many developments in the technology of ventilators, and mechanical ventilation has become a commonly used, lifesaving procedure for patients with respiratory failure.

Ventilators initially were used in conjunction with neuromuscular blocking agents to provide controlled ventilation. Recognition that abolition of spontaneous breathing rapidly leads to deconditioning of the respiratory muscles stimulated the development of ventilatory strategies designed to deliver assistance in synchrony with the patient's spontaneous breathing efforts. The first mode to allow a patient to initiate and terminate a predefined level of pressure support was introduced in the early 1980s, initiating a process that led to a growing awareness of the complexity and consequences of patient-ventilator interactions and more recently to the development of ventilatory modes that allow individualization of the assist on a breath-by-breath basis.

This chapter outlines the indications for and contraindications to invasive mechanical ventilation, illustrates the operation of various ventilatory modes, describes the essentials of mechanical ventilation in patients with obstructive and with restrictive pulmonary disease processes, and summarizes the potential complications of mechanical ventilation.

INDICATIONS AND CONTRAINDICATIONS

The goals of mechanical ventilation include decreasing the oxygen cost of breathing by unloading the respiratory muscles and maintaining adequate gas exchange, while minimizing potential complications associated with ventilation, including ventilation-induced lung injury (VILI), patient-ventilator asynchrony, hemodynamic compromise, and negative effects on other nonpulmonary organs. Mechanical ventilation is indicated when the patient is unable to maintain the function of their respiratory system as a result of underlying pulmonary disease, failure of the respiratory muscles, instability of the chest wall, increased metabolic demand, or the requirement for deep sedation or for neuromuscular blockade, and when noninvasive ventilation has failed or is contraindicated (e.g., in an unconscious patient, during surgery, with rapid progression of respiratory failure).

A number of methods can be used to monitor mechanical ventilation, including clinical assessment (e.g., respiratory pattern, auscultation, patient-ventilator interaction) and assessment of gas exchange (e.g., arterial blood gases, pulse oximetry, carbon dioxide tension in exhaled air). Monitoring the pressure waveforms and flow applied to the airways allows calculation of the variables of respiratory system mechanics; chest radiography or computed tomography helps assess the underlying disease process or some complications of mechanical ventilation (e.g., displacement of the endotracheal tube, pneumothorax); and monitoring the function of nonpulmonary organs (e.g., cardiac performance, central nervous system function, urinary output) may indicate adequacy of global and regional oxygen delivery. For safety reasons, virtually all ventilators contain adjustable alarm limits for the various functional components, such as upper and lower limits of applied ventilator pressure (i.e., pressure wave forms [PVENT]), ventilatory rate, tidal volume (VT), minute ventilation, and other variables.

TECHNIQUES

MODES OF INVASIVE MECHANICAL VENTILATION

Most mechanical ventilators are capable of delivering ventilation in a fully controlled manner, to assist spontaneous breathing, and to facilitate nonassisted spontaneous breathing (Figure 32-1). Normally, the means by which inhalation is terminated (cycled off) is used to classify the ventilatory modes. Common mechanisms to cycle off the inhalation include volume, pressure, airflow, and time. Initiation of an inhalation (i.e., trigger-on) can be based either on predefined time intervals or on systems in which the patient's inspiratory effort has to exceed a specific threshold. Most frequently, pneumatic systems are used that require a predefined, adjustable change in pressure or airflow within the ventilator circuit to trigger the initiation of an inhalation by the ventilator. Alternative trigger-on and cycling-off methods, such as changes in pleural pressure (PPL) (as can be assessed by esophageal pressure [PES] measurements) or changes in the amplitude of the diaphragm electrical activity (Edi), are currently entering clinical practice.

With *volume-cycled* ventilation, the ventilator delivers a predefined VT with a frequency that is either predefined or set by the patient's inspiratory effort. The pressure used to deliver the VT depends on the mechanical properties of the two major components of the respiratory system (see also further on): (1) the resistance of the inspiratory limb of the ventilator circuit (including the endotracheal tube) and the central airways and (2) the compliance of the respiratory system, consisting of the lung and chest wall.

Figure 32-1 Characteristics of available modes of mechanical ventilation including the method used to terminate (cycle-off) the inhalation and the method to initiate (trigger-on) the inhalation. The available modes include time-cycled, volume-targeted, or pressure-targeted (or -controlled) modes (volume-targeted" or "-controlled" ventilation [*VCV*], pressure-targeted" or "-controlled" ventilation [*PCV*]); modes combining controlled ventilation with assist to spontaneous breathing (synchronized intermittent mandatory ventilation [*SIMV*], pressure-regulated volume control [*PRVC*], volume support [*VS*], airway pressure release ventilation [*APRV*], bilevel positive airway pressure [*BiPAP*]); modes of pure assist to spontaneous breathing (pressure support [*PSV*], proportional assist ventilation [*PAV*], neurally adjusted ventilatory assist [*NAVA*]); and finally, modes that do not deliver assist to the patient but allow unrestricted breathing while delivering a constant pressure (continuous positive airway pressure [*CPAP*]). The work of breathing can completely or largely be taken over by the ventilator during controlled modes of ventilation, whereas during modes that assist spontaneous breathing, the load on the respiratory muscles is shared between the patient and the ventilator.

With *pressure-cycled* ventilation, the ventilator will stop delivering pressure as soon as a predefined pressure level is reached. With this system, the delivered VT depends on the respiratory system mechanics, and minute ventilation is not guaranteed.

With *flow-cycled* ventilation, the ventilator will cease delivery of pressure as soon as the airflow drops to a predefined level of its maximum. For example, with pressure support ventilation, a preset pressure is applied as soon as the patient's effort exceeds the trigger-on threshold. The ventilator will stop delivering pressure when the inspiratory flow has decreased to a predetermined percentage of its peak value.

With *time-cycled* ventilation, the ventilator will deliver a predefined level of pressure for a predefined time.

MODES THAT TARGET VOLUME OR PRESSURE

Controlled modes of ventilation (i.e., volume- or pressure-targeted or -controlled ventilation) normally are used when deep sedation or muscle paralysis is required (e.g., during surgery), when the patient is making no breathing efforts (e.g., after drug overdose), as a last resort when sufficient synchrony between the ventilator and the patient cannot be achieved, or when maximal reduction of the oxygen cost of breathing and complete unloading of the respiratory muscles from the work of inspiration are desired (e.g., respiratory muscle fatigue, severely altered mechanics of the respiratory system, or severely compromised oxygenation). Adaptation of the patient to controlled mechanical ventilation may require deep sedation and occasionally muscle paralysis.

Volume-Targeted (or -Controlled) Ventilation

With time-cycled, volume-targeted (i.e., volume-controlled) ventilation (VCV), VT is preset, and the minute ventilation is guaranteed by the ventilator, depending on the ventilatory rate. Triggering delivery of additional breaths with the preset VT occurs when the patient's breathing efforts exceed a caregiver-defined trigger-on threshold. Volume assist-control (A/C) refers to a variation of VCV in which the patient initiates delivery of a fixed VT by the ventilator, whereas a VCV backup rate ensures that the patient receives a minimum minute ventilation. Parameters that can be modified with most of the ventilators are the rate of inspiratory flow or ratio of the inspiratory to expiratory times (I/E ratio), the inspiratory rise time, the duration of the end-inspiratory pause time, and with some ventilators, the flow pattern during inhalation (**Figure 32-2**). The effects of changes in these parameters on the pressure and flow waveforms are demonstrated in Figure 32-2, *B* and C.

Pressure-Targeted (or -Controlled) Ventilation

With pressure-controlled ventilation (PCV), a maximum inspiratory pressure is targeted by the caregiver. The ventilator increases the pressure to this level during each breath. The flow pattern is decelerating; flow is high initially but decreases as the PVENT limit is approached. Inhalation is terminated when a predefined time limit or flow level is reached. The applied VT depends on the relative stiffness (elastance) of the respiratory system (e.g., VT is lower if pulmonary edema develops or if the patient contracts the abdominal or chest wall musculature) and on the resistance to airflow (e.g., VT will be lower if secretions markedly increase airway

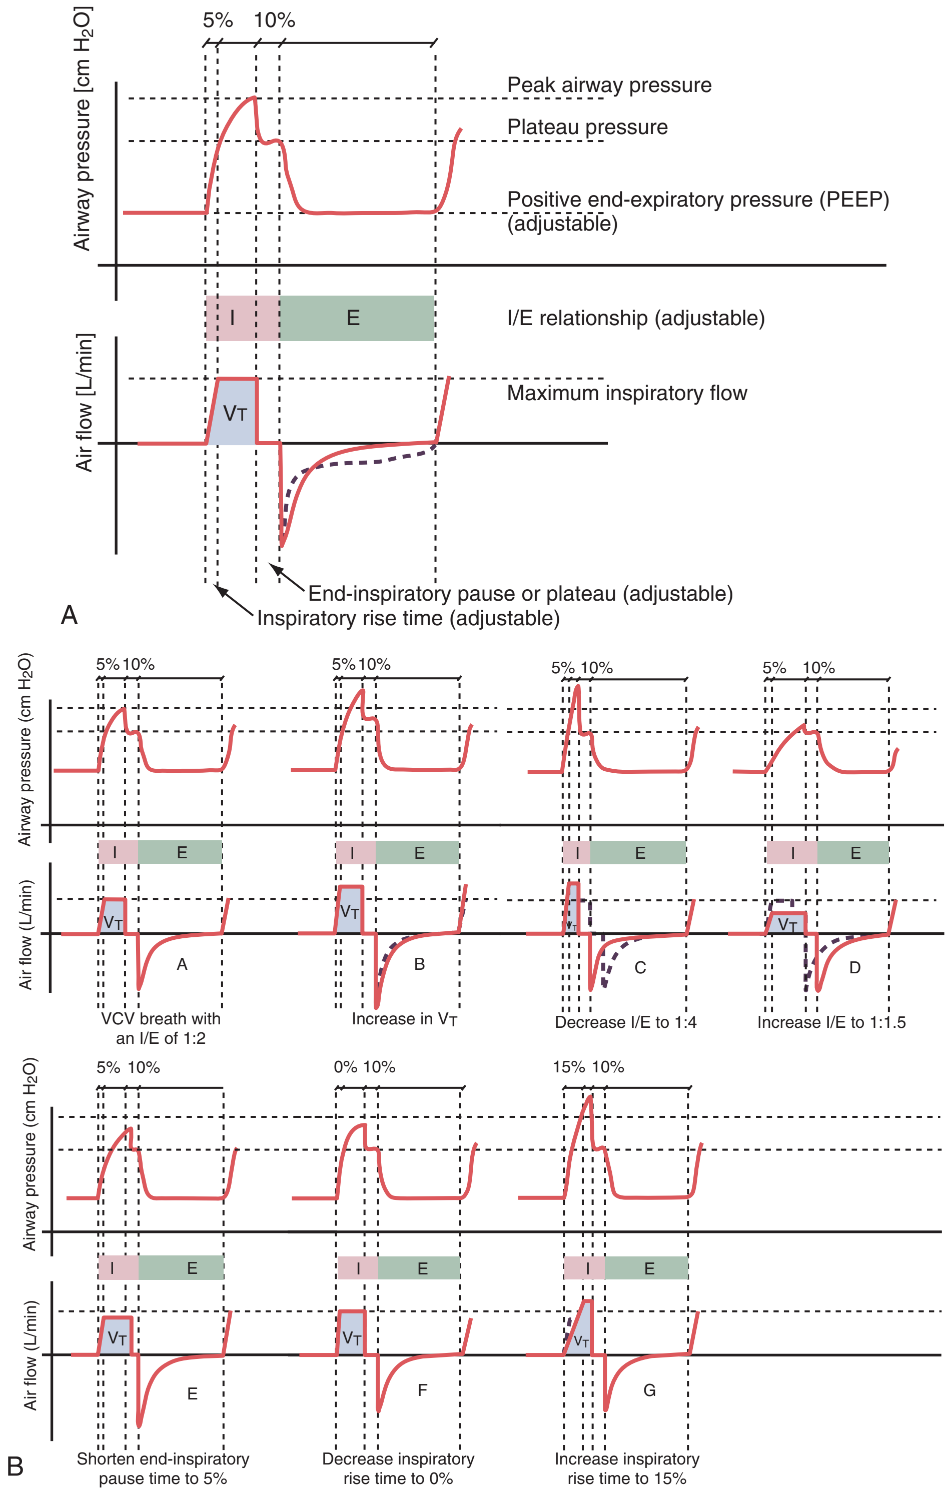

Figure 32-2 **A,** Volume-targeted (or volume-controlled) ventilation (VCV) with a square-wave flow pattern. The delivered tidal volume (VT) is calculated by integrating the area under the flow curve, as indicated by the *blue-shaded area.* During the end-inspiratory pause, the inspiratory and expiratory valves of the ventilator are closed for a predefined time interval (expressed as a percentage of the entire breath period). Ideally, at the end of expiration, the full tidal volume applied during inhalation (minus that lost during gas exchange) has left the lung and the airflow is reduced to zero. This may not be the case in a patient with dynamic collapse of the airways during expiration (e.g., in a patient with chronic obstructive pulmonary disease), where dynamic hyperinflation of the lungs may result from incomplete exhalation of the applied VT and persistence of expiratory airflow is detectable at end expiration (*dashed line*). The inspiratory flow pattern can be varied with many of the modern ventilators to constant (square-wave), decelerating (ramp), or sinusoidal. **B,** Changes in the adjustable parameters with volume-controlled ventilation (*VCV*) result in characteristic changes of the pressure and volume waveforms. The plotted curves demonstrate isolated changes in parameters, under conditions in which all other ventilatory parameters, as well as the mechanical characteristics of the respiratory system, are assumed to remain unchanged. The area under the inspiratory flow curve reflects the tidal volume (VT). *A,* Baseline conditions. *B,* An increase in VT results in an increase in the maximum inspiratory flow and hence in an increased peak airway pressure and end-inspiratory plateau pressure. *C,* Decreasing the I/E ratio results in a prolongation of expiration, while the maximum inspiratory flow and hence the peak airway pressure both increase. *D,* An increase in the I/E ratio has the exact opposite effect. *E,* A reduction in the inspiratory pause time reduces the maximum inspiratory flow and hence the peak airway pressure, while the plateau pressure and the inspiratory and expiratory times remain unchanged. *F,* When the time to reach the maximum inspiratory flow (inspiratory rise time) is shortened, the maximum inspiratory flow and the peak airway pressure will both decrease, whereas prolongation of the inspiratory rise time, *G,* has the opposite effect. In both situations, the end-inspiratory plateau pressure and the inspiratory and expiratory times do not change.

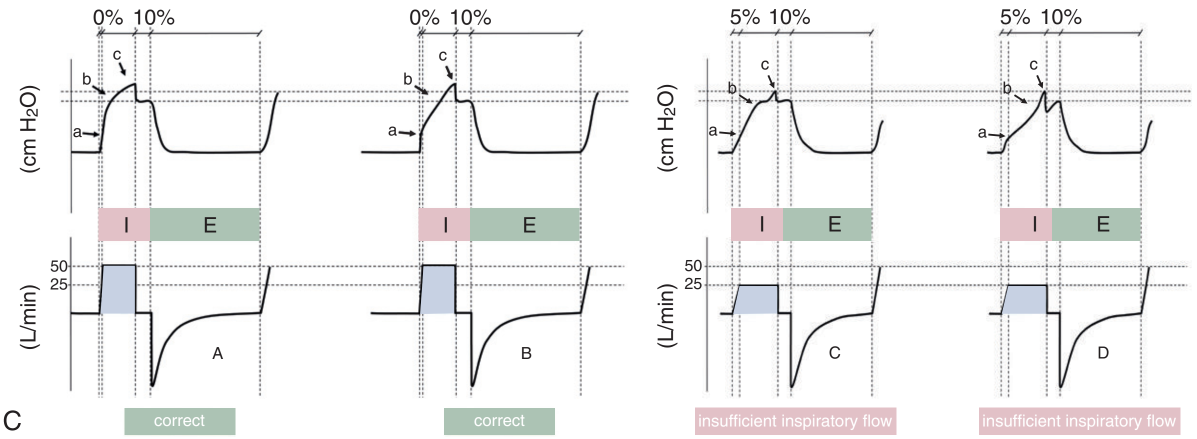

Figure 32-2, cont'd **C,** Airway pressure tracings during volume-controlled ventilation. The shape of the airway pressure waveform may provide an indication of whether settings of inspiratory flow are adequate. *A* and *B* are normal waveforms: *a*, fast pressure increase; *b*, convex or straight pressure shoulder; *c*, peak pressure. The interrupted (*C*) or even concave (*D*) segments *a* and *b* of the pressure waveform indicate that the maximal inspiratory flow falls short of the patient's actual demand. This may be the case in patients with high respiratory drive, such as in hypermetabolic states, sepsis, and delirium.

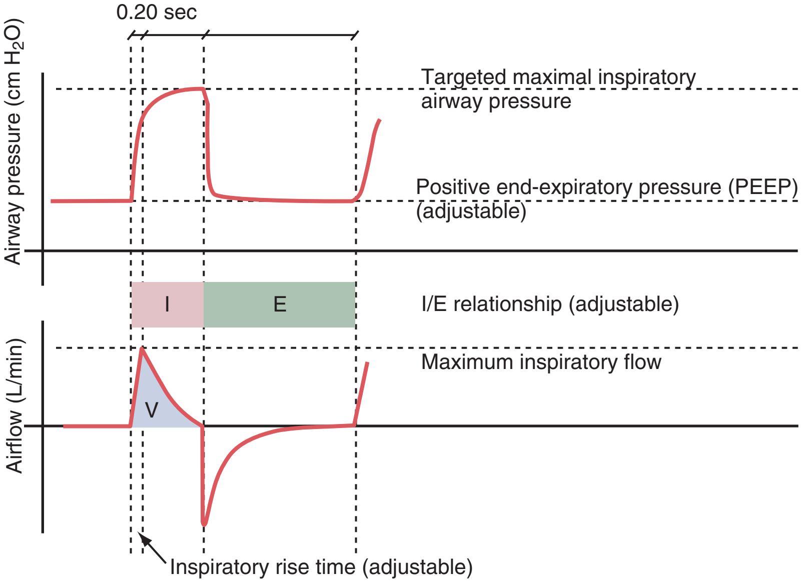

Figure 32-3 Pressure-targeted (or pressure-controlled) ventilation (PCV). Delivery of the predefined pressure level is initiated after a trajectory defined by the preset ventilatory rate. Additional triggering-on also is possible when the patient's effort exceeds a predefined trigger-on threshold. The delivered tidal volume (VT) is calculated as the time integral of the flow curve. The inspiratory rise time defines how quickly the maximal airflow is reached. Inspiration is terminated after a caregiver-specified time interval that results from choosing a ratio of inspiratory-to-expiratory times (I/E ratio) and a ventilatory rate or, alternately, from choosing an absolute inspiratory time.

resistance). The adjustable parameters are the targeted PVENT, the inspiratory rise time, and, in some ventilators, the inspiratory time (Figure 32-3).

MODES THAT DELIVER ASSISTANCE TO SPONTANEOUS BREATHING

Patients often are ventilated with volume- or pressure-targeted modes (i.e., controlled ventilation) in the early phase of the disease process, whereas modes delivering assistance to spontaneous breathing usually are applied later. Assistance to spontaneous breathing is used to prevent respiratory muscle atrophy as well as to maintain physiologic feedback and intrinsic defense mechanisms, such as the Hering-Breuer reflex, based on the hypothesis that integration rather than abolition may help to minimize VILI. This approach should be better suited than "caregiver-controlled" mechanical ventilation to accommodate the typically rapid changes in lung mechanics and metabolic demands in critically ill patients. Ventilatory modes in which patients breathe spontaneously early in the course of the acute lung injury (ALI) process may have certain advantages, such as improved pulmonary ventilation-perfusion (V/Q) matching (Figure 32-4), increased oxygenation, preserved cardiac function, reduced need for excessive sedation, prevention of ventilation-associated respiratory muscle dysfunction, and ventilation at lower mean airway pressure, compared with controlled modes of ventilation. Induction of respiratory muscle fatigue or failure secondary to increased work of breathing is a potential disadvantage, but this frequently can be minimized with use of the appropriate level of positive end-expiratory pressure (PEEP) and adjustment of inspiratory flow rates. Of interest, recent data suggest that early neuromuscular blockade for 48 hours in patients with ALI may decrease mortality (see further on).

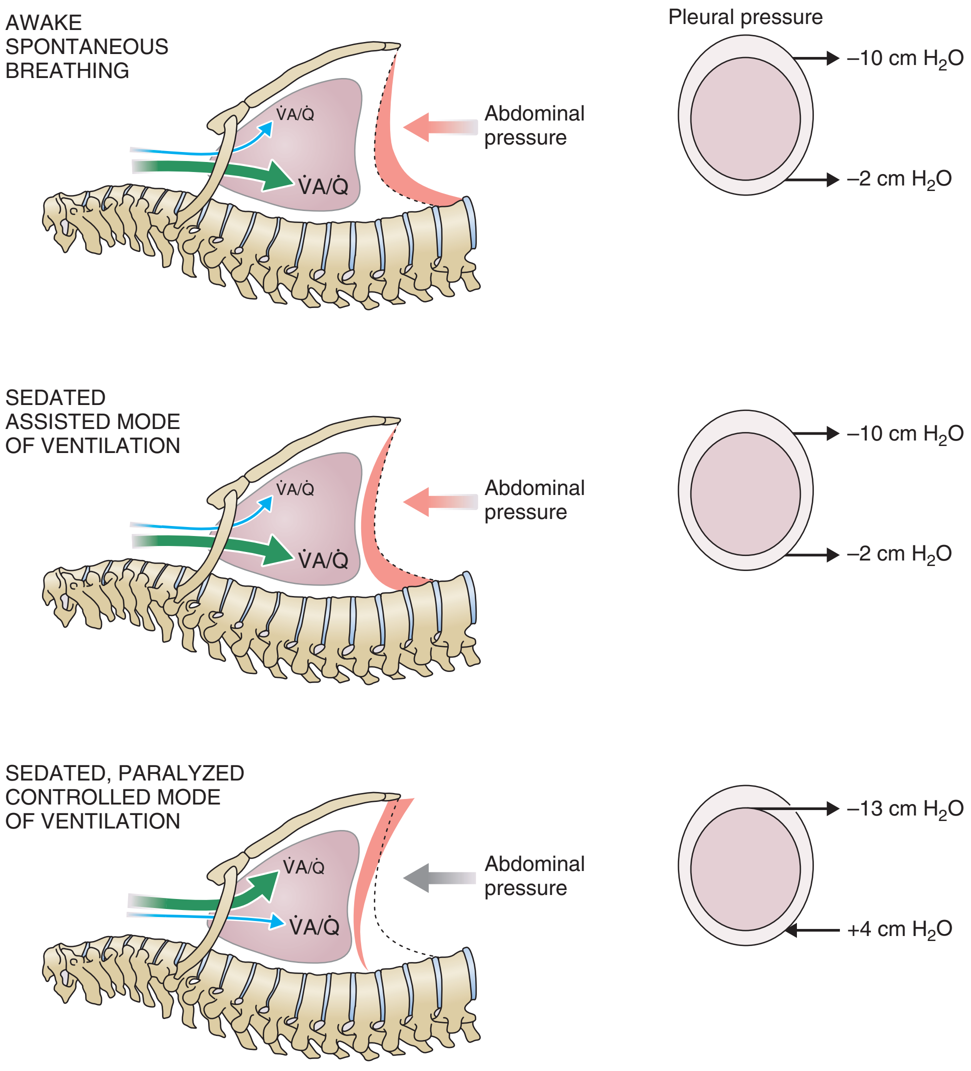

Figure 32-4 Ventilation-perfusion ($\dot{V}_A/\dot{Q}$) distribution during spontaneous breathing and during mechanical ventilation. In a classic article, Froese and Bryan demonstrated that with spontaneous breathing (in either an awake or sedated patient), dorsal excursions of the diaphragm were more pronounced than ventral excursion. The active diaphragm generates a greater negative pressure in the dorsal pleural space, thereby increasing the pressure gradient between the central airways and the pleural space (transpulmonary pressure); this promotes alveolar recruitment and ventilation of the dependent lung regions. Ventilation of dependent, usually well-perfused parts of the lungs, along with an increase in blood flow to previously minimally perfused or nonperfused areas, helps to convert shunt units to units with normal $\dot{V}/\dot{Q}$ distribution, thereby increasing oxygen content of arterial blood, and to lower pulmonary vascular resistance. During application of positive-pressure ventilation with inactive or only minimally active inspiratory muscles (e.g., with neuromuscular blockade or with hyperventilation), gas is preferentially distributed toward the ventral regions of the lungs, where the impedance to airflow is lower than in the dependent, partially atelectatic regions. Generation of positive pressure in the dorsal pleura promotes collapse of alveoli in the dorsal lung regions and the $\dot{V}/\dot{Q}$ mismatch becomes worse. *(Data from Froese AB, Bryan AC: Effects of anesthesia and paralysis on diaphragmatic mechanics in man,* Anesthesiology *41:242–255, 1974; Warner DO, Warner MA, Ritman EL: Atelectasis and chest wall shape during halothane anesthesia,* Anesthesiology *85:49–59, 1996; Hedenstierna G, Lichtwarck-Aschoff M: Interfacing spontaneous breathing and mechanical ventilation. New insights,* Minerva Anestesiol *72:183–198, 2006; Oczenski W, editor:* Atmen-Atemhifen, *Stuttgart, Georg Thieme Verlag, 2006.)*

Pressure Support Ventilation

Pressure support ventilation is patient-triggered and, normally, flow-cycled, allowing the patient to actively control the start of each breath. Once the patient's inspiratory effort exceeds the trigger-on threshold, a caregiver-defined level of P_{VENT} is delivered to the airways (Figure 32-5, *A*). After a high initial airflow that is required to rapidly approach the targeted pressure, the airflow progressively decreases. Once a predefined percentage of the maximum inspiratory flow is reached, the ventilator terminates inhalation and opens the expiratory valve. Parameters that can be adjusted with pressure support ventilation are the trigger-on threshold, the inspiratory rise time, and the pressure level (see Figure 32-5, *B*). To better match termination of the inhalation with the patient's individual demand, the cycling-off airflow threshold can be varied in some ventilators.

Analogous to all pressure-targeted ventilation modes, pressure support ventilation does not guarantee a specific V_T or minute ventilation. Changes in V_T and minute ventilation can be achieved by adjusting the level of pressure support and/or the cycling-off criteria.

Difficulties with Conventional Modes of Assistance to Spontaneous Breathing

It is sometimes assumed that assisting spontaneous breathing will decrease respiratory effort; however, unless the ventilator settings are selected to satisfy the patient's demand, such a mode can actually result in the opposite. Ideally, assistance

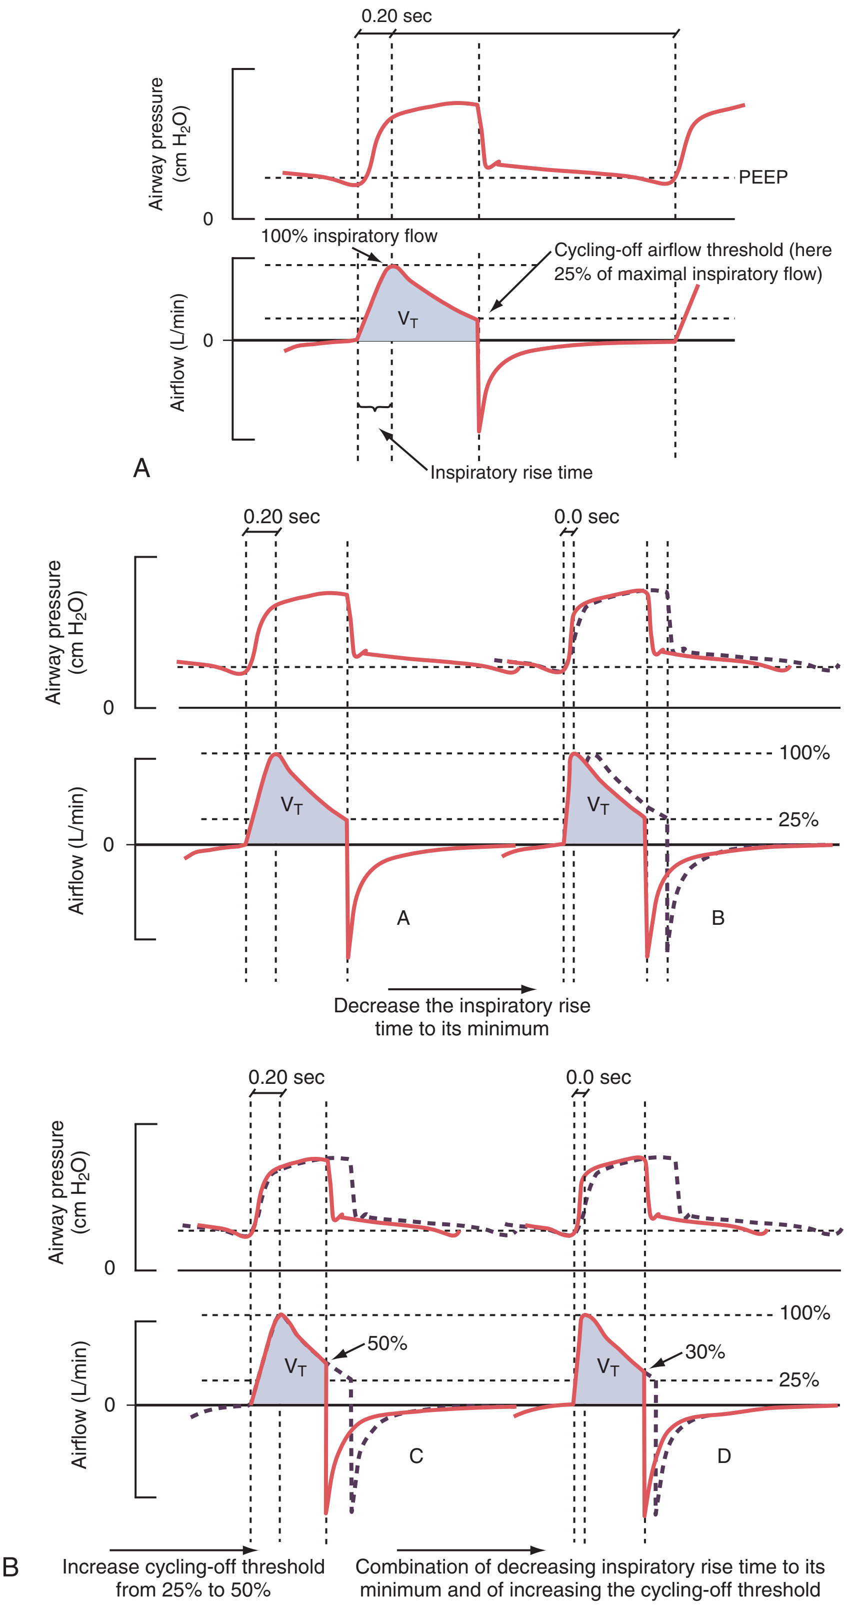

Figure 32-5 **A,** Pressure support ventilation (PSV). The delivered tidal volume (V_T) is calculated by integrating the area under the flow curve, as indicated by the *blue-shaded area.* The inspiratory rise time defines how fast the maximal airflow (100%) is achieved. Thereafter, the inspiratory airflow continuously decreases because, once the pressure target is reached, maintaining this level requires progressively less air to flow into the lungs. As soon as the cycling-off airflow threshold (i.e., a preset percentage of maximal air flow) is reached, the ventilator ceases to deliver inspiratory flow, and the expiratory valve is opened to allow passive exhalation. **B,** Changes in the parameters of pressure support ventilation result in characteristic changes of the pressure and volume curves. Panels *A* to *D* demonstrate isolated changes of parameters assuming that all other ventilatory parameters and the mechanical characteristics of the respiratory system remain unchanged. *A,* PSV breath with an inspiratory rise time of 0.20 second. *B,* After reducing the inspiratory rise time to its minimum, the peak inspiratory flow and consequently also the cycling-off airflow threshold are both reached earlier. Decreasing the inspiratory rise time results in a shorter inspiratory time, while the V_T remains unchanged. Note that although the inspiratory rise time is decreased to 0 seconds, the peak inspiratory flow is reached with a small delay. *C,* Increasing the cycling-off airflow threshold from 30% to 50% similarly shortens the inspiratory time; however, V_T decreases in this case. *D,* A combination of a maximal decrease in the inspiratory time and a moderate increase in the cycling-off airflow threshold shortens the inspiratory time, whereas the loss in V_T is only minimal. Such an approach can be used to achieve a prolongation of the expiratory time in patients at risk for dynamic hyperinflation because of expiratory flow limitation (e.g., patients with COPD) (see also Figure 32-19). *COPD,* chronic obstructive pulmonary disease.

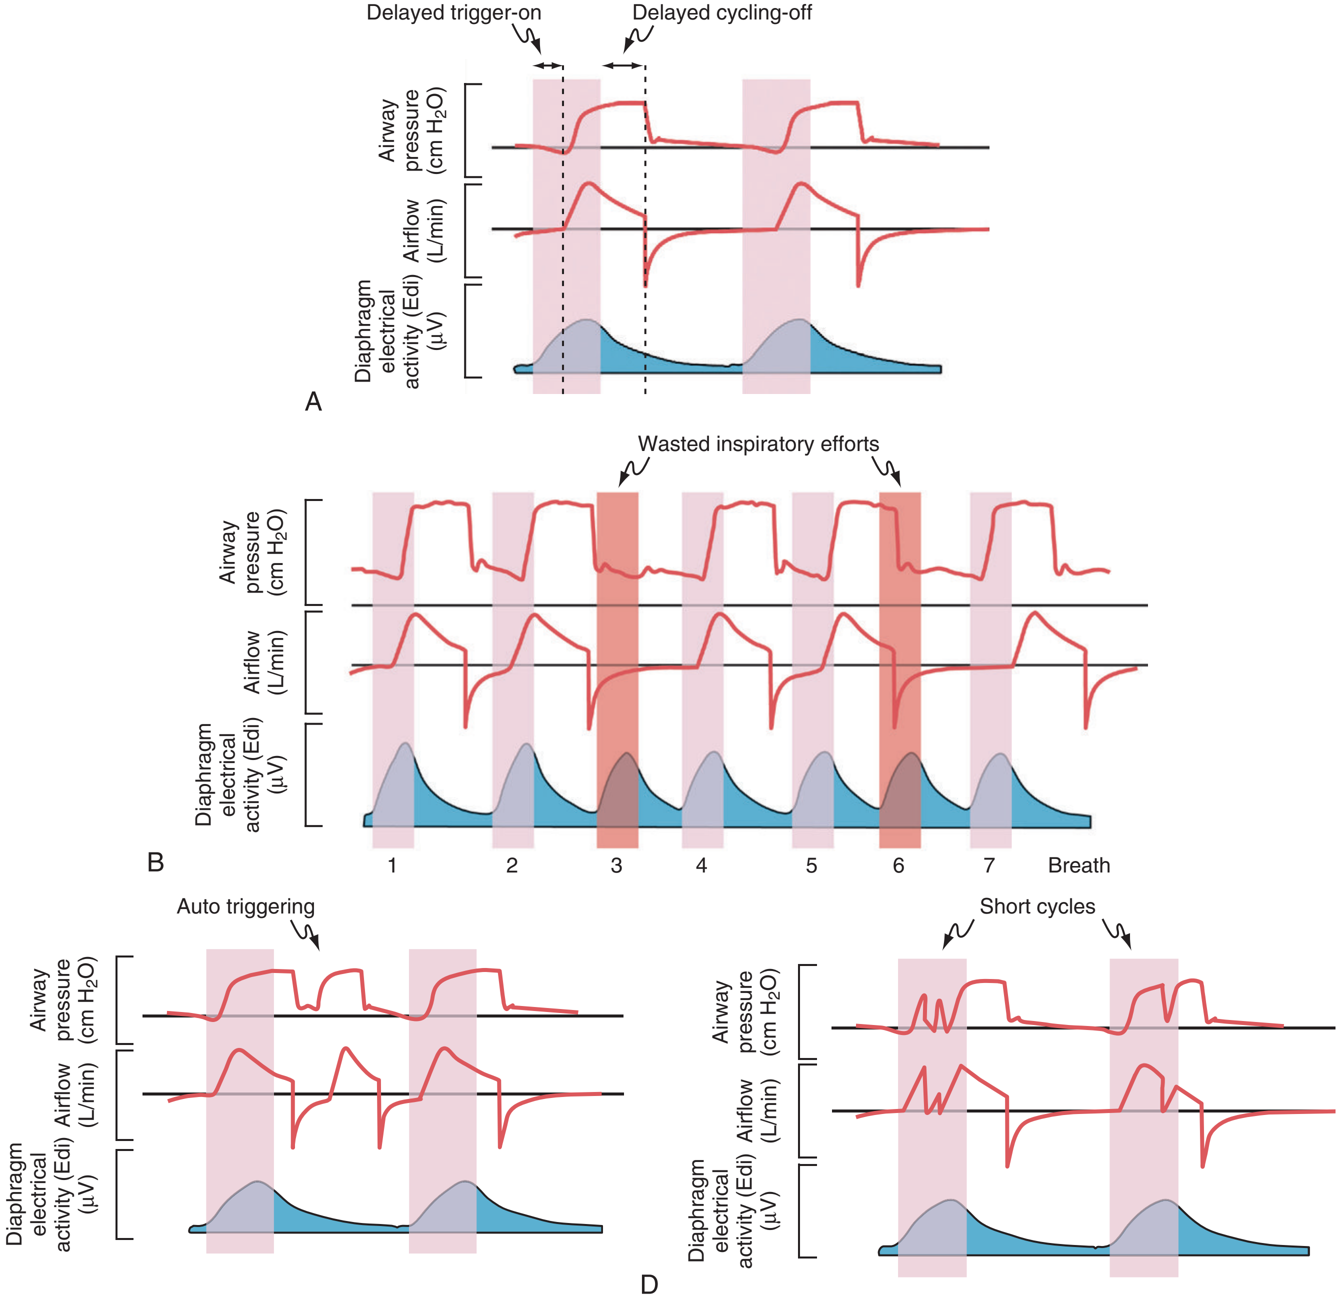

Figure 32-6 Examples of patient-ventilator asynchrony. **A,** Both the initiation and the termination of the assist delivered by the ventilator are delayed relative with the patient's respiratory demand, as reflected by the electrical activity of the diaphragm (Edi). Note that the neural expiration normally starts at approximately 70% to 80% of the maximum Edi. **B,** The ventilator delivers assist in response to the breathing efforts *1* and *2*, whereas effort *3* fails to trigger the ventilator. Wasted inspiratory efforts frequently occur when settings for the trigger threshold are inadequate, when excessive inspiratory efforts are required because of auto-PEEP, when delay in cycling-off is excessive, or when the respiratory muscles are too weak to translate a neural inspiratory effort into an effective breath. **C,** Auto triggering may occur when the generation of airflow or negative pressure in the expiratory limb of the ventilatory circuit is not related to an inspiratory effort (e.g., transmission of pressure oscillations because of cardiac activity, leaks in the ventilator circuit). Auto triggering often occurs when the trigger-on threshold is set at a level that is too sensitive. **D,** Short cycles. Delivery of assist by the ventilator is prematurely terminated and immediately resumed as the patient makes an inspiratory effort. For example, short cycles may occur when the airflow is impeded by a high resistance within the ventilator circuit (e.g., secretion in the endotracheal tube or in the trachea) or when the patient actively blocks inspiratory airflow that might be delivered in excess of the patient's demand.

should be delivered in synchrony with and in proportion to the patient's actual respiratory demand (i.e., both the timing and magnitude of the assist delivered by the ventilator are synchronized to the patient's inspiratory effort).

Although important improvements have been made in the trigger-on characteristics and the cycling-off characteristics of ventilators, ideal synchrony between the ventilator and the patient has not been achieved with most modes of ventilation, and patient-ventilator asynchrony is common (Figure 32-6). Patient-ventilator asynchrony may result in increased inspiratory and expiratory muscle activity and may introduce an unnecessary burden, in terms of work of breathing, in patients whose respiratory muscles are already under stress. Technologies that allow delivery of assistance in proportion to the patient's demand on a breath-by-breath basis have only recently been developed (e.g., proportional assist ventilation [PAV] and neurally adjusted ventilatory assist [NAVA], as described later on).

Variables that can be adjusted to improve synchrony between the patient and the ventilator include the trigger-on threshold, the inspiratory rise time or flow rate, and the cycling-off airflow threshold. The mechanisms used to initiate a breath (trigger-on) detect changes in airflow or pressure in the ventilatory circuit. Hence, negative deflections of short duration (pneumatic trigger mechanisms) may be detectable in the airway pressure and/or flow tracings when a breath is triggered by the patient's effort. Delivery of the assistance is terminated either after a predefined time has elapsed (time-cycled) or after a prespecified cycling-off airflow threshold (flow-cycled) has been reached (see Figure 32-5). Rise time refers to the time required by the ventilator to increase the inspiratory airflow from zero to peak. As demonstrated in **Figure 32-7**, the rise time changes the slope of the increase in pressure during early inspiration. Generally, rise time (or the inspiratory flow pattern) should be set to ensure that air is delivered rapidly (fast increase in airway pressure) after initiation of a breath. By establishing an optimal inspiratory rise time, synchrony to the patient's respiratory demand can be optimized and work of breathing can be reduced.

The fact that conventional modes of ventilation always deliver a uniform, predefined level of assist but do not take into account the physiologic variability of the breathing pattern stimulated the development of the PAV and NAVA modes, which deliver pressure assistance in proportion to the patient's demand.

Proportional Assist Ventilation

PAV, the first patient-triggered mode that adapted the level of assist to the patient's inspiratory effort, was introduced in 1987. With PAV, the ventilator delivers positive pressure throughout inspiration in proportion to the inspiratory airflow and volume generated by the patient (**Figure 32-8**). The magnitude of unloading is based on measuring elastance and resistance of the respiratory system. Whereas with conventional modes of ventilation the VT or the delivered PVENT is relatively constant from breath to breath, with PAV only the relationship between delivered PVENT and the inspiratory effort of the patient is constant, whereas VT and the delivered PVENT become dependent variables. Although PAV requires that the patient always assume a portion of the respiratory work, this mode has been demonstrated to effectively unload the respiratory muscles.

Limitations of PAV include the necessity to determine elastance and resistance of the respiratory system (a task that is not easy to perform in spontaneously breathing patients) and the occurrence of runaway phenomena at high levels of assist.

Neurally Adjusted Ventilatory Assist

A relatively new strategy of mechanical ventilation, NAVA, uses the Edi to control the ventilator (**Figure 32-9**). Because breathing signals originate from the brain and reach the diaphragm by way of the phrenic nerves, Edi represents the neural respiratory effort with respect to both timing and amplitude. During NAVA, positive pressure is applied to the airway opening in direct proportion to the Edi amplitude, so defining a target pressure or volume is not required. The patient's respiratory control mechanisms, including feedback from mechanoreceptors and chemoreceptors, adjust the Edi and thereby

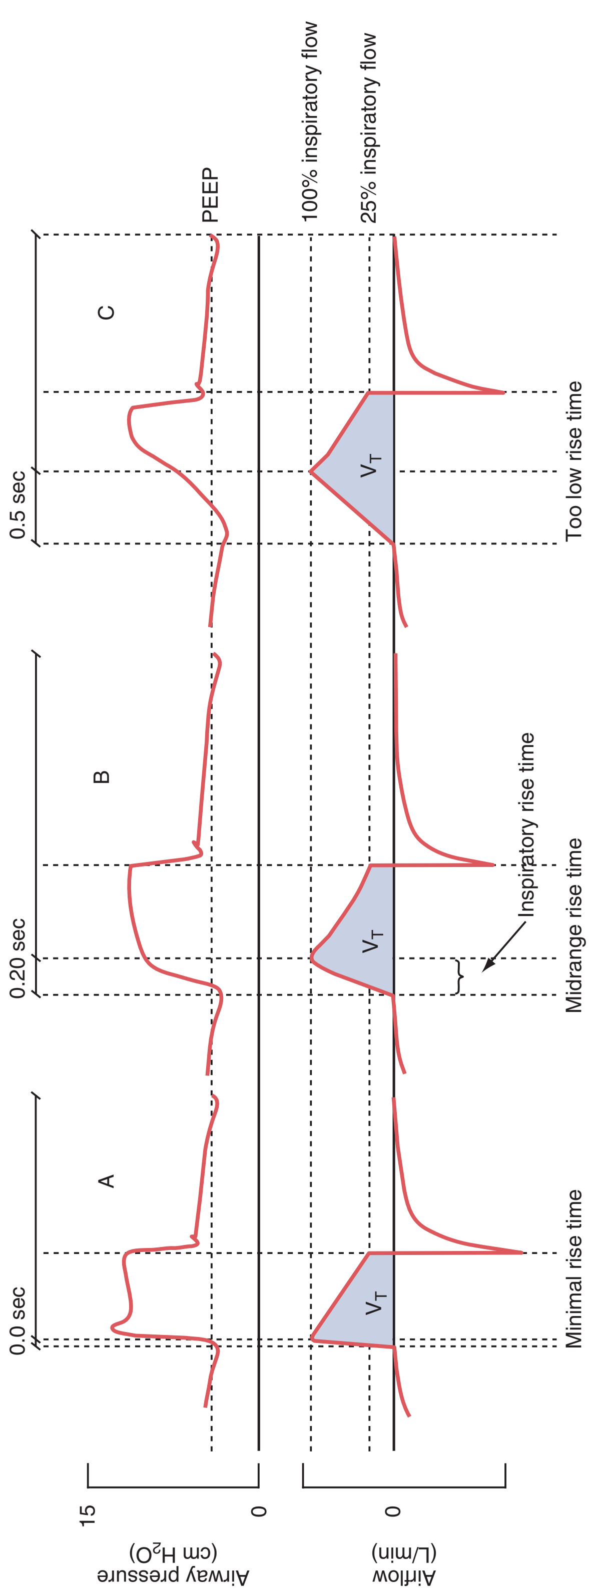

Figure 32-7 The rise time of the inspiratory flow is adjustable with most current ventilators. **A,** A pressure spike in early inspiration may indicate inspiratory flow in excess of the patient's demand or an obstruction in the central airways including the tracheal tube. **B,** No deformation of the inspiratory pressure waveform is visible with a midrange rise time. **C,** A concave deformation of the inspiratory pressure waveform indicates that the patient is making an inspiratory effect, because demand is higher than the flow provided by the ventilator. *(Modified from Branson RD, Campell RS: Pressure support ventilation, patient ventilator synchrony and ventilator algorithms,* Respir Care *43:1045–1047, 1998.)*

Figure 32-8 Proportional assist ventilation (PAV) as volume assist. **A,** With PAV, the assist is delivered in proportion to inspiratory effort. The pressure delivered to the airways increases until the end of inspiration. **B,** An increase in volume assist results in a higher pressure delivered for the same tidal volume. Note that with PAV delivered as flow assist, the waveforms appear different, although the basic principles are very similar to those for delivery of PAV as volume assist. *(Modified from Oczenski W, editor:* Atmen-Atemhilfen, *Georg Thieme Verlag, 2006.)*

Figure 32-9 **A,** With neurally adjusted ventilatory assist (NAVA), the electrical activity of the diaphragm (Edi) is derived by use of an array of electrodes mounted on a nasogastric tube. The signals from each electrode pair on the array are differentially amplified, filtered, and multiplied by a proportionality factor (NAVA level) before the signal is used to control the pressure generated by the ventilator. Hence, with NAVA, the pressure delivered to the patient is synchronous and (virtually) instantaneously proportional to the patient's Edi. **B,** Neuromechanical coupling and control of the ventilator. Chain of steps necessary to transform central respiratory drive into an inspiration (neuromechanical coupling) that ultimately results in delivery of assist by the ventilator (neuroventilator coupling). The current technology requires transmission of the electrical excitation into a contraction of the respiratory muscles (e.g., the diaphragm) and in generation of a pneumatic signal (pressure or flow at the airway opening) that is sufficient in magnitude to exceed the trigger-on threshold of a sensor within the ventilator. With NAVA, the Edi is used to control the ventilator. Hence, with NAVA, control of the ventilator is independent of the force generated by the respiratory muscles and also is independent of leaks in the ventilator circuit. *(**A** and **B**, Modified from Sinderby C, Navalesi P, Beck J, et al: Neural control of mechanical ventilation in respiratory failure,* Nat Med *5:1433–1436, 1999.)*

regulate the pressure and delivered volume. Animal data and a number of clinical studies suggest that NAVA is applicable in the ICU environment, efficiently delivers assistance synchronous to the subject's demand, unloads the respiratory muscles, maintains gas exchange, and preserves cardiac performance during invasive ventilation and also during noninvasive ventilation even with use of an excessively leaky interface. Simultaneous measurement of the Edi (which reflects the patient's neurally generated effort) and the delivered assist allows monitoring the patient's ability to translate a neural effort into ventilation, referred to as *neuroventilatory efficiency.* NAVA does not require measurement of respiratory system mechanics, and runaway phenomena are unlikely to occur.

PAV and NAVA both depend on presence of an intact respiratory drive. Although the concept of delivering assistance in proportion to the patient's demand is appealing, and although data from experimental and clinical studies are promising, these modes need to be tested in clinical trials to better define their indications and limitations.

COMBINED MODES

Airway Pressure Release Ventilation

With airway pressure release ventilation (APRV) (**Figure 32-10**), the pressure in the ventilator circuit alternates between a high and a lower level (normally the higher pressure level is of longer duration than the lower pressure level) and spontaneous breathing is allowed in any phase of the cycle. The high- and low-pressure levels, the rate of change between the two levels, the respiratory system compliance, and the airway resistance to flow are the main determinants of the "mechanical ventilation" portion with APRV, whereas the complementary "spontaneous breathing" portion mainly depends on the patient's respiratory drive. In contrast with continuous positive airway pressure (CPAP), APRV interrupts PVENT briefly to augment spontaneous minute ventilation and thereby increases alveolar ventilation and CO_2 removal without increasing the work of breathing. Spontaneous efforts during APRV are not actively assisted except for those breaths that happen to occur during the change from the lower to the upper pressure level. Total minute ventilation with APRV is the sum of the mechanical, pressure-controlled ventilation and the complementary spontaneous breathing. APRV *without* spontaneous breathing is essentially the same as PCV.

APRV has a number of interesting features. First, APRV overcomes shortcomings inherent in many modes of assisted spontaneous breathing related to triggering-on and cycling-off the ventilator by simply avoiding inspiratory and expiratory valves in the ventilator circuit. However, the time-cycled release and reestablishment of the high PVENT is not synchronized to the patient's breathing efforts, so patient-ventilator asynchrony may result. Second, the application of CPAP recruits some atelectatic areas, increases lung volume, and allows spontaneous breathing to occur on a portion of the pressure-volume curve where impedance to airflow is low and only a small transpulmonary pressure change is required to produce the VT. Third, APRV maintains PVENT at high levels for a prolonged period. Because alveoli are continually recruited along the inspiratory limb of the pressure-volume curve, recruitment may be more efficient with APRV than with shorter-application positive pressure (e.g., with pressure support ventilation).

Bilevel Positive Airway Pressure Ventilation

With BiPAP ventilation, two levels of continuous positive pressure are used, as with APRV, and unrestricted spontaneous breathing is allowed on both pressure levels (**Figure 32-11**, *A*). As an additional option, assistance to spontaneous breathing efforts can be provided at the lower pressure level (see Figure 32-11, *B*), at the higher pressure level, or at both levels. The transition from the low-pressure to the high-pressure level is coordinated with the patient's breathing effort. The designations Bi-Vent, DuoPAP, and Bi-level used by ventilator manufacturers are synonymous with BiPAP.

Despite the theoretical advantages of APRV and BiPAP, trials showing clinically relevant benefits are currently lacking. Further work is needed before these modes can be recommended for specific patient conditions or phases in the process of mechanical ventilation.

Synchronized Intermittent Mandatory Ventilation

Synchronized intermittent mandatory ventilation (SIMV) combines volume- or pressure-targeted breaths at a caregiver-defined rate (mandatory breaths) with unassisted spontaneous breathing (**Figure 32-12**). Because ideally the mandatory

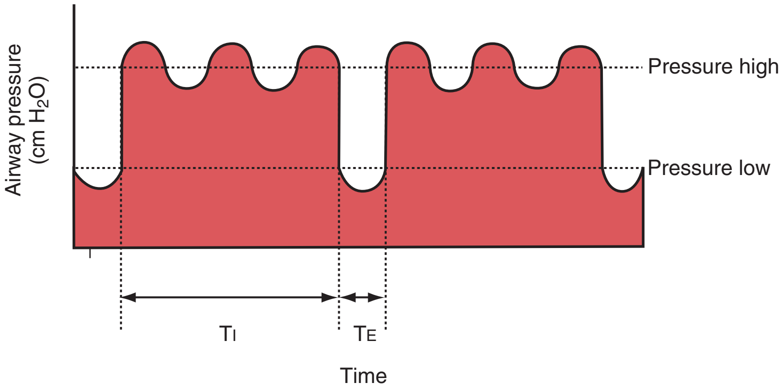

Figure 32-10 With airway pressure release ventilation (APRV), two levels of continuous positive airway pressure (CPAP) are delivered by the ventilator. The higher pressure level is maintained until the inspiratory time (TI) has elapsed; the pressure is then changed to the lower pressure level, usually for a short period of time (TE, typically 0.5 to 1.5 second), before the high-pressure level is resumed. The duration of TI and TE is defined by the caregiver. Spontaneous breathing is allowed in any phase of the cycle. Because the pressure release periods are of short duration, a residual expiratory positive airway pressure (intrinsic PEEP) will be maintained in the lung compartments with a high time constant (slow passive exhalation), preventing end-expiratory collapse of these lung regions. While preventing end-expiratory collapse of the lungs, this helps improve oxygenation as a result of a better match between ventilation and perfusion, and periodic release of the airway pressure assists in removal of carbon dioxide.

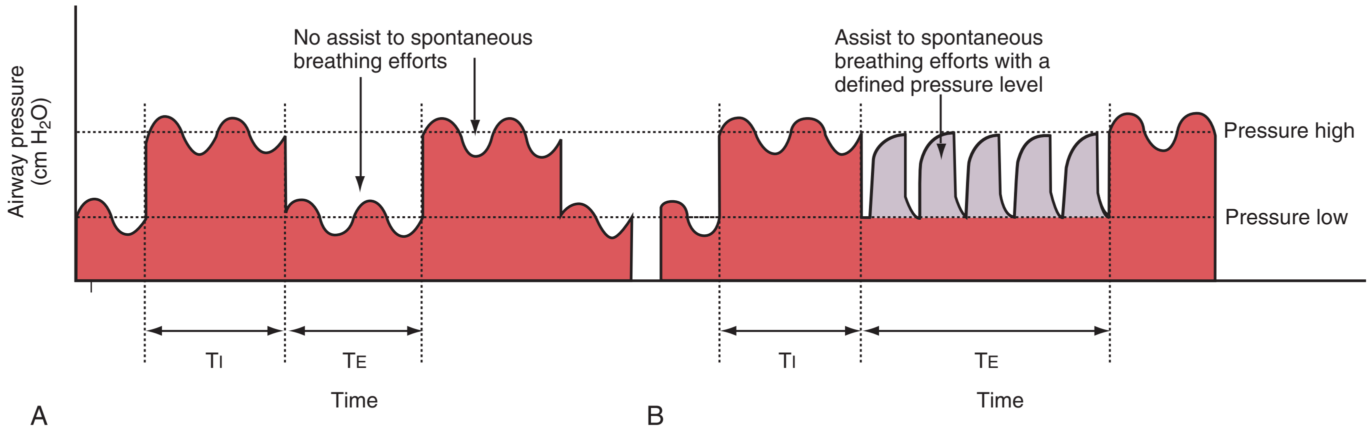

Figure 32-11 **A,** With bilevel positive airway pressure (BiPAP) ventilation, two levels of continuous positive airway pressure are delivered by the ventilator. The pressure levels and the relationship between inspiratory and expiratory times (TI and TE) are both defined by the caregiver. **B,** Delivery of assist to individual spontaneous breathing efforts is optional; this modality can be combined with BiPAP to compensate for the additional inspiratory work imposed by the flow resistance of the endotracheal tube. Of note, changes between the lower and the higher pressure levels are synchronized to the patient's efforts. The major difference between BiPAP and airway pressure release ventilation (APRV) is the longer duration at the low-pressure level with BiPAP, with a higher probability of derecruitment of lung regions. *(Modified from Oczenski W, editor:* Atmen-Atemhifen, *Stuttgart, Georg Thieme Verlag, 2006.)*

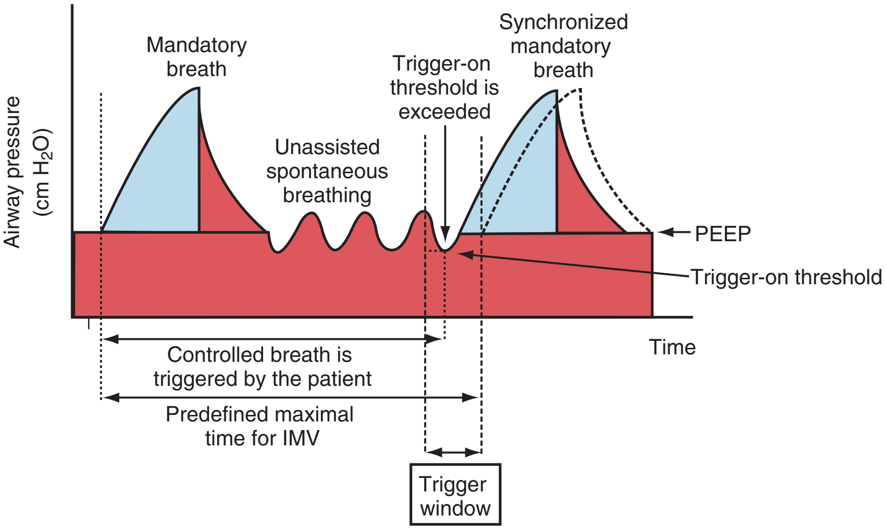

Figure 32-12 Synchronized intermittent mandatory ventilation (SIMV) with unassisted spontaneous breathing between two volume-targeted breaths. Within a short period before starting the next mandatory breath, a trigger window allows synchronization of the controlled breath to the patient's breathing effort. When the patient's breathing effort does not exceed the trigger-on threshold during this trigger window, the ventilator will deliver a mandatory breath (either volume- or pressure-targeted as defined by the caregiver) after the maximal time interval for intermittent mandatory ventilation (IMV) has elapsed. This time interval is defined by the preset rate for IMV. *PEEP*, positive end-expiratory pressure. *(Modified from Oczenski W, editor:* Atmen-Atemhifen, *Stuttgart, Georg Thieme Verlag, 2006.)*

breaths should be synchronized to the patient's own breathing effort, SIMV requires that the ventilator settings for the trigger-on threshold be adequate for this purpose.

The main differences between SIMV and BiPAP are that SIMV does not allow spontaneous breathing during the mandatory breaths, whereas spontaneous breathing is possible during all phases with BiPAP, and that with SIMV, all mandatory breaths are volume- or pressure-targeted, whereas BiPAP provides only pressure-targeted breaths. Despite its name, concerns similar to those with all pneumatically triggered modes of mechanical ventilation, regarding the delivery of ventilator assistance in synchrony and in proportion to the patient's demand, apply for SIMV as well.

Pressure-Regulated Volume Control and Volume Support

Pressure-regulated volume control (PRVC) and volume support (VS) use either pressure-targeted ventilation (for PRVC) or pressure support ventilation (for VS) to achieve a predefined VT. Basically, both modes first deliver a test breath at a low-pressure level, measure the achieved VT, and calculate the necessary adjustments in the inspiratory pressure to achieve the targeted VT in the subsequent breath. The same procedure is repeated for every breath. It has been suggested that these modes may be useful in weaning the patient from the ventilator on the basis of the rationale that the stronger the respiratory muscles (e.g., the higher the share of the VT produced by the inspiratory effort of the patient), the lower the level of assistance needed by the ventilator. The major concern with both PRVC and VS is that if the patient's breathing efforts increase because of an increased respiratory demand (e.g., hypoxemia, fever, increased metabolism), the level of assistance will paradoxically decrease. Also, spontaneous breathing patterns in critically ill patients often are highly variable, and the required VT may vary on a breath-by-breath basis. Again, PRVC and VS are designed such that the level of assist paradoxically decreases during periods of high demand, and vice versa.

MODES THAT FACILITATE SPONTANEOUS BREATHING

Continuous Positive Airway Pressure

With CPAP, a caregiver-defined level of positive pressure is maintained by the ventilator while the patient is breathing spontaneously (Figure 32-13). Of note, because the patient's

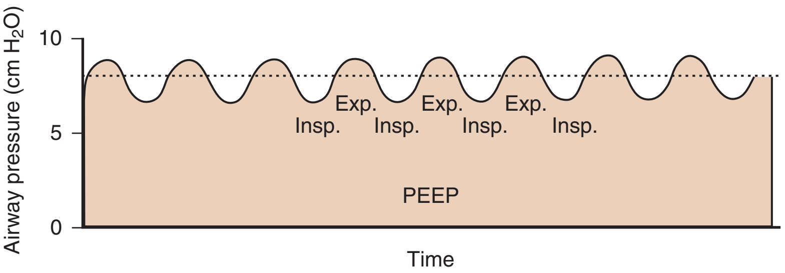

Figure 32-13 With continuous positive airway pressure (CPAP), a caregiver-defined level of pressure within the ventilatory circuit is maintained. Changes in the airway pressure with inspiration and expiration are constantly compensated for by pressure generated by the ventilator. *PEEP*, positive end-expiratory pressure.

breathing efforts are not assisted with CPAP, the patient must have adequate respiratory drive and adequate respiratory muscle function. CPAP helps to increase and maintain the functional residual capacity (FRC) and thereby to increase the lung units available for gas exchange (reduction of intrapulmonary right-to-left shunt), prevent end-expiratory airway collapse, and counter the effects of auto-PEEP or intrinsic PEEP.

Positive End-Expiratory Pressure

PEEP refers to the airway pressure (relative to atmospheric pressure) at the end of a breath. PEEP can be applied with most ventilation modes. Patients with respiratory failure from asthma or chronic obstructive pulmonary disease (COPD) who require mechanical ventilation have increases in FRC and in alveolar pressure at the end of exhalation that exceeds atmospheric pressure (i.e., auto-PEEP or intrinsic PEEP), thereby increasing the inspiratory work of breathing. Applying PEEP counters the effect of auto-PEEP on work of breathing. Patients with the acute respiratory distress syndrome (ARDS), acute lung injury (ALI), or hypoxemic respiratory failure from obesity have a reduced FRC that leads to alveolar and/or airway collapse. In these patients, PEEP is used to restore FRC, to recruit regions with collapsed alveoli or airways, to prevent derecruitment of open alveoli, to redistribute fluid within the lung, and to make dependent lung regions available for ventilation. All of these effects can improve the match between ventilation and perfusion, improve oxygen saturation, and decrease the need for high fractions of inspired oxygen. PEEP also has been used in patients with flail chest to stabilize the chest wall.

All of the aforementioned beneficial effects of PEEP are lost and adverse or even harmful effects may occur when excessive levels of PEEP are used. For example, excessive PEEP may increase dead space by over-distending alveoli and concomitantly decreasing alveolar capillary blood flow or may add to the hyperinflation of the lungs in patients with COPD or asthma. High levels of PEEP may reduce pulmonary blood flow by impeding venous return, thereby increasing pulmonary vascular resistance (i.e., decreasing cardiac output in the face of constant pulmonary arterial and venous pressure translates to an increased pulmonary vascular resistance). If pulmonary vascular pressures are kept constant relative to the level of PEEP, however (as will be the case unless cardiac output decreases), the effect of increasing lung volume on pulmonary vascular resistance is small. Of note, the effects of PEEP on cardiac performance are more pronounced during hypovolemia and can partially be reversed by ensuring adequate intravascular fluid volume.

In the past, PEEP was used mainly to increase oxygenation, thereby improving oxygen transport; however, there has been a change in the rationale underlying the use of PEEP, with a greater focus on its use to minimize cyclic air space opening and closing (i.e., atelectrauma) and hence to decrease ventilator-induced lung injury, rather than simply to improve oxygenation.

*Partial pressure of arterial oxygen (Pa_{O_2}) of 55 to 80 mm Hg or oxyhemoglobin saturation measured by pulse oximetry (Sp_{O_2}) of 88% to 95%.
Modified from Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. The Acute Respiratory Distress Syndrome Network, *N Engl J Med* 342:1301–1308, 2000.

Given the current lack of tools to monitor both alveolar overdistention and collapse, and given the heterogeneity of the distribution of most disease processes within the lung, identification of the “best PEEP?” level is not straightforward in clinical practice. In fact, the gravitational gradient in pleural pressure and end-expiratory lung volume that exists in both normal subjects and patients requiring mechanical ventilation implies that there cannot be a single level of PEEP that is “best” for all regions of the lung. Pending further clarification on how to set PEEP, a pragmatic approach for daily clinical practice in patients with ALI is to adhere to the algorithm used in the large Acute Respiratory Distress Syndrome Network (ARDSNet) trial (Table 32-1) and to carefully observe the effect of changes in PEEP on parameters such as blood oxygenation, cardiac performance, and expiratory flow limitation. Of note, in patients with stiff chest walls (e.g., massive ascites), higher levels of PEEP are warranted.

PRINCIPLES OF RESPIRATORY SYSTEM MECHANICS RELEVANT TO MECHANICAL VENTILATION

Adjusting ventilator parameters to the patient's individual condition and interpreting pressure and airflow tracings requires an understanding of the fundamental principles of respiratory system mechanics in ventilated patients. Although these general principles apply to the entire respiratory system, regional inhomogeneities (e.g., lower end-expiratory lung volumes, airway closure, and/or atelectasis in dependent regions) and regional differences in disease processes result in ventilation is never distributed uniformly within the lungs in mechanically ventilated patients. The compliance of a specific alveolar region and the resistance of the associated airways ultimately determine the portion of the VT received by a particular lung region.

AIRWAY RESISTANCE AND LUNG ELASTANCE

To a simplified approximation, the patient-ventilator unit can be considered as an in-series mechanical system that consists of a resistive element (ventilator and endotracheal tubing + central airways) and an elastic element (lung-thorax compartment). During inflation, the pressure applied to the tube inlet (PVENT) is equal to the sum of the pressure required to overcome the resistive elements (PRESIST) and the pressure required to distend the lung and chest wall (PELAST). The flow through the resistive element is a function of the difference in pressure between the tube inlet and the tube outlet (PRESIST) and the resistance of the tubing system (i.e., flow [L/min] = PRESIST [cm H_2O]/resistance [cm H_2O × min/L]). For example, forcing air at a low flow rate through a large-bore tube requires less pressure than if a high flow is applied to a small bore tube. Because PRESIST is used to overcome the resistive element, only PELAST is applied across the respiratory system (i.e., the lungs and the chest wall). **Figure 32-14** demonstrates the relationship between PVENT and the pressure within the central airways (PAW) throughout a respiratory cycle.

PELAST is made up of two components: the pressure required to distend the lung and the pressure required to distend the chest wall (which includes both the ribcage and the diaphragm, along with the abdomen). The elastance (1/Compliance = applied pressure [PELAST] divided by the applied VT) of the chest wall (ECW) and that of the lung (EL) are mechanically in series, and their sum equals the elastance of the entire respiratory system (ERS). In clinical practice, PVENT measured either at the airway opening or in the ventilator circuit is considered to be the "driving pressure," and PVENT typically is used to assess the propensity for induction of VILI. Such an approach has important shortcomings, however, and may yield misleading results. PVENT is referenced to ambient pressure and therefore reflects the pressure gradient across the entire respiratory system (i.e., across both the lung and the chest wall). The key variable defining the degree of lung distention and the propensity for induction of VILI, however, is only the pressure across the lung (i.e., the transpulmonary pressure [PL]).

The relative stiffness (or elastance) of the lung and the chest wall define what proportion of PAW is used to distend the chest wall and what proportion is used to distend the lung (**Figure 32-15**). For example, if the elastance of the chest wall is twice that of the lung, then two thirds of PAW is used to distend the chest wall and only one third is used to distend the lung. The fractions EL/ERS and ECW/ERS determine how PAW is apportioned between the lung (PL = PAW × EL/ERS) and the chest wall (PCW = PAW × ECW/ERS). Predicting PL on the basis of PAW without information on the elastance of the lung and the chest wall is not possible. Furthermore, lung and chest wall elastance vary among individuals and may also change over time during critical illness (e.g., with accumulation of edema or ascites). Although calculating the elastance of the entire respiratory system (ERS) is relatively easy (ERS = PVENT/VT), calculating the elastance of the lung and the chest wall separately is unfortunately not straightforward and requires knowledge of PL. **Figure 32-16** illustrates the intrabreath changes in PL during unassisted spontaneous breathing and during volume-targeted ventilation.

PL equals the difference between the alveolar pressure (PALV) and the pleural pressure (PPL). Because PVENT closely approximates PALV during an end-inspiratory and end-expiratory airway occlusion, PL can be calculated as PL = PVENT – PPL after performance of an appropriate maneuver to occlude the airways. Because direct measurement of PPL is invasive, and because the pressure in the lower third of the esophagus closely approximates that in the adjacent pleura, measurement of Pes (by means of inflatable latex balloons) can be used to estimate PPL. Hence, PL can be estimated as PL = PVENT – Pes (with a number of caveats, such as the effect of mediastinal weight on Pes in a supine patient, gravitational gradients, and spatial heterogeneity of PPL). Accordingly, approximation of PPL from measured Pes is not widely used currently in routine clinical practice.

Patients with ALI or ARDS may demonstrate an increase in ERS that is mainly attributed to an alteration in the EL. Some studies suggest, however, that the increase in EL results from presence of fluid filling a large portion of the lung such that the tidal volume delivered now expands the ventilated lung to a higher end-inspiratory lung volume (requiring a higher distending pressure, which is reflected in a greater EL). An increase in ERS also could be due to an increase in ECW. Of note, the chest wall in this context comprises not only the thoracic cage but also its caudal boundary, the diaphragmatic-abdominal compartment. ECW is increased in patients with severe obesity, chest wall injury, surgical dressings, and ascites and after major abdominal surgery. For example, in a patient with ALI associated with abdominal surgery, ECW may increase when intraabdominal hypertension (e.g., bowel edema, ascites) develops, even when the lung mechanics are normal. With the assumption that PVENT remains unchanged in the patient described previously, the pressure distending the lung actually decreases, because a greater share of PVENT is used to distend the chest wall (i.e., to displace the diaphragm toward the abdomen). Thus, arbitrarily limiting PVENT to a specific uniform value may not be necessary to prevent VILI in patients with high ECW but may potentially even cause harm by leading to marked reductions in tidal volume, insufficient ventilation, and severe hypoxemia.

PRACTICAL APPROACH TO VENTILATING PATIENTS WITH OBSTRUCTIVE AIRWAY DISEASE

An increase in airway resistance leading to expiratory airflow limitation and gas trapping is the major pathophysiologic abnormality in patients with asthma or COPD. With healthy lungs, the elastic recoil forces are sufficient to promote passive exhalation until FRC is reached. Partial loss of the elastic lung

Figure 32-14 **A,** During inspiration, the ventilator generates pressure (PVENT) to force a predefined volume of air (VT) in a predefined time into the lungs of the patient. The pressure loss over the total resistance of the endotracheal tube and of the central airways (PRESIST) defines what proportion of the PVENT reaches the central airways (PAW). **B,** Because the pressure within the respiratory system and the central airways equilibrates when the inspiratory and expiratory valves are closed, assessment of the respiratory system elastance (ERS) is possible during an end-inspiratory hold. For a given VT, the ERS defines the plateau pressure (PPLAT) at the end of inspiration. Note that because of the inhomogeneity of the time constants among different lung regions, the duration of the end-inspiratory plateau (normally approximately 10% of the breath cycle) often is too short for sufficient equilibration of the pressure across all lung regions. Hence, an end-inspiratory hold of longer duration (e.g., longer than 5 seconds) is necessary to adequately assess respiratory system mechanics. **C,** The expiration is passive (not actively supported by the ventilator) and driven only by the elastic recoil of the lungs and the chest wall. *PEEP*, positive end-expiratory pressure.

recoil in patients with COPD further aggravates this problem. Patients with limitation of expiratory airflow often activate expiratory muscles in an attempt to force the inspired volume through the partially collapsed or constricted central airways.

DYNAMIC HYPERINFLATION AND AUTO-PEEP

Dynamic hyperinflation occurs when expiratory flow has not emptied alveoli to their resting FRC values by the end of exhalation. The residual positive pressure within the lungs referenced to atmospheric pressure or to PEEP applied through a ventilator is referred to as *auto-PEEP* (or *intrinsic PEEP*). Although auto-PEEP usually implies dynamic hyperinflation, the two are not synonymous, because lung volume at end-expiration can be normal when expiratory muscles are highly activated. The presence of auto-PEEP results in the underestimation of mean pressure within the lung as measured by PVENT, and hence in misinterpretation, if assessment of lung mechanics is solely based on PVENT.

Classically, dynamic hyperinflation is present in patients with COPD, in whom the unstable airways collapse during exhalation (Figure 32-17), and in patients with asthma, in whom increased bronchomotor tone impedes exhalation. Exacerbation of the disease process such as bronchospasm in asthma or bronchitis with thickening of the mucosa in COPD worsens the condition. Of note, auto-PEEP also may develop in patients with more restrictive disease processes such as ARDS, in which intrapulmonary time constants are widely inhomogeneous, or when low VT settings at high ventilatory rates are used. A narrow-diameter or kinked endotracheal tube, inspissated secretions, an obstructed filter in the expiratory limb of the ventilatory circuit, a highly variable respiratory rate, or tachypnea will further predispose the respiratory system to development of auto-PEEP.

Persistent airflow at the end of exhalation, especially in combination with consistent failure to trigger the ventilator with inspiratory efforts, should heighten clinical suspicion for the presence of dynamic hyperinflation. Measurement of auto-PEEP requires equilibration of the pressure across the entire lung during occlusion of the expiratory valve at end-expiration (Figure 32-18), ideally performed during muscle paralysis (but paralysis usually should not be undertaken solely to make this measurement). Measurement of auto-PEEP during spontaneous breathing is difficult and often unreliable, because the inspiratory and expiratory efforts interfere with the procedure, and studies have shown that expiratory muscle contraction can occur. These contractions may be difficult to detect clinically.

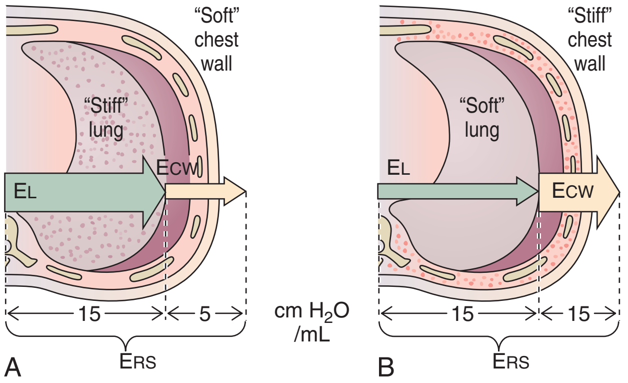

Figure 32-15 The total respiratory system elastance (ERS) equals the sum of its components: ERS = elastance of the lungs (EL) + elastance of the chest wall (ECW). The same ERS may arise from a high EL and a low ECW elastance (**A**) or from identical EL and ECW (**B**). *(Modified from Gattinoni L, Chiumello D, Carlesso E, Valenza F: Bench-to-bedside review: chest wall elastance in acute lung injury/acute respiratory distress syndrome patients,* Crit Care *8:350–355, 2004.)*

Dynamic hyperinflation can markedly increase the oxygen cost of breathing in a spontaneously breathing patient (Figure 32-19). Because the compliance of the respiratory system is lower at high lung volumes, more energy is required to expand the lungs. Furthermore, with dynamic hyperinflation the patient needs to produce large pleural pressure swings to overcome the auto-PEEP before pressure in the ventilator circuit decreases below the applied PEEP level and before pneumatic trigger systems located in the ventilator can be excited. Because generation of force by the inspiratory muscles is impaired during hyperinflation (decreased resting length of the diaphragm requires a higher-than-normal respiratory drive to lower pleural pressure), triggering the ventilator becomes challenging for patients with COPD and especially for those who have weakness or fatigue of the respiratory muscles—both of these conditions are difficult to distinguish from the effects of trying to inhale while breathing at a lung volume near total lung capacity (TLC).

Dynamic hyperinflation increases resistance of the inferior vena cava and increases pleural and juxtacardiac pressures, thereby impeding venous return to the right atrium, leading in turn to a decrease in cardiac output. Recognition that auto-PEEP and not cardiac dysfunction is the main cause of impaired cardiac performance under such circumstances is important, because treatment strategies are markedly different.

Inappropriate settings during mechanical ventilation can worsen dynamic hyperinflation, especially when high ventilatory rates and/or high VT settings resulting in excessive minute ventilation are used, when the assist is delivered asynchronous to the patient's demand (Figure 32-20), or when PEEP levels higher than those needed to counterbalance auto-PEEP are used.

The first approach to minimizing dynamic hyperinflation in a patient with obstructive airway disease is to decrease the resistance in the expiratory airways by removing any

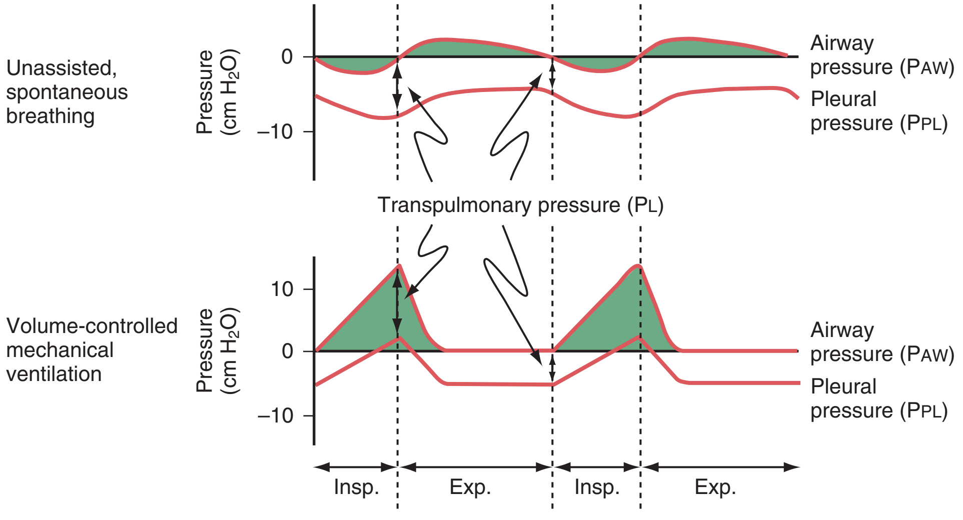

Figure 32-16 Transpulmonary pressure (PL). The pressure applied to the lungs (i.e., PL) equals the intrapulmonary pressure minus the intrapleural pressure: PL = PAW – PPL. The changes of PL from inspiration to expiration, and hence the propensity for development for ventilator-induced lung injury (VILI), are greater with volume-controlled mechanical ventilation than with spontaneous breathing. *(Modified from Oczenski W, editor:* Atmen-Atemhilfen, *Stuttgart, Georg Thieme Verlag, 2006.)*

Figure 32-17 **A,** Ideally there is no airflow at the end of the expiration, and hence alveolar pressure (PALV) is in equilibrium with the pressure in the ventilator (PVENT), and the respiratory system has returned to its functional residual capacity (FRC). Unstable airways collapse during passive or during forced expiration when the pressure surrounding the airways exceeds the intraluminal pressure, resulting in expiratory flow limitation. Consequently, air may be trapped within the lung, and a pressure gradient between the alveoli (PALV) and the ventilator circuit (PVENT) may be established (auto-PEEP) if the expiratory phase is too short to allow complete exhalation. **B,** Application of extrinsic PEEP partially counters the collapse of the airways, reduces the resistance to expiratory airflow, and may help with triggering of the ventilator by the patient. Note that peak and plateau pressure did not change, because extrinsic PEEP partially replaced auto-PEEP without adding to it. Note that expiratory flow may be impeded when an extrinsic PEEP level in excess of the auto-PEEP level is used. *PEEP,* positive end-expiratory pressure.

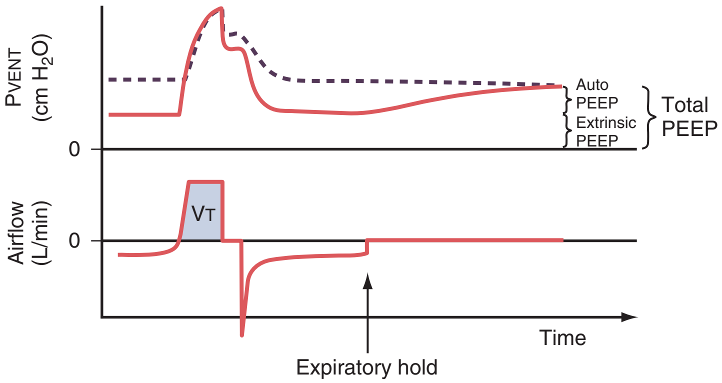

Figure 32-18 Expiratory hold technique to estimate the level of auto-PEEP. The exhalation valve is closed during an expiratory hold. When the expiratory flow equals zero, airway pressure rises to the auto-PEEP level. After reopening of the expiratory valve, flow continues, and the additional exhaled volume equals the volume of trapped gas. Of note, inspiratory and expiratory muscle activity interferes with the measurement of intrinsic PEEP. *PEEP*, positive end-expiratory pressure. *(Modified from MacIntyre NR: Intrinsic PEEP,* Prob Respir Care *4:45, 1991.)*

mechanical obstruction and by treating bronchospasm and airway inflammation. The most effective and abrupt way to decrease auto-PEEP is to reduce minute ventilation, although this may lead to an increase in an already elevated arterial PCO_2 ($PaCO_2$). Alternatively, adding extrinsic PEEP (**Figure 32-21**) will decrease the work of breathing, thereby reducing CO_2 production and lowering the $PaCO_2$ even if alveolar ventilation is unchanged. Because patients with COPD with chronically elevated $PaCO_2$ levels retain sufficient bicarbonate to normalize arterial pH, minute ventilation should not be adjusted to maintain a normal $PaCO_2$. In addition, the inspiratory phase should be shortened (thereby allowing maximum time for exhalation), as demonstrated in Figures 32-19 and 32-20. Of note, the variability in the duration of the expiratory phase and, hence, in the expired volume per breath increases when switching from a controlled mode of ventilation to a mode that delivers assistance to spontaneous breathing. This may result in modification of the degree of dynamic hyperinflation on a breath-by-breath basis and can induce patient-ventilator asynchrony because of wasted inspiratory efforts, especially when high levels of assist are used (see Figure 32-6).

The principles of a ventilatory strategy in acute asthma are very similar to those described for COPD—that is, adjusting the ventilatory rate to low frequencies and using low VT while accepting hypercapnic acidosis. A pH as low as 7.20 normally is well tolerated in these patients, and such an approach helps minimize hyperinflation.

PRACTICAL APPROACH TO VENTILATING PATIENTS WITH RESTRICTIVE PULMONARY DISEASE

A decrease in lung compliance and in FRC is the major pathophysiologic abnormality in patients with restrictive pulmonary disease processes such as pulmonary fibrosis, interstitial pneumonias, sarcoidosis, bronchiolitis obliterans organizing pneumonia, and those with ALI and ARDS.

The challenge in ventilating patients with restrictive diseases is to provide adequate oxygenation, while at the same time not causing further lung injury. Although mechanical ventilation clearly leads to improved survival in patients with ALI or ARDS, its ability to improve survival in patients with other restrictive processes (particularly idiopathic pulmonary fibrosis) is limited at best. The required approach is one of maintaining adequate oxygenation while trying not to overinflate the lung at end-inhalation (see later).

COMPLICATIONS OF MECHANICAL VENTILATION

Complications and side effects of intubation or of invasive mechanical ventilation include upper airway trauma (e.g., vocal cord injury), aspiration of gastric contents, barotrauma (e.g., pneumothorax or pneumomediastinum), disruption of normal host defense mechanisms, reduction in the ability to heat and humidify inspired gases, local tracheal ischemia induced by the cuff of the endotracheal tube, impairment of communication and of swallowing, and the perceived need by health care providers for sedatives and occasionally neuromuscular blocking drugs. Although use of a cuffed endotracheal tube helps prevent gross aspiration, pharyngeal secretions that pool at the top of the cuff may still seep into the lungs, increasing the probability of development of nosocomial pneumonia. An endotracheal tube greatly impairs the patient's inherent cough mechanisms by preventing closure of the glottis.

Mechanical ventilation itself can induce or aggravate lung injury that is clinically, functionally, and histologically indistinguishable from ALI or ARDS. Also, applying positive pressure to the airways may adversely affect cardiac performance and result in hemodynamic compromise.

VENTILATOR-INDUCED LUNG INJURY

Diseased lungs are more susceptible than healthy lungs to the development of VILI. VILI also can initiate and propagate cascades (e.g., upregulation of a systemic inflammatory response) that ultimately culminate in multiple system organ failure (MSOF) (**Figure 32-22**). A ventilatory strategy that uses low VT and limited PVENT is not only protective to the lung but also has the potential to reduce the incidence of MSOF. Exposure to excessive mechanical stresses can result in damage to lung tissue and cell integrity from either of two primary factors: (1) overdistention of the lung (i.e., volutrauma) and (2) repetitive air space recruitment and derecruitment (atelectrauma). The critical feature defining induction of VILI secondary to volutrauma seems to be the degree of regional lung distention, rather than the absolute PVENT reached. High pressures per se in the respiratory system do not necessarily result in VILI. For example, trumpet players repeatedly generate very high airway pressures (more than 150 cm H_2O) without incurring lung damage, because no excessive lung distention occurs.

Alveolar overdistention and shear forces can stimulate lung and immune cells to produce and release inflammatory cytokines and chemokines—that is, biotrauma. Biotrauma encompasses the release of numerous biologic (including inflammatory) mediators into the pulmonary interstitial and alveolar spaces. Concomitant disruption of lung tissue and cell integrity and disruption of lung epithelial and endothelial barriers facilitates the spillover of lung-derived inflammatory mediators, endotoxin, and even bacteria into the bloodstream, resulting in initiation, exacerbation, or propagation of a systemic inflammatory response. In view of the vast aerated surface area of the lung, it is conceivable that release of even small quantities of inflammatory mediators per cell could lead to a large quantity of mediators that could potentially enter the circulation.

The typically heterogeneous distribution of disease in patients with ALI or ARDS puts them at a high risk for VILI,

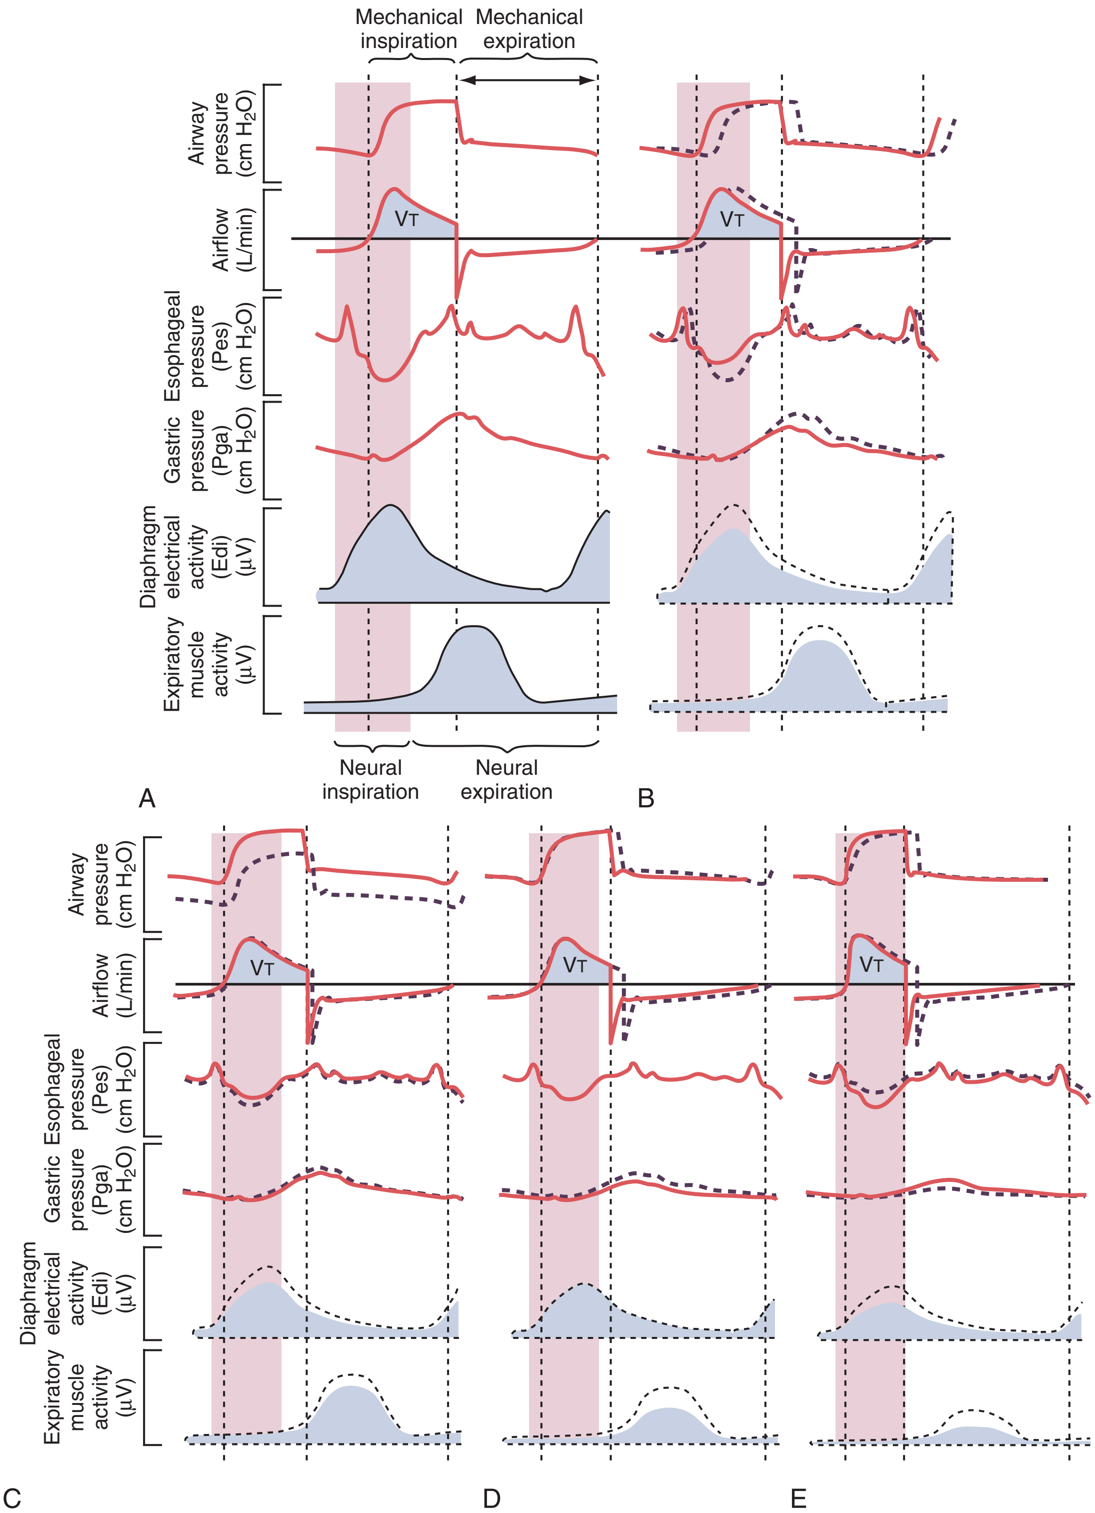

Figure 32-19 **A,** Demonstration of delivery of assist with pressure support ventilation (PSV) in a patient with expiratory flow limitation resulting in dynamic hyperinflation. There is substantial asynchrony (delayed triggering-on and cycling-off) between the assist delivered by the ventilator and the patient's (neural) respiratory demand, as reflected by the electrical activity of the diaphragm (Edi). The high amplitudes for the Edi and for esophageal pressure (Pes) deflections indicate that the inspiratory muscles are highly active during delivery of pressure by the ventilator, whereas the high amplitudes for the expiratory muscle activity and for the gastric pressure (Pga) deflections indicate that the patient uses his expiratory muscles to counter delivery of pressure by the ventilator during neural expiration. **B,** After optimizing the trigger-on threshold, delivery of assist starts earlier (requiring less inspiratory effort) and also ceases earlier (requiring less activation of the expiratory muscles). **C,** Adjusting the level of extrinsic PEEP to compensate for auto-PEEP allows earlier detection of the inspiratory effort by the ventilator (see Figure 32-21) and helps to further reduce the inspiratory workload. **D,** Increasing the cycling-off airflow threshold results in earlier termination of the assist. Hence, expiratory muscle activity can be reduced. Note that the ventilator inspiratory time, as well as the delivered tidal volume (VT), decreases when the cycling-off airflow threshold is increased, whereas the expiratory time increases (provided the respiratory rate remains unchanged). **E,** When the inspiratory rise time is reduced, the peak inspiratory flow and thus the cycling-off airflow threshold both are reached earlier, and the inspiratory time is further shortened. After completion of all steps as demonstrated here (**B** to **E**), ventilator assist is delivered in synchrony with the patient's neural respiratory demand, and unloading of the inspiratory muscles is achieved as reflected by minimization of the amplitudes for Edi and for Pes deflections. Expiration is driven only by the elastic recoil of the lung and the chest wall, as reflected by minimization of the amplitudes for expiratory muscle activity and for Pga deflections. *PEEP,* positive end-expiratory pressure.

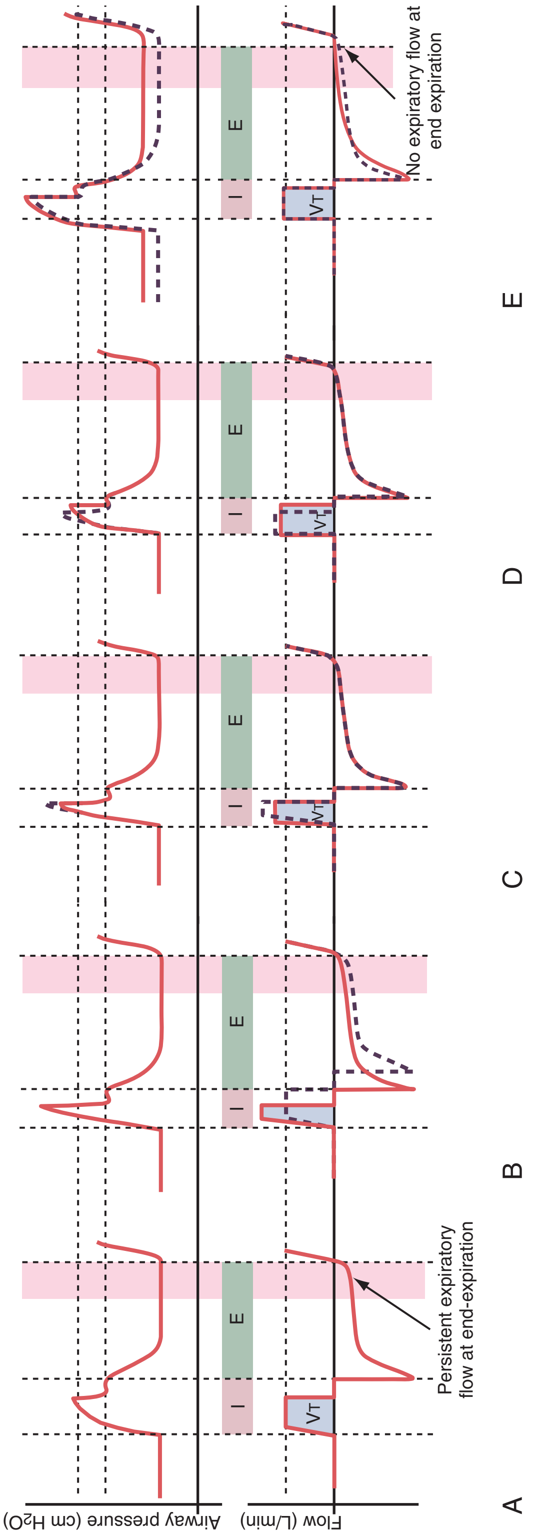

Figure 32-20 Adjustment of ventilatory parameters with volume-targeted ventilation in a patient with expiratory flow limitation and dynamic hyperinflation. **A,** Baseline condition with persistent flow at end-expiration. **B,** Shortening the inspiratory phase by reduction of the inspiratory-expiratory times relationship allows longer expiration provided the ventilatory rate remains unchanged. A higher maximal inspiratory airflow and hence a higher peak pressure during inspiration are required to force the same tidal volume (VT) into the lungs in a shorter period of time. Of note, a high inspiratory flow may result in a moderate increase in the respiratory rate, which will necessitate careful monitoring of the net effect on the duration of the expiration. **C** and **D,** Decreasing the inspiratory rise time (here, from 5% to 0% of the respiratory cycle) while shortening the time of the inspiratory pause at end-inspiration (here from 10% to 5% of the respiratory cycle) allows more time to deliver the tidal volume and hence results in lower maximal flow and lower peak pressure. **E,** Increasing the extrinsic PEEP partially counteracts the dynamic collapse of airways during expiration and diminishes the impedance to expiratory flow. *PEEP*, Positive end-expiratory pressure.

because the consolidated lung regions are susceptible to atelectrauma and the better or normally aerated regions are prone to volutrauma. Barotrauma and volutrauma are likely to occur when volumes and pressures meant for the entire lung (e.g., a VT of approximately 10 mL/kg) are forced into only a small portion of functional lung (the "baby lung"). In addition, shear forces at the interface between the open and closed lung units result in atelectrauma when PEEP levels insufficient to prevent end-expiratory alveolar collapse are used. Hence, ideally, a ventilatory strategy in patients with ALI or ARDS should prevent both alveolar overdistention during lung inflation and alveolar collapse at the end of lung deflation.

STRATEGIES TO PREVENT VENTILATOR-INDUCED LUNG INJURY IN CLINICAL PRACTICE

Although mechanical ventilation is only one of multiple factors contributing to the pathogenesis of multiple organ dysfunction syndrome (MODS), clinical trials have clearly shown that lung-protective mechanical ventilation decreases mortality among patients with ARDS.

The large ARDSNet study demonstrated that a VT of 6 mL/kg predicted body weight (PBW) was associated with decreased mortality compared with use of 12 mL/kg PBW in patients with ALI. It is important in applying this approach to base VT on the PBW, not on measured body weight. For a male patient, PBW = 50 + 0.91 × (cm of height − 152.4); for a female patient, PBW = 45.5 + 0.91 × (cm of height − 152.4). The VT should be lowered if necessary to reduce PPLAT to less than 30 cm H_2O. Some investigators suggest that a ventilatory strategy that keeps PPLAT below 30 cm H_2O is sufficient to ensure lung protection. However, a safe upper limit of PPLAT in patients with ALI or ARDS is not known. A recent post hoc analysis demonstrated that lowering PPLAT even further to values less than 30 cm H_2O could potentially decrease mortality.

The beneficial effects of using relatively low VT, and possibly also higher levels of PEEP, probably are related to the two main components—reduction of VILI and prevention of nonpulmonary organ dysfunction—as suggested by many preclinical and smaller clinical studies. In support of this mechanism, a recent large clinical study by Mascia and colleagues demonstrated that a lung-protective ventilatory strategy using VT of 6 to 8 mL/kg PBW combined with higher levels of PEEP prevented the decline of pulmonary function in brain-dead organ donors and roughly doubled the number of lungs available for transplantation. Another recent large clinical study demonstrated that pharmacologic neuromuscular blockade for 48 hours early in the course of ARDS resulted in both better survival and less time spent on the ventilator, compared with the use of placebo. Possible mechanisms by which neuromuscular blockade might lead to improved outcome are summarized in Figure 32-23.

In a number of studies, the investigators used *permissive hypercapnia* (i.e., allowing the Pa_{CO_2} to increase if necessary to maintain a sufficiently low VT) in the absence of any specific

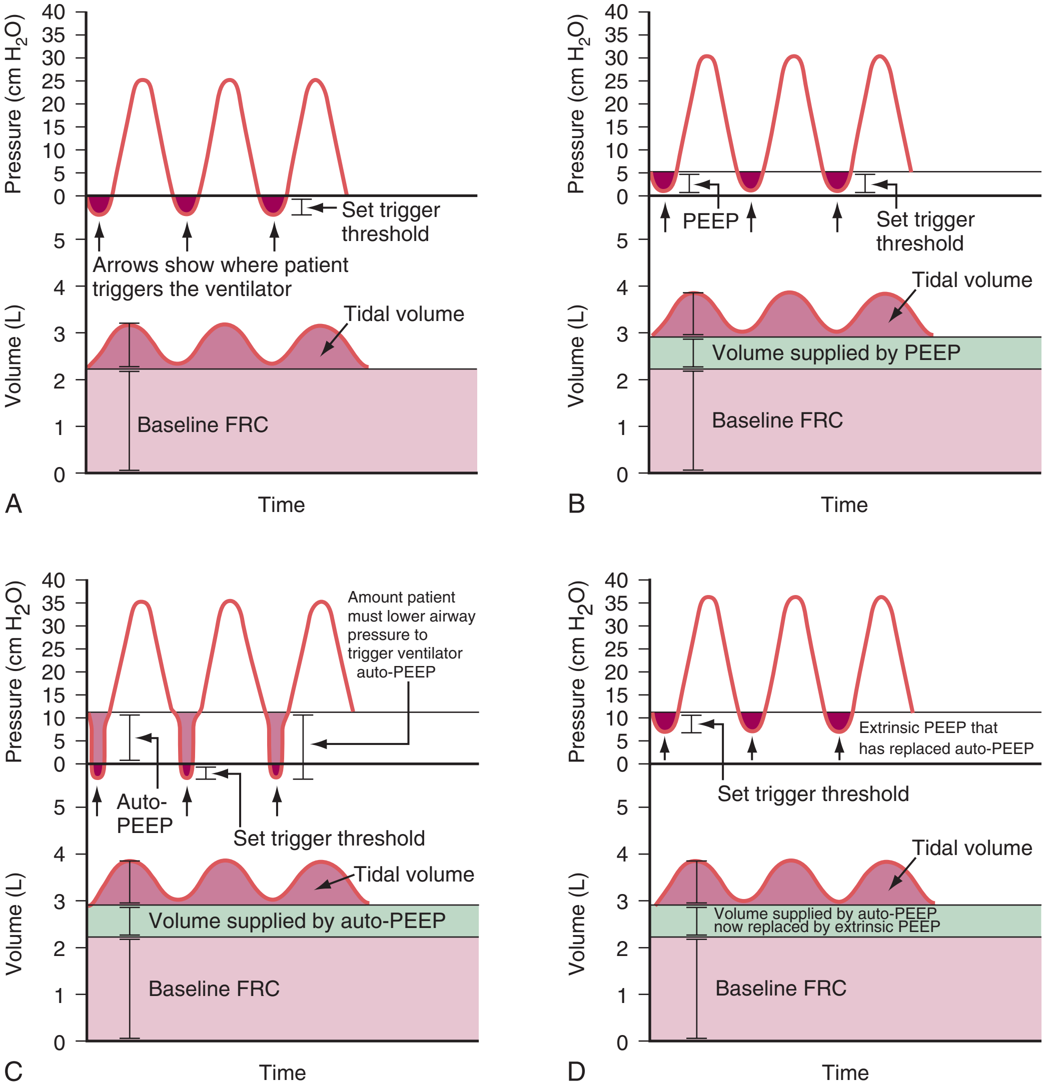

Figure 32-21 **A** and **B,** Without auto-PEEP, a small inspiratory effort is required by the patient to exceed the predefined trigger-on threshold (here, 1 to 2 cm H_2O below extrinsic PEEP). **C,** In the presence of auto-PEEP, the patient first needs to lower alveolar pressure to overcome auto-PEEP before the pressure in the ventilator circuit can be reduced sufficiently to exceed the trigger threshold below extrinsic PEEP. **D,** Applying extrinsic PEEP brings the trigger threshold closer to the alveolar pressure level at end-expiration. Now only a small inspiratory effort is required to exceed the trigger-on threshold. *PEEP*, positive end-expiratory pressure. *(Modified from Howman SF: Mechanical ventilation: a review and update for clinicians,* Hosp Physician *35:26-36, 1999.)*

contraindications (e.g., increased intracranial pressure). The concept is that the detrimental effects of the acute hypercapnia are less than the use of higher VT. How to treat the accompanying respiratory acidosis is still a matter of debate, but decreases in pH to approximately 7.20 to 7.25 usually are well tolerated and probably do not have to be addressed unless detrimental physiologic consequences of the acidosis develop.

How to adjust PEEP in patients with ARDS continues to be widely debated. Three recent large studies on higher versus lower PEEP levels in patients with ALI and ARDS, as well as two metaanalyses, found that random application of either higher or lower levels of PEEP in an unselected population does not significantly improve outcome. However, both metaanalyses suggested that in the subgroup of patients with severe, hypoxemic ARDS (as opposed to those without ARDS), higher levels of PEEP might be associated with a reduction in mortality. Some workers have suggested that in the aforementioned clinical studies, a potentially beneficial effect of higher PEEP in some ("lung-recruitable") patients might have been negated by a detrimental effect occurring in others (i.e., "non–lung-recruitable"). In fact, a cohort study recently demonstrated that the effect of PEEP on lung recruitment is closely associated with the percentage of potentially recruitable lung as determined by computed tomography.

Pending further clarification of how to define optimal PEEP levels in individual patients, a pragmatic approach for daily clinical practice is to adhere to the algorithm used in the large ARDSNet trial (see Table 32-1). Determining optimal ventilator setting in an individual patient with ALI or ARDS is always a continuous, iterative process of evaluation, intervention, and reevaluation that must take into account changes in the disease process over time.

VENTILATOR-INDUCED DIAPHRAGM DYSFUNCTION

Acquired neuromuscular disorders, referred to as critical illness polyneuromyopathy (CIPM), are frequently encountered in critically ill patients. The inability of the patient to resume the

entire work of breathing due to reduced respiratory muscle strength and endurance, with consequent difficulties in weaning from mechanical ventilation, is a hallmark of the syndrome and may be the first symptom to alert the clinician of the disorder. In fact, many patients who experience weaning failure display diaphragmatic weakness as manifested by reduced pressure generation by the diaphragm after supramaximal magnetic stimulation of the phrenic nerves.

It has been suggested that in addition to the well-established risk factors for CIPM (i.e., corticosteroids, neuromuscular blocking agents, severe sepsis, MODS and severe pulmonary diseases), the use of controlled modes of mechanical ventilation may be another factor that contributes to the development of respiratory muscle weakness. For example, two recent studies demonstrated that about 1 to 3 days of complete diaphragm inactivity in brain-dead organ donors (i.e., in absence of any spontaneous muscle activity) associated with mechanical ventilation resulted in a roughly 50% reduction in the cross-sectional areas of diaphragm muscle fibers and in a marked decrease in diaphragm force generation during phrenic nerve stimulation. By contrast, the early and preferential use of ventilation modes that assist spontaneous breathing (i.e. the work of breathing is shared between the ventilator and the patient) has been suggested to help prevent or delay the development of respiratory muscle weakness. However, how much such assistance would adequately meet the patient's demand and would thus prevent both respiratory muscle disuse atrophy and fatigue has not been established.

LUNG RECRUITMENT

Recruitment maneuvers can decrease the heterogeneities present in the lung, improve gas exchange, and potentially mitigate VILI by reducing cyclic air space opening and closing. Recruitment refers to the process of reopening collapsed alveoli by transiently increasing PVENT. This can be accomplished by maintaining a static PVENT of 40 cm H_2O for 40 seconds or by increasing PEEP transiently. Although animal studies seem to indicate that recruitment maneuvers are effective in decreasing VILI, human data indicating improved clinical outcomes are not available. This may be because recruitment maneuvers are likely to be effective in patients who have "recruitable" lungs, and none of the studies to date have stratified patients on the basis of lung recruitability. If recruitment maneuvers are used, it is important to monitor for adverse effects such as hypotension, barotraumas, and arrhythmias.

ALTERNATIVE APPROACHES TO LUNG RECRUITMENT

Prone positioning and high-frequency ventilation (HFV) represent alternative ways of attaining lung recruitment.

Placing patients with ARDS in a prone position improves PaO_2 in approximately 70% of patients and also may decrease VILI by improving the homogeneity of end-expiratory lung volume. Recent large clinical trials have been unable to confirm a specific survival benefit for prone positioning in diverse populations of patients with ALI and ARDS. However, posttrial studies and metaanalyses indicate that the subgroup of patients with severe hypoxemia, defined by baseline PaO_2/FIO_2 below 100 mm Hg, but not in patients with less severe hypoxemia, may indeed benefit from prone positioning. The optimal duration of prone positioning has not been established. In clinical practice, an empirical trial of such positioning may be attempted when severely impaired oxygenation fails to respond to usual measures, including sedation, recruiting maneuvers, and high PEEP; during such trials, every possible effort should be made

Figure 32-23 Possible mechanisms by which use of neuromuscular blocking agents (NMBAs) may lead to improved survival in patients with the acute respiratory distress syndrome (ARDS). Before induction of paralysis (*top*), increased respiratory drive from multiple causes can lead to increased tidal volumes (VT) and patient-ventilator asynchrony, all of which can potentially worsen various forms of ventilator-induced lung injury (VILI). VILI combined with impaired cardiac performance and consequent decrease in oxygen delivery to vital organs may lead to increased organ dysfunction and ultimately death. After paralysis is obtained (*bottom*), lower VT and improved patient-ventilator synchrony allow for better lung-protective ventilation, less VILI, and less impairment of cardiac performance. VILI also may be lessened by reduced pulmonary blood flow from decreased oxygen consumption. NMBAs also may indirectly improve arterial oxygenation by decreased muscular oxygen consumption and by improving the distribution of ventilation relative to perfusion ($\dot{V}/\dot{Q}$). Finally, NMBAs may have direct antiinflammatory effects. *(From Slutsky AS: Neuromuscular blocking agents in ARDS,* N Engl J Med *363:1176–1180, 2010.)*

to prevent misadventures associated with postural changes (e.g., displacement of endovascular lines or of the endotracheal tube).

HFV encompasses a number of ventilatory modes, including high-frequency positive-pressure ventilation (HFPPV), high-frequency jet ventilation (HFJV), high-frequency flow interruption (HFFI), and high-frequency oscillatory ventilation (HFOV), all of which use substantially higher ventilatory frequencies (i.e., in the range of 1 to 25 Hz) and much lower VT than with conventional modes (Figure 32-24). During HFV, the VT typically is less than the dead space. Gas transport is accomplished by various aspects of convection and diffusion. With HFV, a high mean PVENT is used to recruit alveoli and maintain lung volume above FRC. Thus, in contrast with controlled modes of ventilation, HFV maintains lung volume at a relatively constant level and uses very small VT to accomplish

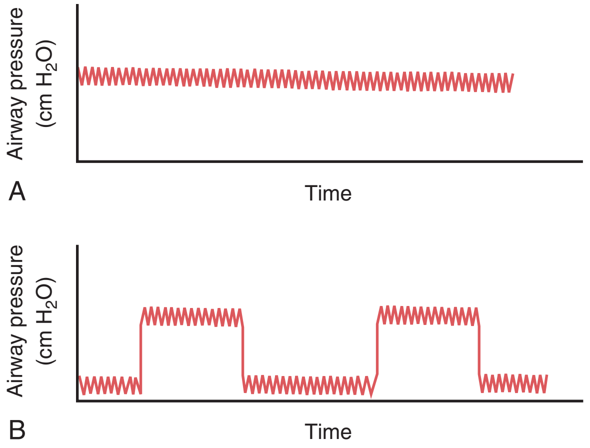

Figure 32-24 With high-frequency ventilation (HFV), extremely small tidal volumes (typically 1 to 3 mL/kg) are applied at very high ventilatory rates (typically 60 to 1500/minute, equivalent to 1 to 25 Hz). HFV allows maintenance of a relatively high mean airway pressure, whereas tidal excursions, and hence alveolar recruitment and derecruitment, are minimized. HFV can be applied either with a constant mean airway pressure (**A**) or alternating between lower and higher mean airway pressures (**B**).

ventilation. Intermittent sighs or sustained inflations are optionally used to recruit collapsed lung regions and to avoid atelectasis.

HFV is a potentially interesting ventilatory approach in patients with ARDS, because the small VT and the small pressure excursions allow the use of a relatively high mean PVENT without overdistending the lungs or allowing cyclic collapse to occur. Recent clinical studies in infants and adults with ARDS suggest that HFV may be as effective as conventional mechanical ventilatory support, but no studies have demonstrated that it reduces mortality.

WEANING FROM MECHANICAL VENTILATION

“Weaning” often is used interchangeably with “liberation” from mechanical ventilation and refers to the transition from full ventilatory support to resumption of unassisted spontaneous breathing by the patient.

All mechanically ventilated patients should be allowed to progress to spontaneous breathing at the earliest possible time, because unnecessary prolongation of ventilation is associated with increased risk for adverse effects such as ventilation-associated pneumonia, VILI, or perhaps respiratory muscle atrophy. On the other hand, premature discontinuation of ventilatory support in a patient not yet ready to assume the entire work of breathing also entails potential harm, including complications related to reintubation. Conventional weaning predictors measure the patient’s ability to breathe without assistance but do not assess the ability to clear respiratory tract secretions or to protect the lower airways from aspiration.

Initiation of weaning requires that the patient can and will trigger the ventilator, a prerequisite that often can be achieved only when the level of sedation is reduced or when the $PaCO_2$ is allowed to increase by reducing the minute ventilation. It is not surprising that “protocolized” interruption of sedation on a daily basis reduces the total time spent on mechanical ventilation.

Good clinical judgment in this regard is essential: Only patients with a reasonable likelihood of being able to breathe on their own are suitable candidates for attempts at weaning.

Box 32-1 Criteria for Initiation of a Spontaneous Breathing Trial*

- Evidence of some reversal of the underlying cause of respiratory failure
- Adequate oxygenation: PaO_2/FIO_2 ratio ≥150-200, required PEEP ≤5-8 cm H_2O, FIO_2 ≤0.4-0.5, and pH ≥7.25
- Hemodynamic stability as defined by the absence of active myocardial ischemia and the absence of clinically significant hypotension—that is, a condition requiring no vasopressor therapy or therapy with only low-dose vasopressors (e.g., dopamine or dobutamine given at a dose of less than 5 µg/kg/minute).
- The patient is able to initiate an inspiratory effort.

The decision to use these criteria for initiation of a spontaneous breathing trial must be individualized.

*Some patients in whom not all of these criteria are satisfied (e.g., patients with chronic hypoxemia values below the thresholds cited) may be ready for attempts to discontinue mechanical ventilation.

PaO_2/FIO_2, ratio of arterial partial pressure of oxygen to fraction of inspired oxygen; *PEEP*, positive end-expiratory pressure.

Modified from MacIntyre NR, Cook DJ, Ely EW Jr, et al: Evidence-based guidelines for weaning and discontinuing ventilatory support: a collective task force facilitated by the American College of Chest Physicians; the American Association for Respiratory Care; and the American College of Critical Care Medicine, *Chest* 120(suppl):375–395, 2001.

Although measuring a variety of physiologic variables may help guide this decision, the process often entails a “trial and error” component. Careful monitoring of the patient’s comfort, gas exchange, respiratory mechanics, and hemodynamics during a trial of spontaneous breathing is mandatory. The protocol-based use of spontaneous breathing trials (SBTs) is recommended to identify patients who are likely to be able to breathe spontaneously without assistance (Figure 32-25). Criteria to initiate an SBT as recently recommended by a consensus conference are summarized in Box 32-1 (for details, see the cited source paper authored by MacIntyre and co-workers), but each patient must be evaluated for specific factors that might modify the recommendation or mandate an alternate approach.

A formal SBT often is not required after short-term ventilation (e.g., in patients ventilated for less than 24 hours as, for example, in the postoperative period), whereas an SBT should be performed on a daily basis during a daily interruption of sedation in those patients who meet certain criteria (see Box 32-1). Conventionally, an SBT is performed with use of a minimal level of assist (i.e., 0 to 7 cm H_2O, preferably 0 cm H_2O), an FIO_2 of 0.5, and a PEEP level of 5 to 7.5 cm H_2O. An initial brief period of spontaneous breathing can be used to assess the advisability of continuing on to a formal SBT. The criteria used to assess the patient’s readiness to continue tolerance during SBTs are the respiratory pattern, the adequacy of gas exchange, hemodynamic stability, and subjective comfort. Tolerating an SBT for 30 to 120 minutes warrants discontinuation of the ventilator. Removal of the artificial airway is a separate consideration and is based on assessing airway patency and the ability of the patient to protect the airway.

When an SBT fails, the cause should be determined. Once reversible causes for failure are corrected, and if the patient still meets the criteria listed in Box 32-1, subsequent SBTs should be performed at least every 24 hours. Patients who fail an SBT should receive a stable, nonfatiguing, comfortable form of ventilatory support. Anesthesia and sedation strategies and ventilator management aimed at early extubation should be used in postsurgical patients. Weaning protocols designed for nonphysician health care professionals should be developed and

implemented by intensive care units (ICUs). Protocols aimed at optimizing sedation also should be developed and implemented.

FAILURE TO WEAN FROM MECHANICAL VENTILATION

A number of factors may be involved in failure to wean a patient from mechanical ventilation, including mismatch between respiratory muscle strength and endurance and the respiratory load (e.g., with CIPM), altered mechanical properties of the respiratory system (e.g., with restrictive or obstructive pulmonary diseases or obesity), inability of the patient to sufficiently clear secretions and to maintain patency of the airways, or presence of a neuropsychological disorder (e.g., delirium, anxiety).

A frequently underrecognized predisposing factor in unsuccessful weaning is cardiac failure after removal of positive-pressure delivery during mechanical ventilation. A combination of several mechanisms may be involved and may result in either preferential right or left ventricular failure, or both. Consequences include myocardial ischemia in predisposed patients, arterial hypotension, cardiogenic pulmonary edema, and a mismatch between increased work of breathing and global oxygen delivery. Right ventricular failure most frequently results from increased right ventricular load due either to increased return of venous blood to the right ventricle or to increased pulmonary vascular resistance secondary to hypoxemia, hypercapnia, pulmonary edema, elevated intrinsic PEEP, or a combination of these factors. Left ventricular failure may be related to increased afterload (e.g., as a result of removing the positive intrathoracic pressure or arterial hypertension), to impaired filling due to right ventricular distention (interventricular dependence), or to diastolic dysfunction, which may be worsened by arterial hypertension or by catecholamines discharged during a stressful SBT or extubation period. In patients in whom cardiac dysfunction is suspected during weaning from mechanical ventilation, close monitoring (e.g., pulmonary artery pressure, pulmonary capillary wedge pressure, cardiac stroke volume, mixed venous oxygen saturation using a pulmonary artery catheter, or echocardiography) may be helpful to differentiate the mechanisms involved and to closely monitor the effect of therapeutic interventions.

Tracheotomy should be considered after an initial period of stabilization on the ventilator when it becomes apparent that the patient will require prolonged ventilator assistance. Unless there is evidence for clearly irreversible disease (e.g., high spinal cord injury or advanced amyotrophic lateral sclerosis), a patient requiring prolonged mechanical ventilatory support for respiratory failure should not be considered permanently ventilator-dependent until 3 months of weaning attempts have failed. Weaning strategies in patients requiring prolonged mechanical ventilation should be slow-paced and should include gradual lengthening of SBTs.

CONTROVERSIES AND PITFALLS

Better understanding of the potential harm of mechanical ventilation, of the interaction between the patient and the ventilator, and of the importance of optimizing treatment processes associated with mechanical ventilation (e.g., sedation and weaning protocols) has fostered the development of many technical and conceptual improvements in recent years. Nevertheless, further advances are required in numerous areas, including the development of ventilatory strategies that individualize ventilation to the specific patient at a specific point in time and that minimize VILI and its systemic consequences, improvement of alternative approaches to protecting the lung during mechanical ventilation, improving patient-ventilator interactions, and prevention of respiratory muscle deconditioning during mechanical ventilation. Current controversies include the precise role of recruitment maneuvers and ways to individualize PEEP levels, as well as the indications for invasive versus noninvasive ventilation.

Although further research is likely to provide new insights, an important challenge for researchers and clinicians alike is to identify elements of the current knowledge that can be incorporated into daily clinical management to improve outcomes for patients who require ventilatory assistance. In general, a protocolized approach is more likely to result in lasting improvement in care for ventilated patients. Implementing such protocols requires adequate resources, and institutions must make a commitment not only to develop protocols but also to the iterative process of implementation, reassessment, and refinement.

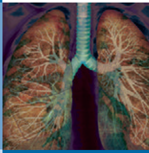
CRITICAL CARE RESPIRATORY MEDICINE



Chapter 33

Noninvasive Mechanical Ventilation

Paolo Carbonara • Stefano Nava

Noninvasive ventilation (NIV) is mechanical ventilatory support delivered to the airways in the absence of invasive devices such as an endotracheal tube or tracheotomy cannula. The most common devices used to establish the ventilator-patient interface are nasal, oronasal, and full face masks, along with nasal pillows and helmets. The role of NIV has grown steadily in recent years, and in expert hands, it now represents an extremely valuable tool for the management of acute respiratory failure (ARF). The key factors in successful use of NIV are proper patient selection and a high level of competence and experience in both medical and adjunctive personnel on the respiratory care team. It has been shown that in the appropriate setting, NIV is effective in improving gas exchange and alveolar ventilation, as well as in avoiding intubation in patients with ARF. A role for this ventilatory mode also has been proposed in the management of chronic hypercapnic respiratory failure in chronic obstructive pulmonary disease (COPD), although its use is associated with more controversial results.

In general, the main goal of NIV is to provide adequate ventilatory support while avoiding the risks related to tracheal intubation (laryngeal and tracheal damage, lower-airway infections, accidental extubation, higher risk of barotrauma, and volutrauma), as well as sparing the patient the level of pharmacologic sedation commonly required for intubation. In addition, NIV can be performed outside the intensive care unit (ICU)—for example, in step-down units or the emergency department, or on respiratory care wards. On the other hand, it is obvious that NIV cannot guarantee the level of airway control provided by invasive ventilation in terms of leak avoidance, effective delivery of flow and pressure to the airways, and control of minute ventilation. Accurate positioning of the interface device is crucial to minimize air leaks, and patients should be constantly monitored for timely detection of signs of worsening that may necessitate a prompt switch to invasive ventilation.

INDICATIONS FOR IMPLEMENTATION OF NONINVASIVE VENTILATION

In general, NIV is indicated in patients showing clinical and functional signs of acute respiratory distress, in particular:

- Poor alveolar gas exchange level (as indicated by PaO_2/FIO_2 less than 200 mm Hg)
- Ventilatory pump failure with hypercapnia and respiratory acidosis ($PaCO_2$ greater than 45 mm Hg and pH below 7.35)
- Severe dyspnea accompanied by use of accessory respiratory muscles
- Tachypnea (with respiratory rate greater than 24 breaths/minute)

These signs indicate a combination of increased work of breathing and decline in respiratory pump efficiency and point to the need for ventilatory support to relieve the rapidly worsening inspiratory muscle fatigue and to restore acceptable levels of gas exchange and alveolar ventilation. In the presence of these conditions, NIV should be initiated as soon as possible.

It also is important to bear in mind the conditions that preclude use of NIV and dictate prompt intubation with no delay—severely impaired neurologic state as evidence by a Kelly score (a scale specifically devised to assess patient responsiveness) higher than 4, respiratory arrest, shock, severe cardiovascular instability, and presence of excessive airway secretions. Facial lesions that prevent the fitting of nasal or facial masks also will prevent the use of NIV.

MODES

This chapter focuses exclusively on positive-pressure ventilation, which can be broadly defined as the intermittent delivery of pressure to the airways by means of a machine connected to the airway opening. The modes more frequently used for noninvasive ventilation are pressure support ventilation (PSV) and proportional assist ventilation (PAV), often with the addition of extrinsic positive end-expiratory pressure (PEEP); the use of continuous positive airway pressure (CPAP) in the acute setting is confined mainly to the treatment of hypoxemic respiratory failure, especially if the cause is related to cardiogenic pulmonary edema.

EQUIPMENT

VENTILATORS

A simple, informal way of classifying mechanical ventilators on the basis of their performance distinguishes three main types:

1. *Typical ICU ventilators*, powered by compressed gas, usually from wall outlets, and interfaced to the patient exclusively by means of a double circuit, with separate inspiratory and expiratory limbs. These systems are equipped with a screen to allow complete monitoring of ventilatory parameters and graphic display of flow, volume, and pressure curves. They typically are used for invasive ventilation. When set for pressure ventilation, they function on the PSV/PEEP algorithm, in which, as mentioned, the PSV level is superimposed on

the PEEP, with total inspiratory pressure thus resulting from the sum of PSV and PEEP.

2. *Portable home ventilators* (bilevel ventilators), electrically powered and providing only a single circuit for both inspiration and expiration. These machines are used exclusively for noninvasive ventilatory support. They function on the IPAP/EPAP algorithm, in which the inspiratory positive airway pressure (IPAP) is not superimposed on the expiratory pressure (EPAP).
3. *"Hybrid" ventilators*, usually powered by electricity, allowing both single- and double-circuit options. They use the PSV/PEEP algorithm. They can be used for both invasive as well as noninvasive ventilation.

INTERFACES

Patient-circuit interfaces for NIV can be nasal (nasal mask or nasal pillows or plugs), oral (mouthpiece), or facial (oronasal mask, full face mask, helmet). The choice of the appropriate interface is crucial to ensure the success of the treatment and patient compliance. In general, the nasal mask is better tolerated by patients, because it allows expectoration and creates less overall discomfort and is associated with less subjective claustrophobia. In acutely ill patients, face masks usually are preferred over nasal masks by most clinicians, because they provide better control of air leaks, especially in view of the difficulty of breathing exclusively through the nose for patients with acute respiratory failure. In fact, leak control is a key determinant of success for NIV, because it has been shown that air leaks represent the single most important cause of patient-ventilator asynchrony, even when such leaks are relatively modest. On the other hand, placement of nasal or oronasal masks should never be too tight, to prevent development of severe pressure skin lesions, especially frequent across the bridge of the nose, and to improve tolerability. The marked difference in internal volume associated with different interfaces does not usually affect NIV outcome in terms of clinical response and gas exchange variables, when the treatment is delivered by an experienced staff, as shown by a randomized prospective study that compared full face masks, oronasal masks of various sizes, and mouthpieces.

CLINICAL INDICATIONS

In the past decade, the role of NIV has steadily grown, so that it has now become a first-line intervention in a number of clinical conditions. In particular, on the basis of solid evidence gathered over the past 2 decades, NIV has been established as a first-choice intervention in the treatment of acute respiratory failure in the setting of COPD exacerbations and cardiogenic pulmonary edema. The role of NIV also appears to be well established in the management of respiratory failure developing in immunocompromised patients. Finally, NIV has been used as a weaning strategy and to reduce extubation failure.

EXACERBATIONS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Acute respiratory failure frequently complicates COPD exacerbations for a number of reasons deeply rooted in the pathophysiology of the disease. In particular, a combination of airway disease and loss of elastic recoil contributes to the generation of airflow limitation, which in turn can lead to air trapping and lung hyperinflation. As a consequence, the diaphragm is flattened, with loss of optimal length of its muscle fibers and diminished contractile efficiency. Moreover, intrinsic positive end-expiratory pressure (PEEPi) often is present, as a result of the nonreversible airflow limitation. PEEPi places a further burden on inspiratory muscles, because it has to be overcome before a negative alveolar pressure, necessary to the initiation of inspiratory airflow, can be generated.

The contraction of the diaphragm initially is isometric, and only after PEEPi has been counterbalanced can chest expansion begin. The combined effect of increased work of breathing and loss of contractile efficiency places the diaphragm at risk for development of fatigue, a precursor to acute alveolar hypoventilation with hypercapnia and respiratory acidosis. The first studies on the role of noninvasive ventilation in patients with COPD experiencing acute hypercapnic respiratory failure were conducted in the late 1980s. Since then, several controlled randomized studies have shown that NIV added to standard medical treatment is effective in reducing mortality, avoiding intubation, relieving dyspnea, and reducing length of hospital stay in patients with COPD with acute respiratory failure when compared with medical management plus oxygen therapy alone.

A randomized controlled study conducted on 236 patients showed that the rate of success with NIV was especially high in subjects with mild acidosis (pH greater than 7.30), whereas patients with more severe acidosis did not fare equally well and were more likely to require intubation. These findings point to the need for an early and accurate differentiation between patient subgroups on the basis of severity of illness, to allow prompt initiation of the most effective treatment. Patients with mild to moderate acidosis can receive NIV in hospital units outside the ICU, so long as they are staffed with trained personnel. More severely affected patients can still undergo a NIV trial, but only under strict management in an ICU setting, where they can be intubated with no delay in case signs of failure become apparent. Patients treated with NIV, irrespective of their initial severity status, had lower rates of infectious complications (ventilator-associated pneumonia, sepsis). A recent prospective study conducted in the United Kingdom in 9716 inpatients with COPD exacerbation and ARF managed in general clinical practice showed an overall mortality rate of 25% for patients receiving NIV—significantly higher than rates reported in the randomized controlled trials (RCTs). The study pointed to several potential explanations, including inaccurate selection of candidate patients for NIV, including, in some cases, patients with mixed acidosis or prevailing metabolic acidosis; the use of NIV as a "ceiling" of treatment in subjects with very severe disease; and substantial delays in initiating the ventilatory treatment. In addition, patients with mild acidosis (those in which the effectiveness of NIV is higher) appeared to be a minority among the overall group and often do not receive NIV at all. These results highlight the need for better implementation, in general clinical practice, of proper use of NIV in accordance with the evidence gathered from the RCTs.

CARDIOGENIC PULMONARY EDEMA

Cardiogenic pulmonary edema is a consequence of left ventricular failure. It frequently leads to a reduction in lung compliance, with decreased functional residual capacity, regional atelectasis, ventilation-perfusion mismatch and poor gas exchange, resulting in lung failure with hypoxemic respiratory failure. The latter condition is characterized by PaO_2/FIO_2 of less than 300. Treatment with CPAP has long been known to improve survival rate and to lower the need for intubation in patients with cardiogenic pulmonary edema, compared with those receiving conventional medical treatment plus oxygen therapy.

CPAP has the advantage of being practical and relatively easy to use; in most cases treatment with CPAP is administered directly in the emergency department.

In hypoxemic patients, conventional NIV has not produced significant improvements over those achieved with CPAP, although it can be effective in patients with cardiogenic pulmonary edema exhibiting hypercapnia. These data were recently questioned by a multicenter trial comparing oxygen therapy alone, CPAP, and NIV. The investigators concluded that with NIV, the physiologic improvements were faster than with oxygen alone, but without any significant effect on intubation or mortality rates. However, the very low intubation rate in this study (less than 3%) raises questions regarding whether the patient population was comparable to that of other studies.

RESPIRATORY FAILURE IN IMMUNOCOMPROMISED PATIENTS

An immunocompromised status, irrespective of its specific cause (hematologic neoplasms, use of immunosuppressant drugs, AIDS) often leads to lung infections of serious entity which may result in severe hypoxemic respiratory failure. Immunocompromised patients can potentially benefit significantly from NIV, especially because they are particularly at risk for infectious complications related to endotracheal intubation and invasive ventilation. In fact, it has been shown that NIV, especially when applied early, can significantly ameliorate the respiratory symptoms of these patients and reduce need for intubation and overall mortality. According to Principi and colleagues, NIV can even be administered to these patients, by trained personnel, outside the ICU, so as to avoid the risks related to exposure to the ICU environment. These data provide a rationale for a timely use of NIV as an effective means of treatment for respiratory failure in these patients.

ROLE OF NONINVASIVE VENTILATION IN HYPOXIC PATIENTS

One of the major confounders of these studies was the marked variability of the case mix; patients with different underlying disorders and pathophysiologic pathways were included under the same generic definition of having hypoxemia. Confalonieri and associates evaluated NIV in patients with ARF ($\mathrm{PaO_2/FIO_2}$ below 250) consequent to community-acquired pneumonia, including both those with and those without COPD. Compared with standard treatment alone, NIV produced a significant reduction in respiratory rate, need for endotracheal intubation, and ICU stay. A subgroup analysis, however, showed that the benefits of NIV occurred only in those patients with COPD.

Antonelli and co-workers compared NIV with conventional ventilation provided using an endotracheal tube in selected patients with hypoxemic ARF. Sixty-four consecutive patients were enrolled. After 1 hour of mechanical ventilation, the $\mathrm{PaO_2/FIO_2}$ ratio had improved in both groups. Ten patients in the NIV group required intubation. Patients randomized to receive conventional ventilation more frequently developed serious complications and, in particular, infections secondary to endotracheal intubation. Among survivors, the duration of mechanical ventilation and ICU stay were shorter in patients randomized to receive NIV. It should be kept in mind, however, that this single study was conducted in selected patients in one well-experienced center.

A study performed in three European ICUs with considerable expertise with NIV clarifies the issue of “real-life” use of NIV in this setting. This study showed that only 16.5% of patients admitted with ARDS can be successfully treated with this technique. In two years’ time, 479 patients were hospitalized for this disorder, a large majority of whom (69%) were already intubated at admission, so that only 147 were eligible for the study. NIV improved gas exchange and avoided intubation in 54% of this subset of patients, for an overall success rate of less than 20%. In these patients NIV was associated with less ventilator-associated pneumonia and a lower ICU mortality rate (6% versus 53%). It should be noted, however, that the study was conducted in three ICUs with solid expertise with NIV. In summary, the use of NIV as an alternative to invasive ventilation in severely hypoxemic patients generally is not advisable and should be limited to hemodynamically stable patients who can be closely monitored in an ICU.

Major surgery is sometimes complicated by the occurrence of atelectasis and pneumonia, which lead to hypoxemia and respiratory distress during the early postoperative period.

One randomized study showed that nasal CPAP delivered through a helmet decreased atelectasis and prevented pneumonia more effectively than did standard therapy alone during an episode of mild respiratory failure after upper abdominal surgery. In another study, NIV significantly ameliorated gas exchange and pulmonary function abnormalities after gastroplasty in obese patients.

NIV may be used in the early treatment of ARF secondary to lung resection, a fatal complication in up to 80% of cases. Auriant and colleagues showed that NIV is safe and effective for reducing the need for intubation and improving survival.

The use of NIV for severe acute respiratory syndrome (SARS) and other airborne diseases has generated debate. Two observational studies from China found no evidence of viral spread to caregivers who took appropriate precautions. In the event of a bird flu pandemic, ventilator resources are likely to be severely strained, and NIV may offer a means of supporting some of the afflicted, mainly those with initial respiratory failure. Some investigators, however, consider NIV to be contraindicated in respiratory failure from communicable respiratory airborne diseases unless it is used in a negative-pressure isolation room and strict precautions are taken against pathogen transmission.

In conclusion, the outcome of NIV in patients with hypoxemic ARF for whom endotracheal intubation is not mandatory yet depends primarily on the type and evolution of the underlying disorder. The high rate of failure of NIV in community-acquired pneumonia and acute respiratory distress syndrome suggests that for patients with these disorders, a cautious approach consisting of early treatment and avoidance of delay of needed intubation is advisable, and patients should be monitored in an ICU setting to assess progression toward the need for invasive ventilation.

ROLE OF NONINVASIVE VENTILATION IN THE PREVENTION OF POSTEXTUBATION FAILURE

Postextubation failure occurs in a percentage of patients varying from 2% to 20%. Necessity for reintubation usually becomes apparent 48 to 72 hours after extubation and is associated with a high mortality rate, as well as a high risk for lower respiratory tract infections. NIV has been applied as a mean of preventing extubation failure with a variable degree of success, depending on the nature and severity of the underlying disease. Recently an RCT conducted on 106 patients with chronic pulmonary disease and hypercapnic respiratory failure who were treated either with NIV for 24 hours after extubation or with oxygen therapy alone, showed a significant effect of NIV in reducing the incidence of postextubation respiratory failure, the need for reintubation, and the overall 90-day mortality. This study seems to confirm a potential role for early NIV treatment in the prevention and treatment of post-extubation failure, at least in patients with chronic respiratory disease.

NONINVASIVE VENTILATION AND WEANING

The first randomized controlled study of an NIV strategy was performed in severely ill patients with COPD ventilated through an endotracheal tube. Patients who failed the T-piece trial were randomized to undergo either extubation, with immediate application of NIV, or continued weaning with the endotracheal tube in place. The study showed that the likelihood of weaning success is increased, while the duration of mechanical ventilation and ICU stay are decreased, when NIV is used as a weaning technique.

A second randomized controlled study was conducted in patients with chronic respiratory disorders, intubated for an episode of ARF. This study also found a shorter duration of invasive mechanical ventilation in the group weaned noninvasively, although no differences were found in ICU or hospital stay or 3-month survival rate.

In a third randomized controlled trial, patients who failed spontaneous breathing trials on three consecutive days were randomized to be extubated and receive NIV or to remain intubated and continue a conventional weaning protocol. Most of the patients were affected by hypercapnic respiratory failure. The duration of conventional mechanical ventilation, time spent in the ICU, and duration of hospitalization were significantly reduced in the NIV group. Patients treated with NIV also had lower rates of nosocomial pneumonia and septic shock and better 90-day survival.

In a recent report, unselected patients who failed trials with a spontaneous-breathing T-piece were randomized either to undergo extubation and NIV or to attempt a traditional weaning trial during invasive ventilation. The percentage of complications in the NIV group was lower, with lower frequency of pneumonia and tracheotomy. Length of stay in the intensive care unit and mortality were not statistically different between the groups. Further studies are clearly needed to assess the real benefits of NIV in weaning with other forms of respiratory failure, such as acute respiratory distress syndrome, postsurgical complications, or cardiac impairment.

In conclusion, in accord with the results of a recent meta-analysis, NIV may be safely and successfully used in the ICU setting to shorten the process of liberation from mechanical ventilation in clinically stable patients recovering from an episode of hypercapnic ARF who had previously failed a weaning trial.

PHYSIOLOGIC EFFECTS OF NONINVASIVE VENTILATION

NIV has been proved to achieve a variety of effects in patients with ARF, largely irrespective of the ventilator mode (PSV or PAV). In particular, in patients with hypercapnia, NIV can restore acceptable levels of alveolar ventilation, significantly reducing $Pa\text{CO}_2$ and decreasing respiratory acidosis. Alveolar gas exchange also is significantly improved, as evidenced by an increase in $Pa\text{O}_2$, which appears to be more rapid and dramatic in patients with cardiogenic pulmonary edema. The improvement in gas exchange seems to involve multiple mechanisms: increased functional residual capacity (FRC) with positioning of the lung volume along the linear part of the pressure-volume curve, facilitating the distensibility of lung parenchyma, and rendering areas of atelectasis or dystelectasis more accessible to ventilation; more uniform overall ventilation with improvement in the ventilation-perfusion ratio; and a higher alveolar pressure opposing fluid extravasation from the capillary bed.

A variable degree of inspiratory muscle rest also usually is obtained, although total diaphragm rest is almost never achieved with NIV because the required inspiratory pressure level would be too high, leading to excessive air leaks and gastric overdistention. Work of breathing is almost constantly reduced, as signaled by a marked reduction in the amplitude of esophageal pressure inspiratory shift (ΔPes). Diaphragmatic rest during noninvasive ventilation is also shown by a reduction in the pressure-time product and of diaphragm electrical activity as measured by electromyography.

Amelioration of diaphragm fatigue and improvement in alveolar ventilation as indicated by reduction in the level of hypercapnia are associated with a more normal breathing pattern, with reduction in breathing frequency. In patients with COPD, NIV increases dynamic compliance (usually decreased in this condition as a consequence of ventilation inhomogeneity and pendelluft), thus allowing a more uniform distribution of ventilation.

Moreover, NIV effectively prevents the increase in $Pa\text{CO}_2$ often induced by oxygen therapy in ARF due to COPD exacerbations.

In addition to these favorable effects on respiratory mechanics and gas exchange, the potential for unfavorable hemodynamic effects also should be considered. In particular, even in normal persons, positive pressure, especially when applied throughout the entire ventilatory cycle, can reduce venous return to the heart, resulting in reduction in cardiac output. This effect has been demonstrated both in patients with “stable” COPD and during COPD exacerbations.

FUTURE DIRECTIONS

As reviewed in this chapter, the accumulating evidence seems to point to a number of more specific indications for the use of NIV. Several RCTs favor the use of this mode of ventilation. Smaller observational and pilot studies suggest the benefit of NIV in certain disease states; however, further large-scale trials are needed to confirm these findings. In certain geographic areas, old age is considered a barrier to ICU admission. Among patients older than 75 years, the use of NIV rather than standard therapy has been shown to significantly reduce mortality rate.

Some observation studies also have demonstrated that NIV may be successfully used to treat, rather than prevent, an episode of overt respiratory failure during exacerbations of a neuromuscular disease, cystic fibrosis, trauma, obesity-associated hypoventilation, and pancreatitis and eventually as a bridge to lung transplantation.

Indeed, other investigations suggested that NIV may be used in the weaning process in hypoxic patients, and in the treatment of postextubation failure in the subset of hypercapnic patients.

CONTROVERSIES AND PITFALLS

Despite the growing evidence for a role for NIV in the management of ARF, still unresolved are a few questions concerning its optimal utilization in clinical practice. The main controversy concerns the safety of NIV when applied outside the ICU setting, specifically in emergency departments and on regular wards. Although some evidence shows that NIV can be performed with good results in regular respiratory wards, the limiting factor for its success is the availability of specifically trained staff (doctors, nurses, and respiratory therapists). Such availability is far from consistent across hospitals and countries, so the experiences of different groups often are difficult to compare and to generalize. Availability of skilled and experienced staff is obviously crucial for proper patient selection and monitoring, appropriate handling of the equipment, and timely recognition of signs of worsening that might require escalation to invasive ventilation.

The same observations apply in the emergency department, where most patients with ARF who could potentially benefit from NIV initially are evaluated. In fact, many of these patients, for logistical reasons (such as shortage of ICU beds), first receive NIV in this setting, where monitoring is critical for ensuring success, because a delay in switching from noninvasive to invasive ventilation when necessary may result in increased mortality. Accordingly, knowledge and proper evaluation of the predictors of NIV outcome are extremely important.

As indicated by the foregoing considerations, the effectiveness of NIV is strictly dependent on location of implementation, timing, and staff training. Its success or failure will therefore depend on careful, case-by-case judgment that is firmly rooted in the reality of the available resources.

CONCLUSIONS

In summary, the past 2 decades have witnessed a dramatic increase in the use of NIV, which has become a clear-cut first-line treatment in the management of ARF in conditions as diverse as COPD and cardiogenic pulmonary edema and, in many instances, in immunocompromised patients. Moreover, NIV is no longer confined to the ICU, but in expert hands, it has crossed ever more often into the regular ward, thus broadening the spectrum of options available for the treatment of respiratory failure. Current research is focusing on improving the quality and safety of the devices and establishing new ventilatory modes to extend even further the indications for use of NIV, as well as improving its rate of success.

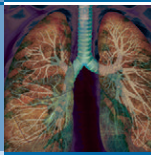
Section 6
CRITICAL CARE RESPIRATORY MEDICINE



Chapter 34

Airway Management in the Intensive Care Unit*

Michael Spiro • Alan McGlennan

The decision to instrument the airway of a patient is one of the most crucial taken; this approach to airway management, although often required in an emergency situation, requires considerable skill, experience, and knowledge of the different types of procedures available. The main reasons to instrument the airway are (1) failure of oxygenation, (2) failure of ventilation, and (3) protection of the airways.

Patients with a variety of medical and surgical diseases may require ventilatory assistance or improved airway control. Such patients include those with primary respiratory failure or with respiratory insufficiency secondary to other pathologic conditions. Implementation of respiratory support may be undertaken semielectively or on an emergency basis.

Airway instrumentation should be performed only by a skilled physician who has assessed the patient thoroughly addressing the risks and benefits for that patient. A vital step in this assessment is prediction of the ease with which intubation is likely to be possible, with identification of an appropriate alternative approach to use in case difficulties arise. An important point to remember is that patients die not because of a failure to intubate but as a result of failure to oxygenate; therefore, recurrent failed attempts to gain airway control should be avoided. Problems with ventilation can quickly lead to severe hypoxia, brain damage, or death.

INDICATIONS FOR AIRWAY SUPPORT

The most common indication for ventilatory support in intensive care is acute respiratory failure, resulting in hypoxia, hypercapnia, or increased work of breathing, necessitating the need for positive-pressure ventilation. This can be provided as noninvasive ventilation (NIV) or as invasive ventilation requiring intubation. Intubation also may be indicated with loss of airway reflexes associated with a reduced level of consciousness, meaning that the patient is unable to protect their airway. Airway protection may be needed in cases of airway soiling or excessive secretion with inadequate cough. The neurosurgical patient managed in the ICU may require ventilation to regulate PaCO_2 for control of intracranial pressure. Endotracheal intubation also may be needed when swelling or trauma to the upper respiratory tract results in impending airway loss.

NONINVASIVE VENTILATION

Patients with respiratory failure and preserved airway reflexes may benefit from NIV. The rationale for this application, most commonly seen in acute exacerbations of chronic obstructive pulmonary disease (COPD), is that NIV may reduce the work of breathing and help to correct hypercapnic or hypoxic respiratory failure. NIV is contraindicated, however, with cardiovascular or respiratory instability, compromised ability to handle secretions, aspiration risk, or inability to tolerate a tight-fitting face mask (see Chapter 33 on NIV).

AIRWAY ASSESSMENT

Before instrumentation of the patient's airway, a thorough assessment should be performed to ascertain the likelihood of difficulty in achieving airway control. Several specific aspects of this assessment are considered next.

PREDICTORS OF DIFFICULT MASK VENTILATION

Difficult mask ventilation is encountered in 8% of patients. Patients at risk for such difficulty include those with preexisting partial airway obstruction, snorers, those with facial asymmetry, the obese, persons with Mallampati class IV airway anatomy (complete lack of epiglottis visualization), and the edentulous. Management of patients with facial hair, which often hides a receding mandible and in itself makes a seal for mask ventilation difficult, can present significant problems.

PREDICTORS OF DIFFICULT INTUBATION

Difficult intubation is common in the ICU population, with frequency of reported difficulty between 6.6% and 22%. A history of airway problems should be sought—for example, snoring, sleep apnea, congenital diseases (such as Down or Pierre-Robin syndrome), and previous anesthetic problems.

Examination of the patient should determine the following: ability to protrude the mandible, range of neck movement, atlantooccipital flexion and extension, interincisor distance (less than 3 cm indicates a high likelihood of difficulty), and modified Mallampati test (**Figure 34-1**). Other predictors of difficult intubation include thyromental distance of less than 7 cm (Patil's test) and obesity. Further investigations when indicated could include the view of the larynx obtained at nasal

---

*Additional content for this chapter can be found on Expert Consult.

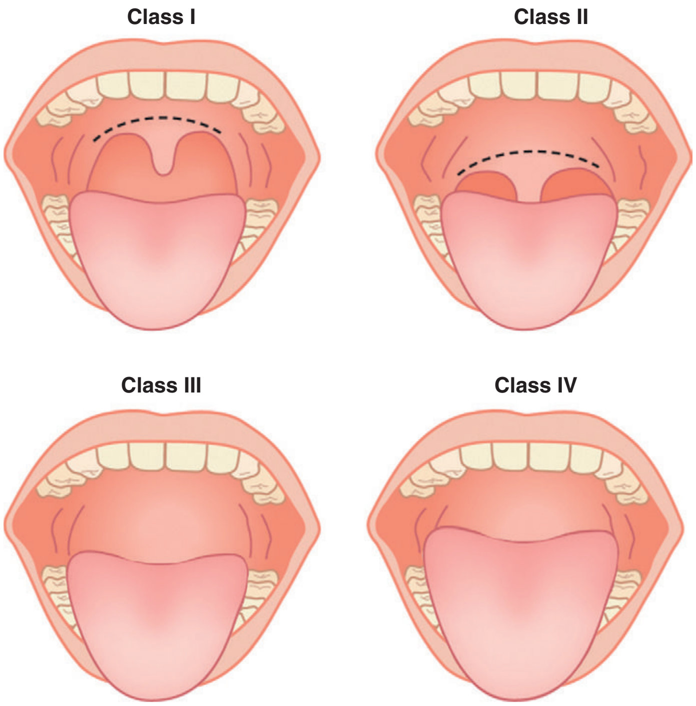


Figure 34-1 Mallampati test to classify view of the pharynx. For this test, the patient is asked to protrude the tongue fully while opening the mouth maximally, with the head in the neutral position. *Class I*: The pharyngeal pillars, soft palate, and uvula are visible. *Class II*: Only the soft palate and uvula are visible. *Class III*: Only the soft palate is seen. *Class IV*: Only the hard palate is seen. Mallampati class correlates with Cormack and Lehane grade for the view at laryngoscopy (see Figure 34-5). Increasing class suggests more difficult laryngoscopy.

Box 34-1 Risk Factors for Aspiration at Time of Intubation

Instrumentation before postprandial interval of less than 6 hours

Symptomatic reflux

endoscopy, which may predict the view at laryngoscopy; chest radiographs, which may show tracheal deviation or mediastinal masses; and CT scans, which may be useful when abnormal anatomy is suspected—for example, in association with tracheal stenosis.

ASPIRATION RISK

Aspiration of gastric contents can cause significant morbidity and mortality. Evidence suggests that reducing gastric volume and increasing pH of gastric contents will limit the risk of disorders associated with aspiration. Acid aspiration may lead to a chemical pneumonitis, but aspiration of food particles can result in physical obstruction of the bronchial tree with secondary bacterial pneumonia (Box 34-1 and Table 34-1).

Table 34-1 Drugs to Reduce Aspiration Risk

Drug Class	Specific Agent	Mechanism of Action
Histamine H_2 receptor antagonists	Ranitidine 50 mg IV	Increases pH and decreases gastric volume
Proton pump inhibitors	Omeprazole 40 mg IV	Irreversibly binds H^+/K^+-ATPase; increases pH and decreases gastric volume
Nonparticulate antacids	0.3 M sodium citrate, 10 mL	Neutralizes gastric pH but increases volume Very effective at increasing gastric pH if given within 30 minutes
Prokinetics	Metoclopramide 10 mg	Reduces gastric volume

BASIC AIRWAY MANEUVERS AND AIRWAY ADJUNCTS

Patients with complete or partial airway obstruction may benefit from basic airway maneuvers to open the airway. Depending on the cause of airway compromise, suctioning may be needed to remove foreign bodies. Neck flexion with extension at the atlantooccipital joint and a chin lift can be used when upper airway tone is reduced; a jaw thrust should be used with in-line stabilization when cervical spine injury is suspected. In patients with a reduced level of consciousness, insertion of an appropriately sized oropharyngeal or nasopharyngeal airway may be helpful.

ENDOTRACHEAL INTUBATION WITH MUSCLE RELAXATION

POSITIONING

Putting the patient in the optimal position is the first and most important step. Appropriate positioning allows good access to the airway and allows efficient preoxygenation. Other advantages include improvement of the laryngoscopic view and, with the head held slightly up, a reduced risk for aspiration of gastric contents. The "head-up" position also increases functional residual capacity by allowing better diaphragmatic excursion, thereby increasing oxygen reserves. The patient should be positioned with the neck flexed on a pillow, but with the head extended, so long as cervical spine injury is not suspected. Positioning is of particular importance in the obese patient (Figure 34-2).

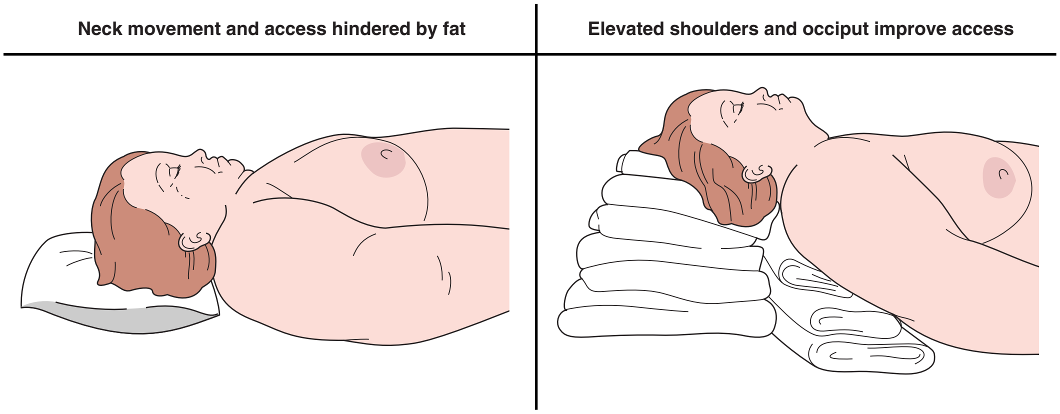
BAG MASK VENTILATION

In an elective setting, patients who are adequately fasted may be anesthetized and administered a nondepolarizing muscle relaxant. While awaiting the onset of muscle relaxation, the patient is oxygenated by positive-pressure bag mask ventilation before endotracheal intubation. In other circumstances, a profoundly hypoxic patient may need bag mask ventilation before intubation—for example, in a cardiac arrest scenario. Implementation of this ventilatory mode is therefore a key, lifesaving skill for all physicians to possess. Successful bag mask ventilation requires an open airway, a good seal with the face mask, and the application of positive pressure achieved by compressing the reservoir bag connected to high-flow oxygen.

In patients at risk for aspiration, *rapid sequence induction* can be performed. With the classic technique, the initial step is formal preoxygenation of the patient, followed by the administration of a predetermined dose of rapid-onset general anesthetic agent and then a rapid-onset muscle relaxant. Cricoid pressure is applied, and the patient is intubated as soon as muscle relaxation has occurred.

Table 34-2 **Drugs Used in Airway Management in the Intensive Care Unit**

Drug	Dose	Action	Comments
Thiopental	3-5 mg/kg	General anesthesia	Barbiturate with rapid onset and offset after bolus administration Potent anticonvulsant
Propofol	1.5-2.5 mg/kg	General anesthesia	Rapid onset, offset slower than with thiopental bolus; causes more hypotension Pain on injection
Suxamethonium	1-2 mg/kg	Relaxation within 30 seconds	Rapid offset, multiple unwanted effects Myalgia, hyperkalemia, arrhythmias, allergy, “suxamethonium apnea”
Rocuronium	1 mg/kg	Muscle relaxation within 60 seconds	Long duration of action, risk of allergic reactions
Suggamadex	2-16 mg/kg	Rapid reversal of rocuronium	Reversal of muscle relaxation in l to 2 minutes Reports of bradycardia



Neck movement and access hindered by fat
Elevated shoulders and occiput improve access

Figure 34-2 Positioning the obese patient. Correct positioning is important to optimize the view during laryngoscopy. Flexion of the lower cervical spine brings the trachea in line with the pharynx, and extension at the atlantooccipital joint aligns the trachea with the oral cavity. With the obese patient in the supine position, neck movement and access with a laryngoscope are hindered by fat. When the patient is repositioned with the shoulders elevated and the occiput further elevated so that the head assumes a “sniffing” position, access to the airway is facilitated. *(From Wiener-Kronish JP, Shimabukuro DW: Airway management. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

PREOXYGENATION

Before induction of anesthesia, the patient should be fully preoxygenated. The patient breathes 100% oxygen through a tight-fitting face mask for 3 minutes. In an emergency, five vital capacity breaths of 100% oxygen can be used in an attempt to fill the functional residual capacity lung compartment with oxygen, thereby significantly raising the alveolar PO_2. This step prolongs the time to desaturation after the onset of apnea, affording the operator significant time to manage the airway safely (Table 34-2).

CRICOID PRESSURE

A major concern with an emergency intubation is the risk of aspiration of gastric contents. Cricoid pressure can be applied to prevent passive regurgitation of stomach contents, with subsequent airway soiling. The assistant exerts firm pressure (equivalent to 30 newtons [N] of backward pressure) on the cricoid cartilage to compress the esophagus against the body of the sixth cervical vertebra as the level of consciousness diminishes (Figure 34-3). Cricoid pressure should be removed only if the patient actively vomits (associated with risk for esophageal rupture) or in specific instances of inability to oxygenate (see the difficult intubation algorithm presented in Figure 34-7).

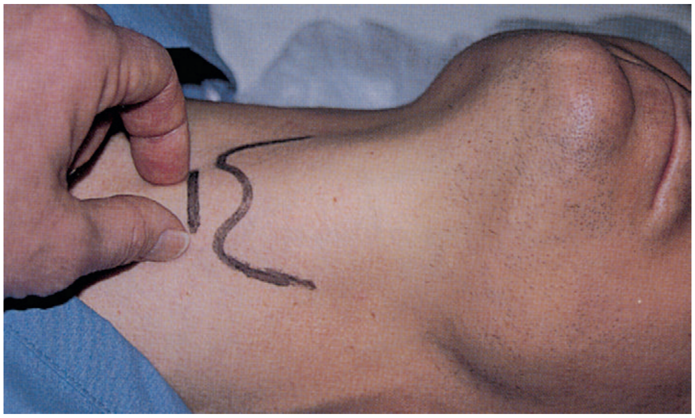


Figure 34-3 Cricoid pressure. The cricoid cartilage is identified by palpation below the thyroid cartilage. Firm pressure is placed on this structure to occlude the esophagus against the body of the sixth cervical vertebra. Pressure is maintained until after intubation is accomplished and airway control is achieved. *(From Wiener-Kronish JP, Shimabukuro DW: Airway management. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

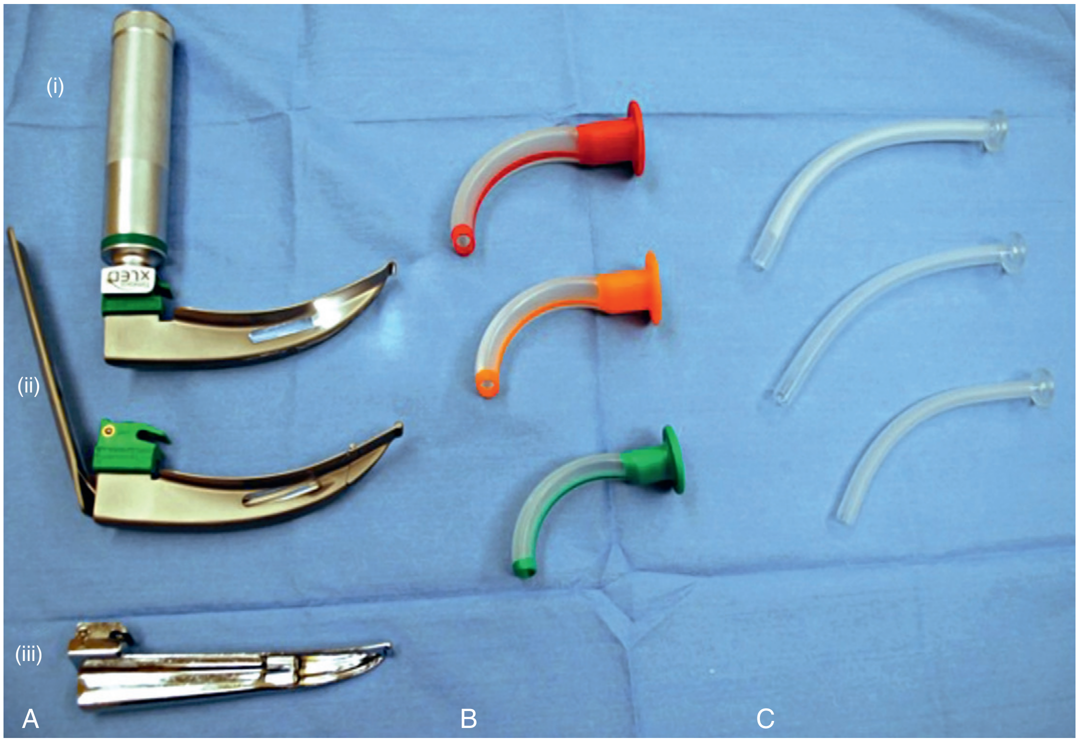

Figure 34-4 Airway management equipment. **A,** Laryngoscope blades: *(i),* The Macintosh blade size 3, the most commonly used blade for intubating an adult. *(ii),* The McCoy blade size 3. Note the hinged tip, which can be activated by depressing the lever; this can be used to elevate the epiglottis when the view of the laryngeal inlet is obscured. *(iii),* The Miller blade size 3, a straight blade that is used to lift the epiglottis directly with the tip, to obtain a view of the larynx. **B,** Oropharyngeal airways in the most common sizes used in adult patients: size 4 (*red*), 3 (*orange*), and 2 (*green*). **C,** Nasopharyngeal airways in different sizes, from *top*: 8.5F, 7.5F, and 6.5F. The size chosen will depend on the size of the patient and appropriate length.

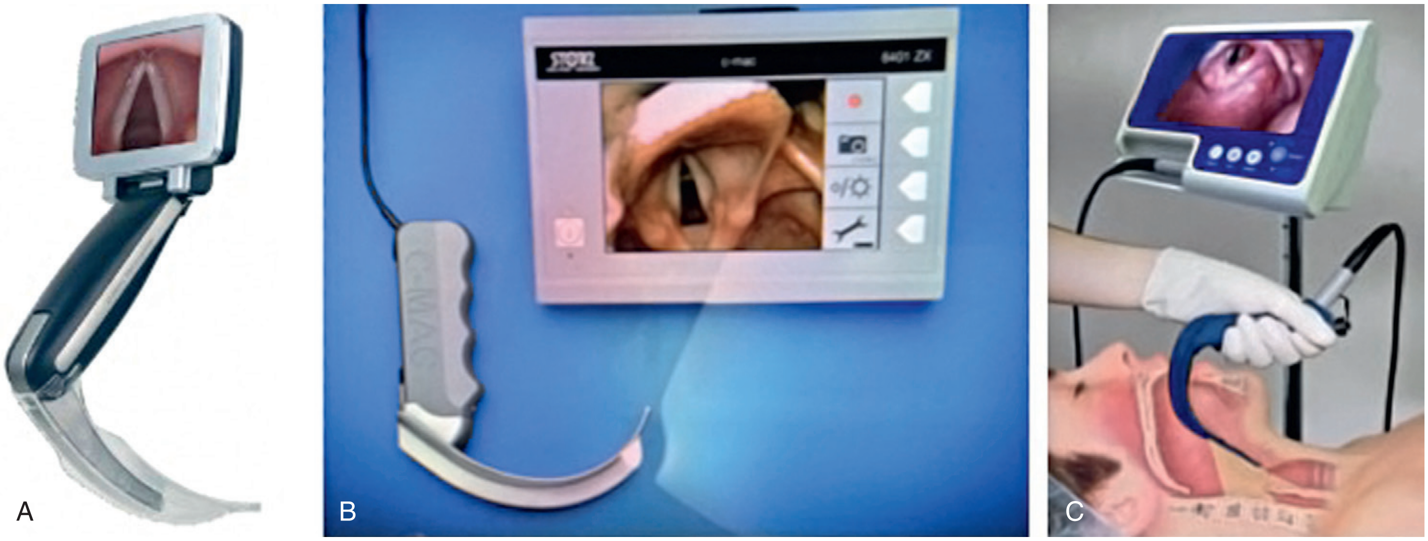

Figure 34-5 Video laryngoscopes. Indirect laryngoscopy performed using a video laryngoscope allows intubation with less manipulation of the cervical spine and often provides an improved view of the laryngeal inlet when problems have been encountered with direct laryngoscopy. **A,** The Venner AP Advance, a handheld laryngoscope with a screen built into the handle. **B,** The Storz C-Mac scope. **C,** The Glidescope. The instruments shown in **B** and **C** both are handheld laryngoscopes with a separate video display screen.

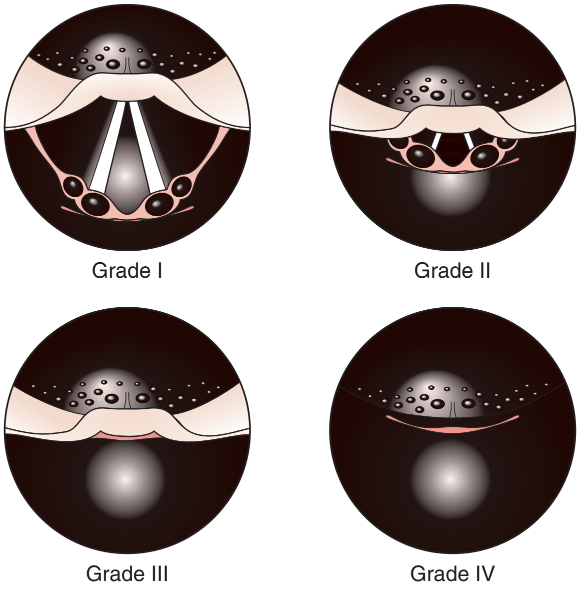
EQUIPMENT

The most common laryngoscope blade used for intubation in adults is the curved Macintosh blade (Figure 34-4). This is inserted into the right side of the mouth to displace the tongue laterally. The tip of the blade sits in the vallecula and is lifted forward to elevate the epiglottis and expose the laryngeal inlet. The McCoy blade is a variant of the Macintosh and has a hinged tip to further lift the epiglottis. A straight Miller blade can be useful in adults in whom the epiglottis is difficult to displace. This blade is inserted further to directly lift the epiglottis. Where laryngoscopy may be difficult a video laryngoscope can be used. There are now a variety of different models available on the market (Figure 34-5). They require less manipulation of the cervical spine and allow intubation in a seated



Grade I Grade II

Grade III Grade IV

Figure 34-6 Cormack and Lehane grading of laryngoscopic views: *Grade I*: The entire laryngeal inlet is visible. *Grade II*: The arytenoids and posterior vocal cords are seen. *Grade III*: Only the epiglottis is visible, *Grade IV*: The epiglottis is not visualized. Grade III and grade IV views suggest difficulty in passing an endotracheal tube. They often will mandate the use of a bougee or an alternative intubation technique.

position, reducing the aspiration risk (Videos 1-4). Awake fiberoptic intubation may be used were visualization of the larynx may be difficult by other means or if access to the mouth is restricted.

LARYNGEAL ANATOMY

The view of the laryngeal inlet obtained at direct laryngoscopy can be graded in accordance with the Cormack and Lehane classification (Figure 34-6). Grade I and grade II views indicate straightforward intubation. A grade III view frequently necessitates the use of a gum elastic bougee to "railroad" the endotracheal tube (ETT) into position, whereas a grade IV view often will mandate a different strategy to achieve successful intubation.

Awake Fiberoptic Intubation

Awake intubation is used in patients with a predicted difficult airway or an unstable cervical spine. This technique allows patients to maintain their own airway until intubation is achieved, thereby greatly reducing the risk for aspiration: risk. No manipulation of the cervical spine is needed. If problems are encountered at any stage, the procedure can be safely abandoned.

The nostrils are prepared with local anesthetic and a vasoconstrictor. An endotracheal tube is mounted on a fiberoptic bronchoscope, which is then maneuvered through the nose, the nasopharynx, and finally the larynx until the scope is situated superior to the carina. Once appropriately positioned, the endotracheal tube is railroaded over the scope. The cuff is inflated and tube position is confirmed before induction of anesthesia.

Gaseous Induction

In patients with stridor or in other situations characterized by partial airway obstruction, a gas induction can be performed. The patient breathes volatile anesthetic, often sevoflurane, through a tight-fitting face mask until anesthesia is induced. This aspect of the technique keeps the patient spontaneously breathing and maintains a degree of airway tone, preventing airway loss. Tracheal intubation is then performed with the patient under deep inhalational anesthesia. Muscle relaxants are given only after the trachea is intubated and airway control has been established.

Confirming Intubation

Correct ETT placement is confirmed clinically by visualizing the tube's passage through the vocal cords and observation of fogging of the ETT, symmetric chest movement, and bilateral air entry. The "gold standard" modality for such confirmation is measurement of end-tidal CO_2 on ventilation. In critical care, a chest radiograph is performed to confirm ETT position above the carina. Provision must always be made for unexpected difficult intubation.

RESCUE TECHNIQUES

Whenever the decision is taken to intubate, the physician should always have an alternative plan to use if any difficulties are encountered. In the United Kingdom, the difficult intubation algorithm produced by the Difficult Airway Society is used (Figure 34-7).

MASK VENTILATION

When intubation is difficult or impossible, oxygenation of the patient remains the main priority. Mask ventilation (with application of cricoid pressure if aspiration is a risk) with 100% oxygen should be attempted. If this proves to be difficult, an airway adjunct, such as a Guedel oropharyngeal airway, should be inserted. A four-handed technique may be used, with two hands holding the mask and maintaining the patient's airway while an assistant operates the bag used to ventilate the patient.

LARYNGEAL MASK AIRWAY

The laryngeal mask is a supraglottic device that has revolutionized anesthesia in the past 25 years. It is inserted orally and when inflated sits in the posterior hypopharynx, pushing the tongue base anteriorly and keeping the glottis open. Its design has been modified and improved over time. Using the laryngeal mask airway (LMA) to ventilate a paralyzed patient in the operating room is now considered acceptable, particularly since the advent of such masks with a gastric port to allow venting of any refluxed gastric secretion. The use of LMAs in resuscitation is promoted in certain practice areas owing to its ease of insertion.

The LMA is extremely useful in clinical situations in which mask ventilation would be difficult or when intubation is impossible. It can be used to maintain oxygenation while a plan for definitive airway control is made, or it can be used as a conduit for access to the larynx. A fiberoptic scope can be inserted through the LMA and an ETT passed over the scope into the trachea. The intubating LMA is specifically designed to facilitate tracheal intubation; special features include an epiglottic elevating bar facilitating access to the trachea. It can be useful in patients in whom neck movement is limited (Figure 34-8).

SURGICAL AIRWAYS

CRICOTHYROIDOTOMY

In situations in which it is not possible to either intubate or ventilate the patient, an emergency cricothyroidotomy should be performed (Figure 34-9). The cricothyroid membrane is an

LMA^{TM}
Reduce cricoid force during insertion
Oxygenate and ventilate
Succeed
Postpone surgery and awaken patient if possible or continue anesthesia with LMA^{TM} or ProSeal LMA^{TM} — if condition immediately life-threatening
Failed ventilation and oxygenation
Plan D: Rescue techniques for "can't intubate, can't ventilate" situation

Figure 34-7 Difficult Airway Society guidelines for airway management. If the initial intubation plan (*Plan A*) fails, no more than three attempts at direct laryngoscopy should be performed; an alternative method should be used to facilitate tracheal intubation and maintain oxygenation. Should these techniques fail, then oxygenation is the main priority while the patient is woken up, if appropriate (*Plan C*). Should it be impossible to intubate or ventilate the patient using any of these methods, emergency transtracheal ventilation or cricothyroidotomy should be performed (*Plan D*). *(Courtesy Difficult Airway Society, Association of Anaesthetists of Great Britain and Ireland, London.)*

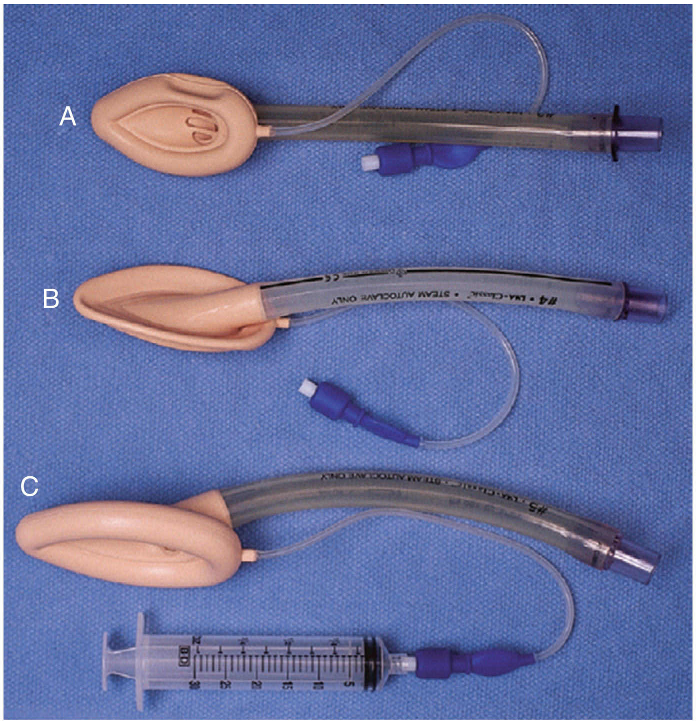

Figure 34-8 Laryngeal mask airway (LMA), available in sizes 1 to 5. Usually, the LMA is inserted fully deflated, with the tongue and mandible gently pulled anteriorly, with continuous pressure posteriorly until a firm end point is reached. Position is confirmed after cuff inflation by the ability to ventilate the patient, as noted by chest rise and auscultation. Most adults will accept a size 4 or 5 airway. The LMA allows ventilation and placement of an endotracheal tube by means of a fiberoptic bronchoscope if direct laryngoscopy has failed. **A,** Size 3, partially inflated. **B,** Size 4, completely deflated. **C,** Size 5, completely inflated. *(From Wiener-Kronish JP, Shimabukuro DW: Airway management. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

avascular membrane joining the thyroid cartilage to the cricoid cartilage. A purpose made kink-resistant cannula can be inserted through the cricothyroid membrane into the trachea, and then the patient is jet ventilated through this tube. Larger cricothyroidotomy devices can be used that allow the patient to be ventilated in a conventional fashion. Surgical cricothyroidotomy requires more skill and involves dissection down to the cricothyroid membrane, followed by insertion of an appropriately sized endotracheal tube (6-mm inner diameter) into the trachea. Cricothyroidotomy is associated with multiple complications, including airway loss, esophageal trauma, bleeding, false passage formation, pneumothorax, and surgical emphysema.

TRACHEOSTOMY

Surgical tracheostomy requires a skilled surgeon. It can be performed to sidestep impending upper airway loss in the awake patient with use of local anesthesia. It is not suitable as a rescue technique because it is time-consuming. Boxes 34-2 and 34-3 lists the indications for and possible complications of surgical tracheostomy.

Box 34-2 Indications for Tracheostomy

Emergency
Impending airway obstruction

Elective
Aid weaning (reduce dead space)
Reduce sedation requirement
Improve oral care
Reduce damage to glottis
Improve patient comfort

Box 34-3 Complications of Tracheostomy

Early
Bleeding
Pneumothorax
Surgical emphysema
Airway loss and hypoxia
Esophageal trauma
Laryngeal trauma

Late
Airway blockage
Dislodged tracheostomy tube
Tracheomalacia
Infection

PERCUTANEOUS TRACHEOSTOMY

Percutaneous tracheostomy is favored by many intensive care physicians because it can be performed at the bedside—useful when an unstable patient is too ill for transfer to the operating room—and because the tracheostomy cannula can be inserted by physicians, thus avoiding the logistics of arranging for a surgeon. Other advantages include less tissue damage, lower risk of bleeding, and lower infection rates. Factors making percutaneous tracheostomy an unsuitable choice include difficult anatomy, short neck, and abnormal vascular anatomy.

The intubated patient is positioned with the neck extended while being preoxygenated with 100% oxygen. Two skilled operators are required, one to perform the procedure and another to manage the airway. Local anesthetic is infiltrated and a small incision is made below the cricoid cartilage. Blunt dissection is performed until the trachea is easily palpable to the operator. A fiberoptic bronchoscope is inserted down the ETT, and a needle attached to a syringe is inserted into the trachea between the second and third tracheal rings under direct vision. Air is aspirated through the syringe, and a wire is threaded through the needle into the trachea. A dilator is passed over the wire to enlarge the tract. The tracheostomy tube is then inserted over the wire.

CONTROVERSIES AND PITFALLS IN AIRWAY MANAGEMENT

The rapid sequence induction technique with application of cricoid pressure is a relatively recent introduction to anesthesia. It is widely adhered to in many countries (e.g., the United Kingdom) for cases in which aspiration of stomach contents is a risk during induction. Many countries, however, do not use cricoid pressure to help prevent aspiration (e.g., France). No agreement has emerged regarding which approach is safer. This lack of uniformity worldwide is set to be complicated by the advent of newer drugs. Suggamadex is a gamma cyclodextrin that directly binds aminosteroidal nondepolarizing muscle relaxants in the plasma. Suggamadex allows the rapid reversal

The membrane is punctured with a catheter while aspirating for air. The catheter is advanced caudally into the trachea after the needle is removed. The catheter is then attached to a high-pressure oxygen delivery system. Exhalation is passive, relying on a patent upper airway. **B,** To perform a cricothyroidotomy, a 3-cm vertical skin incision is made below the thyroid notch; then the cricothyroid membrane is incised with a scalpel blade and the opening dilated with use of the handle, and a small endotracheal tube is placed in the airway. *(From Wiener-Kronish JP, Shimabukuro DW: Airway management. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

of rocuronium-induced muscle relaxation and deep levels of blockade. This may make suxamethonium redundant in anesthesia, since it is used because of its rapid onset, and more important, rapid offset of effects. Suxamethonium also has a considerably worse side effect profile than does rocuronium.

Thiopental has been superseded in most countries by propofol as an induction agent, particularly because of its smoother postoperative profile. Thiopental is retained for rapid-sequence inductions by some operators, however, because of not only its rapid and predictable onset, with a definite end point, but also its rapid offset (generally 5 minutes)—a boon in failed intubation scenarios. In a classic rapid sequence induction, opioids should not be given before the trachea is intubated, mainly because of the increased time to return of spontaneous respiration, which may be dangerous with failure of intubation. Nevertheless, use of these agents is advocated in cases in which a large degree of cardiac stability is needed.

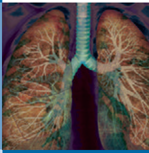
CRITICAL CARE RESPIRATORY MEDICINE



Chapter 35
Hemodynamic Monitoring in Critical Illness

Mark Lambert • Phil Bearfield

The cardiovascular system is subject to rapid and profound changes during critical illness. Tissue hypoperfusion and hypoxia constitute an important cause of organ dysfunction in critically ill patients. Such pathophysiologic changes often are encountered in the setting of shock states attributable to inadequate cardiac output. Therapeutic maneuvers aimed at raising cardiac output have the potential to increase oxygen delivery to the whole body, as can be described by the simplified oxygen flux equation:

$$\dot{D}O_2 = CO \times CaO_2$$

where $\dot{D}O_2$ is whole-body oxygen delivery, CO is cardiac output, and CaO_2 is arterial oxygen content. Increasingly, for the patient as a whole, flow is seen as a more important therapeutic target than pressure, although in certain organs, adequate perfusion pressure is known to be crucial (e.g., brain, heart, kidneys).

Monitoring of cardiovascular parameters allows clinicians to make informed decisions on how to optimize cardiac and circulatory function in order to maintain adequate tissue perfusion. Knowledge of the relevant anatomy and physiology is an essential prerequisite for correct interpretation of the data generated by any monitor.

CIRCULATION MODEL

The circulatory system can be modeled as a hydraulic circuit with a pulsatile pump representing the heart. Cardiac output is the product of heart rate and left ventricular stroke volume. Stroke volume is dependent on preload, left ventricular contractility and afterload. Despite increasingly sophisticated monitoring systems, obtaining accurate quantification of these variables at the bedside remains difficult.

In critical care units, cardiac output monitors are used to measure the hemodynamic impact of a therapeutic intervention. When such equipment is used in this manner, precise measurement rather than accurate measurement may be a more desirable property of any hemodynamic monitor (i.e., precise, reproducible measurement of the *change* in cardiac output is more useful than accurate but imprecise values).

MONITORING DEVICES

Central venous catheters, arterial catheters, and pulse oximeters are used routinely in the critical care setting. In addition, pulmonary arterial catheters, ultrasound-based cardiac output monitors, and devices that measure cardiac output by analysis of the morphology of the arterial pressure waveform also may be used. Despite advances in monitoring technology, significant complications are associated with their use, and to date, evidence for any consequent improvement in survival is lacking. This section addresses the indications, complications, and interpretation of data from the monitoring devices in common use.

ARTERIAL PRESSURE MONITORING

Systolic, mean, and diastolic systemic arterial pressures are routinely measured. Mean arterial pressure (MAP) is a function of cardiac output (CO) and systemic vascular resistance (SVR).

$$MAP = CO \times SVR$$

Because vascular tone and thus SVR are independently controlled, it is not possible to use mean arterial pressure values alone to make assumptions about cardiac output. An adequate systemic blood pressure does not equate to adequate cardiac output or adequate flow in discrete tissue beds.

The systemic arterial pulse wave is generated in the left ventricle and is transmitted through the arterial tree at 6 to 10 meters/second. It comprises an incident pressure wave (from the contraction of the left ventricle) and a reflected pressure wave (from the periphery). As the pulse wave advances through the vascular tree, the systolic pressure is seen to increase as a result of an increase in the magnitude of the reflected wave. Therefore, measured systolic arterial pressure varies depending on the site of measurement. Mean arterial pressure may be a more useful marker than systolic blood pressure, because its value is less dependent on site of measurement, is least altered by damping, and is more relevant in determination of blood flow to vital tissue beds such as the brain and kidneys.

Noninvasive Arterial Blood Pressure Monitoring

Noninvasive arterial blood pressure (NIBP) measurements in critical care most commonly are taken using an automated oscillometric device. This consists of a circumferential pneumatic cuff applied to the arm or leg. The cuff is inflated to a pressure above systolic arterial pressure, followed by controlled slow deflation of the cuff. As the cuff pressure falls below systolic arterial pressure, turbulent flow occurs in the artery beneath the cuff, causing oscillations in cuff pressure, which become maximal at MAP (Figure 35-1). Processing software allows determination of systolic, mean, and diastolic pressures in accordance with the amplitude of these oscillations.

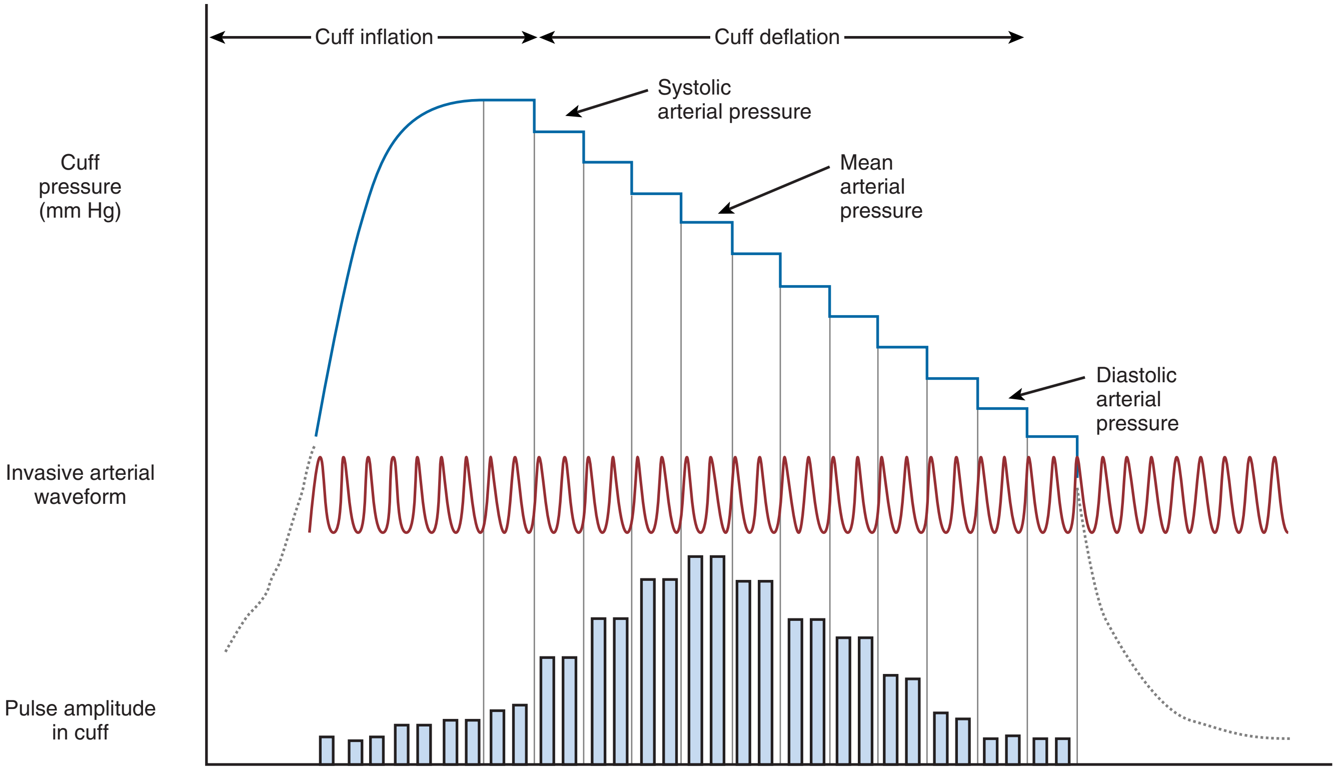


Figure 35-1 Oscillation in blood pressure cuff showing maximum amplitude of cuff oscillation corresponds with mean arterial pressure (MAP).

This technique allows frequent measurement of blood pressure and can be used when continuous monitoring of arterial pressure is not required. It also provides useful confirmation of the reliability of invasive arterial measurement. Measurements in the normotensive range are considered to be accurate but tend to underestimate hypertensive values and overestimate hypotensive values. Measured values are less accurate in the presence of arrhythmia and with incorrect cuff sizing. Cuff width should be 20% greater than arm diameter, with use of a narrow cuff associated with a tendency toward erroneously high values.

Relative contraindications to cuff use include severe peripheral vascular disease, arteriovenous fistulas, local absence of lymph nodes consequent to resection, and local skin or muscle damage.

Complications are rare, but obtaining repeated measurements over short periods may lead to local skin ulceration or bruising. Injury to the ulnar nerve also has been reported.

Invasive Arterial Pressure Monitoring

Under conditions of hemodynamic instability or during therapeutic manipulation of the cardiovascular system, intermittent monitoring of blood pressure provides insufficient clinical information. An indwelling arterial catheter allows direct and continuous measurement of arterial blood pressure, as well as graphical display of the arterial waveform. Arterial blood sampling from the catheter also can be performed, allowing information to be obtained about metabolic status and respiratory function.

The radial, brachial, axillary, femoral, and dorsalis pedis arteries can be used for cannulation, with the radial artery most commonly used. Use of a 20-gauge cannula is recommended to reduce the incidence of vessel occlusion; a cannula of this size also has the most favorable physical properties for accurate pressure measurement. Insertion is performed under conditions of strict asepsis using either direct cannulation or a modified Seldinger technique. Distal perfusion should be periodically assessed after cannulation to ensure that arterial occlusion has not occurred.

The arterial cannula is connected by a continuous column of saline to a pressure transducer which takes atmospheric pressure at the level of the right atrium as its zero reference point. The system is continuously flushed from a pressurized saline source at a rate of 2 to 3 mL/hour to prevent aggregation of thrombus and subsequent occlusion of the cannula. Modifications to the transducer system and maneuvers promoting formation of clots or air bubbles should be avoided, because these can cause loss of energy from the system and "damping" of the measured signal.

Complications of arterial cannulation are listed in Box 35-1.

Box 35-1 Complications of Arterial Cannulation

Thrombosis
Embolization (proximal or distal)
Infection (local or systemic)
Hemorrhage (disconnection)
Damage to adjacent structures (nerves, arteriovenous fistula, false aneurysm)
Inadvertent drug administration

CENTRAL VENOUS CATHETERIZATION

Central venous catheters allow measurement of central venous pressure (CVP) and provide vascular access for blood sampling and administration of vasoactive drugs or parenteral nutrition. Common sites for catheterization include the internal jugular vein, subclavian vein, and femoral vein, although the brachial and cephalic veins also may be used. The chosen site will depend on the patient's anatomy and clinical condition and on the experience of the operator. Two dimensional (2D) ultrasound imaging is readily available in many units and can be used in conjunction with Doppler color flow studies to define the venous anatomy before the procedure. Ultrasound imaging also may be used during the procedure to provide real-time guidance. The U.K. National Institute for Health and Clinical Excellence recommends the use of 2D ultrasound guidance for central venous cannulation. Correct catheter placement is indicated by the characteristic central venous pressure waveform and the radiographic appearance of the line tip positioned at the level of the carina on a plain chest radiograph.

CVP is measured continuously via a pressure transducer, and the CVP waveform may be displayed graphically. The availability and falling cost of disposable transducers have rendered intermittent manometry measurements obsolete. In health, CVP correlates with right ventricular end-diastolic pressure and pulmonary artery occlusion pressure (PAOP). It can therefore be used as an indicator of preload. In critical illness, the normal relationship between right- and left-sided heart pressures may not be maintained. This discrepancy may be the result of many factors, including changes in ventricular compliance, pulmonary hypertension, or pulmonary embolism. Isolated measurements of CVP are poor markers of intravascular volume status; however, dynamic measurements may still be useful. A sustained rise in CVP after a fluid challenge implies that a further increase in preload may not provide an increase in cardiac output.

The complications of central venous cannulation are listed in Box 35-2. Despite advances in catheter technology such as antimicrobial coating, risk for microbial contamination is significant. The corresponding risk of catheter-related sepsis may be mitigated by minimizing the time during which the catheter remains in situ. The benefits of changing the catheter must be weighed against the risks associated with catheter reinsertion (Box 35-3).

PULMONARY ARTERY CATHETERIZATION

The pulmonary artery flotation catheter (PAFC) is a multilumen central venous catheter that is guided by flow to rest in the pulmonary artery (Figure 35-2). It allows measurement and derivation of a wide variety of hemodynamic variables, which are listed in Box 35-4. Indications for its use include the following:

- Determination of the cause of hemodynamic insufficiency
- Discrimination between cardiogenic and noncardiogenic pulmonary edema

Box 35-2 Complications of Central Venous Catheter Insertion

Arterial puncture
Arrhythmia
Infection
Hemorrhage
Pneumothorax

- Measurement of cardiac output and pulmonary artery pressures (for example, in pulmonary hypertension or hepatopulmonary syndrome)
- Guidance in use of inotrope, vasopressor, or vasodilator therapy in critical illness or after major surgery

Use of the PAFC has declined in recent years owing to concerns over the potential for complications. Recent systematic analysis suggests that the use of the PAFC is associated with neither improved survival nor increased mortality, although some data support a reduction in mortality associated with PAFC use in the most critically ill patients. Further studies are required to precisely define a role for the PAFC in modern critical care; in some centers, its use continues as a monitoring tool in critical illness and during major surgery.

INSERTION

An introducer sheath is placed using a Seldinger technique into a central vein; the internal jugular and subclavian veins are most commonly used. The lumens and balloon of the PAFC should be tested before insertion. The PAFC is passed through the sheath into the right atrium with continuous pressure waveform monitoring from the distal lumen. Once in the right atrium, the balloon is inflated with 1.5 mL of air. This adjustment helps to guide the balloon along the direction of blood flow through the heart and also affords some protection to the myocardium. With careful advancement of the catheter, characteristic pressure waveforms of the right ventricle, pulmonary artery, and pulmonary artery occlusion are sequentially encountered. The waveforms observed during passage of the catheter are shown in Figure 35-3.

MEASURING PULMONARY ARTERY OCCLUSION PRESSURE

Accurate measurement of PAOP requires readings to be taken at end expiration and end diastole. Inflation of the balloon at the tip of the PAFC effectively "wedges" the catheter tip in a branch of the pulmonary artery. This creates a continuous column of blood from the catheter tip to the pulmonary venous system. As a consequence of its proximity to the left atrium, the pressures observed can be considered to correlate with left atrial pressure. Left atrial pressure approximates to left ventricular end-diastolic pressure (LVEDP) and therefore may be considered to represent an index of preload. Many factors, including changes in intrathoracic and intraabdominal pressures, catheter position outside West zone 3, mitral valve disease, and changes in left ventricular compliance, may impair the usefulness of PAOP as a predictor of preload (Table 35-1).

MEASURING CARDIAC OUTPUT USING THE PULMONARY ARTERY FLOTATION CATHETER

Adding a sensitive thermistor to the PAFC allows calculation of cardiac output by modification of the Stewart-Hamilton equation:

$$M = Q\int Ct \cdot dt$$

Rapid bolus injection of cold fluid into the right atrium causes a change in temperature of the blood in the pulmonary artery, which varies with time (Ct). Because all of the cold fluid (M) must pass through the pulmonary artery, M is equal to the sum of the temperature changes at each interval (t) multiplied by the flow (Q). Rearranging this equation allows calculation of flow (i.e., cardiac output) through the pulmonary artery.

Table 35-1 Complications of Pulmonary Artery Flotation Catheter (PAFC) Insertion

Complication	Risk Factor	Prevention
Arrhythmia	Catheter coiling in RV Catheter reentry from PA to RV	Ensure balloon inflation during passage from RA to PA Defibrillator/transcutaneous pacing available Minimize insertion time
Complete heart block	LBBB	Avoid insertion in patients with LBBB Consider pacing electrode placement
Catheter knotting	Dilated RV, excessive catheter length	Monitor pressure waveform during insertion; withdraw catheter if no change after advancing 15 cm Avoid forceful insertion
Valve damage	Knotting of catheter around papillary muscle, balloon inflation during withdrawal	Inflate balloon during forward passage and ensure balloon deflation during catheter withdrawal
Pulmonary infarction	Prolonged balloon occlusion, distal catheter migration, pulmonary hypertension, anticoagulation, prolonged duration of insertion	Minimize wedge procedures, <15-second balloon inflation during PAOP measurements Withdraw catheter if spontaneous wedging or wedging achieved with <1.25 mL of air
Pulmonary artery rupture	As for pulmonary infarction	As for pulmonary infarction
Air embolism	Balloon rupture	Avoid repeat attempts to inflate balloon
Infection	Prolonged insertion	Aseptic insertion Remove PAFC when no longer required

LBBB, left bundle branch block; *PA*, pulmonary artery; *PAOP*, pulmonary artery occlusion pressure; *RA*, right atrium; *RV*, right ventricle.

$$Q = \frac{V \cdot (Tb - Ti) \cdot K1 \cdot K2}{Tb(t)dt}$$

where Q is cardiac output, V is volume injected, Tb is blood temperature, Ti is temperature of the injectate, K_1 and K_2 are constants relating to the specific heat capacity of injectate and equipment dead space volumes, and Tb(t)dt is the change in blood temperature as a function of time.

The decrease in temperature in the pulmonary artery can be plotted against time, as shown in Figure 35-4. As the foregoing equation indicates, cardiac output is inversely proportional to the area under this curve

Bolus thermodilution measurements of cardiac output are repeated three times and a mean value is calculated (Box 35-5 and Table 35-2). Using a thermal indicator has several advantages over dye dilution techniques in that the indicator is nontoxic and does not accumulate or recirculate. Cold fluid does, however, cause a transient fall in heart rate, thus reducing cardiac output over the period measured.

In some PAFC designs, a thermal filament wrapped around the PAFC allows semicontinuous measurement of cardiac output. The filament heats the blood in a pulsatile fashion, and the resultant fluctuations in temperature are detected at a downstream thermistor. Comparison of the filament heating time and thermistor output allows calculation of cardiac output. This has been shown to be comparable in accuracy to bolus thermodilution methods and may avoid some of the human error associated with bolus injection of cold fluid.

ARTERIAL WAVEFORM ANALYSIS

PULSE CONTOUR ANALYSIS

If SVR and the mean arterial blood pressure are known, it is possible to calculate the cardiac output:

Table 35-2 Archetypical Hemodynamic Abnormalities in Variables Measured by Pulmonary Artery Flotation Catheter

	Hemodynamic Variable		
Circulatory Condition	**CI**	**PAOP**	**SVRi**
Hypovolemic shock	Low	Low	High
Cardiogenic shock	Low	High	High
Distributive shock (sepsis, anaphylaxis)	High	Normal	Low
Obstructive shock (pulmonary embolism, tension pneumothorax, tamponade)	Low	High	High

CI, cardiac index; *PAOP*, pulmonary artery occlusion pressure; *SVRi*, systemic vascular resistance index.

Box 35-5 Causes of Inaccurate Bolus Thermodilution Cardiac Output Measurement

- Malposition
- Respiratory pattern
- Cardiac shunt
- Tricuspid valve regurgitation
- Arrhythmia
- Injectate temperature misrecorded
- Rapid intravenous infusions
- Injectate port in introducer sheath
- Extremes of cardiac output
- Slow injection
- Incorrect injectate volume

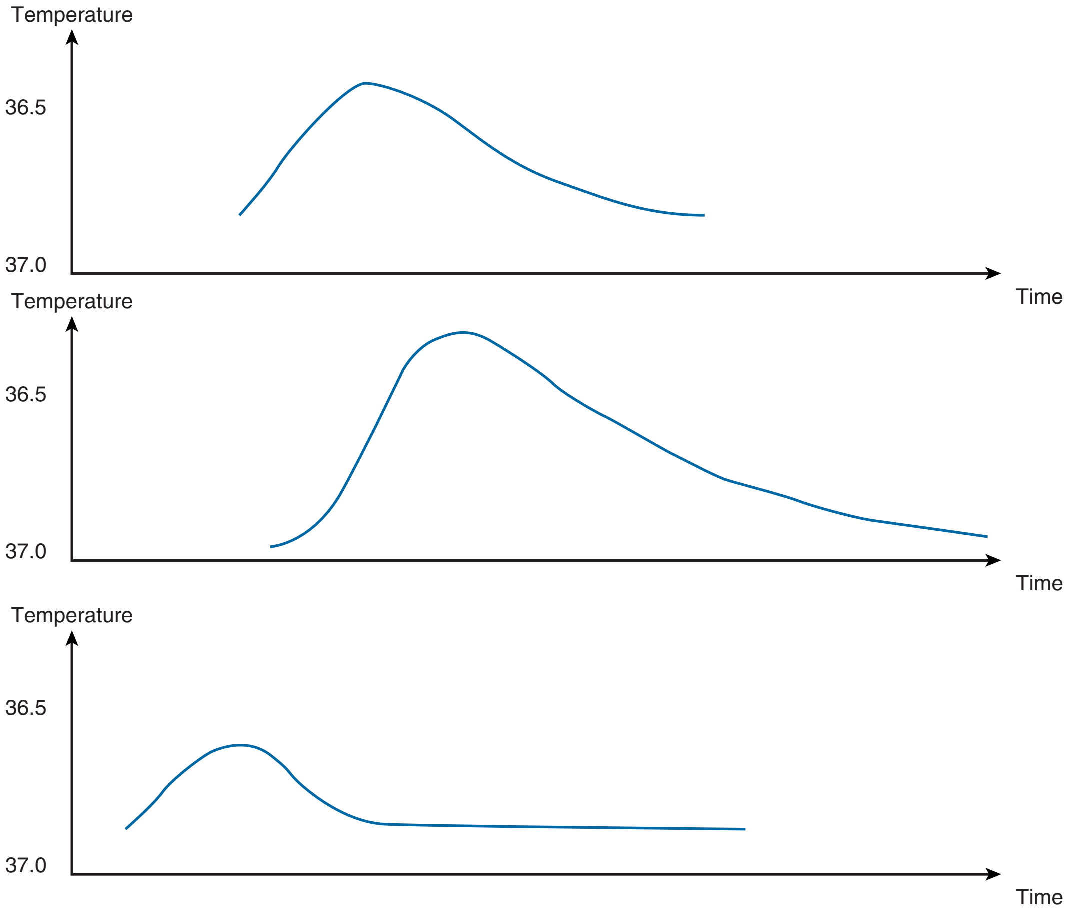

Figure 35-4 Thermodilution curves in normal and low- and high-cardiac output states (*top* to *bottom*, respectively): Changes in the thermodilution waveform with changes in cardiac output. The area under the curve is inversely proportional to cardiac output.

$$\mathrm{CO} = \frac{MAP}{SVR} \cdot k$$

Analysis of various components of the arterial waveform, including pulse wave velocity, pulse pressure, and diastolic pressure decay, permits estimation of the SVR. These principles have been understood for more than a century and refined with increasing sophistication over the last few decades. The complexity of the necessary mathematical algorithms, however, has meant that their development into clinically useful bedside instruments has been possible only with the advent of the microprocessor. Modern understanding of the arterial waveform is in terms of two superimposed waves: an incident wave related to left ventricular ejection and another wave reflected back from the peripheral arterial tree. The characteristics of the resultant waveform change with stroke volume, arterial compliance, site of measurement, and the physiologic state of the subject. Furthermore, the impedance of the aorta (its tendency to oppose *pulsatile* arterial flow) changes not only with arterial compliance but also with cardiac output. As a result of all of these factors, devices in current clinical practice use different proprietary algorithms, require periodic calibration for accurate use, and may be used without calibration to estimate the effect of interventions on hemodynamic variables.

PULSE POWER ANALYSIS

The law of conservation of mass and energy can be applied to the problem of estimating stroke volume from analysis of the arterial waveform. This method is based on the assumption that with every left ventricular ejection, the power change is related to the balance between the mass of blood entering (stroke volume) and the mass of blood leaving the aorta (dissipating to the periphery). Assuming also that power is a function of flow, the change in blood pressure over the course of each arterial pulse wave can be used to determine stroke volume. The constant of proportionality describing this relationship changes with blood pressure, and the mathematical technique has been termed *autocorrelation*.

$$\frac{\Delta V}{\Delta BP} = calibration \times 250 \times e^{-k \cdot BP}$$

Potential advantages of this technology over pulse contour analysis include a reduction in the tendency of damping to affect accuracy and the facility to use any anatomic site for waveform analysis.

Devices using pulse contour and pulse power analysis can be used to demonstrate beat-to-beat changes in stroke volume and pulse pressure. Stroke volume variation (SVV) and pulse pressure variation (PPV) are features of the cyclic change in venous return to the heart during the respiratory cycle. The application of positive pressure to the thorax during mechanical ventilation effectively splints the right ventricle, exaggerating this tendency to variation in left ventricular ejection. High SVV and PPV have been shown to be useful predictors of fluid responsiveness in fully ventilated patients.

TRANSPULMONARY INDICATOR DILUTION

Calibration of arterial waveform analysis systems relies on indicator dilution techniques and application of the Stewart-Hamilton equation. The indicators are administered into a vein and detected at a systemic arterial catheter after passing through the four heart chambers and the pulmonary circulation. Further analysis can be performed on the indicator dilution curves to provide information on additional cardiovascular indices, such as intrathoracic blood volumes and extravascular lung water.

Transpulmonary Thermodilution With Arterial Waveform Analysis

The technique of transpulmonary thermodilution with arterial waveform analysis uses a central venous bolus of cold injectate with the change in blood temperature detected at a thermistor in the femoral, axillary, or brachial artery. A temperature change–versus–time curve is constructed from which cardiac output can be calculated using the Stewart-Hamilton equation. The thermodilution curves are longer and flatter than those seen for the PAFC, which reflects their thermal equilibrium with a larger blood volume. Further analysis of the morphology of a semilogarithmic transformation of the thermodilution waveform allows calculation of intrathoracic thermal volume (ITTV) and pulmonary thermal volume (PTV). A marker of cardiac preload, the global end-diastolic volume (GEDV), is calculated from the difference between ITTV and PTV. This technique also allows calculation of the extravascular lung water, which provides information on the degree of pulmonary edema and is a correlate of the severity of illness (Box 35-6). Cardiac output calculations from the thermodilution curve are used to calibrate continuous cardiac output monitoring by pulse contour analysis (Figure 35-5).

Because a thermistor is necessary for calibration, a special-purpose arterial catheter is required. The cold injectate must also be administered via a central vein, necessitating central venous access.

Transpulmonary Lithium Indicator Dilution and Arterial Waveform Analysis

The technique of transpulmonary lithium indicator dilution and arterial waveform analysis gives continuous cardiac output monitoring through pulse power analysis of the arterial waveform with calibration performed using indicator dilution with lithium. A bolus of lithium is injected intravenously and detected at an external lithium ion–sensitive electrode connected to the arterial cannula. A plasma lithium concentration–versus–time curve is obtained from which cardiac output can be derived using the Stewart-Hamilton method. Because the lithium electrode is external, blood is continuously sampled during the calibration process from a standard arterial line. Of note, plasma sodium also affects the potential across the electrode, so a correction must be made. Lithium distributes only in the plasma compartment; thus, a correction for hematocrit also must be made.

Calibration is performed every 24 hours but may be required more frequently if significant changes in arterial compliance are suspected or the waveform becomes damped. Some models also include a decision-making algorithm to guide fluid administration or therapeutic maneuvers.

These devices can be used in the presence of a “standard” radial arterial catheter, and the lithium bolus can be administered either centrally or peripherally. Ongoing lithium therapy and use of nondepolarizing muscle relaxants can cause errors in calibration. Blood sampled during calibration also must be discarded owing to measurement at an external electrode.

ESOPHAGEAL DOPPLER MONITORING AND ULTRASOUND IMAGING

The Doppler effect refers to the change in observed frequency of a wave function when the source is moving relative to the

observer. The magnitude of this effect is proportional to the velocity of the moving object. Applying this principle to ultrasound waves allows measurement of velocity of red blood cells in the descending thoracic aorta using the following equation:

$$v = \frac{c \cdot f_D}{2 \cdot f_T \cdot \cos\theta}$$

where v is the velocity of red blood cells, c is the speed of ultrasound waves through body tissues, f_D is the observed frequency shift of the reflected ultrasound waves, f_T is the transmitted frequency of the ultrasound wave, and $\cos\theta$ is the cosine of the angle of insonation between the axis of the sound beam and the direction of blood flow.

A flexible probe containing an ultrasound transceiver is passed into the lower esophagus, where the thoracic aorta and the esophagus are closely apposed. Ultrasound waves are emitted from the probe, which is focused on the aorta by the operator, with the probe positioned to obtain the maximum peak velocity. The change in observed frequency of the reflected ultrasound waves from the red blood cells allows calculation of blood velocity in the descending aorta. The spectrum of red cell velocities is plotted against time and displayed as shown in Figure 35-6. The esophageal Doppler monitor traces the maximum velocity waveform to permit calculating the area under this curve during systole. This area is the *stroke distance*, or the distance over which a column of blood moves in the aorta during systole. Aortic red blood cell velocity is measured in the descending thoracic aorta distal to the origin of the left subclavian artery. To estimate left ventricular stroke volume from this measurement, two factors must be known or otherwise accounted for: First, the cross-sectional area of the aorta is required for stroke distance to be converted into volume, and probes have been developed with an M-mode echocardiographic transducer to facilitate this step. Second, a proportion of the cardiac output has left the aorta proximal to the transducer; in a resting healthy adult, this is approximately 30% and must be compensated for. One manufacturer (Cardio-Q ODM, Deltex Medical, Chichester, United Kingdom) uses a nomogram based on the patient's age, height, and weight to directly calibrate descending aorta blood flow velocity to total cardiac output. The process is based on in vivo measurements from an esophageal Doppler monitor and a thermodilution pulmonary artery catheter in an ICU patient population and removes the need to separately account for the fraction of cardiac output distributed into the upper body.

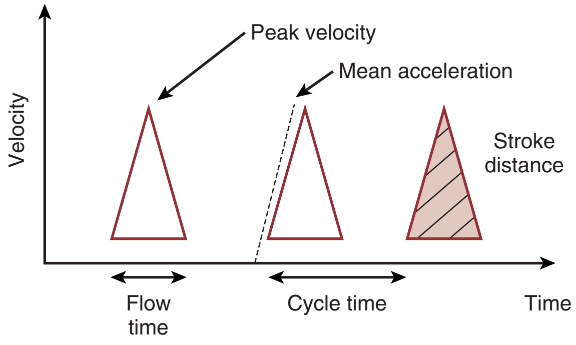

Figure 35-6 Schematic of the esophageal Doppler waveform showing stroke distance, mean acceleration, peak velocity, and flow time. *(From Parrillo JE, Dellinger P, et al, editors:* Critical care medicine, *ed 3, Philadelphia, Mosby, 2007.)*

The width of the base of the velocity waveform represents the systolic ejection time and is displayed as the corrected flow time (FTc). The flow time is corrected to a heart rate of 60 beats/minute to allow comparison of flow times despite the increasing ratio of systolic time to diastolic time at increased heart rates. Variation in FTc may reflect changes in preload and afterload. A low FTc may reflect hypovolemia as ventricular ejection is short with a low left ventricular end-diastolic volume (LVEDV). Changes in SVR (afterload) also will alter the FTc, because they determine the resistance to flow in the arterial system. FTc is inversely correlated with SVR. The peak velocity and mean acceleration of the velocity waveform may provide information regarding the contractile state of the myocardium.

The esophageal Doppler monitor can be used to assess fluid responsiveness by detecting changes in stroke volume after administration of a fluid bolus. After the fluid challenge, a change in stroke volume of greater than 10% suggests that further fluid boluses may result in additional increases in stroke volume—the implication being that the ventricle lies on the steep part of its Starling curve.

The Doppler probes are small, minimally invasive, easy to insert, and allow rapid acquisition of data. Operation of the device can be learned quickly. Contraindications to probe insertion include esophageal pathology (e.g., varices) and facial trauma. Abnormalities of aortic and esophageal anatomy may inhibit probe focusing, limiting the usefulness of the device. The esophageal Doppler monitor cannot be used in the presence of aortic balloon counterpulsation.

In calculation of cardiac output, the esophageal Doppler monitor relies on several assumptions that may not hold true in critical illness. Only flow in the descending aorta is measured (approximately 70% of cardiac output), and a correction is applied to allow calculation of stroke volume. Changes in the regional distribution of the circulation that occur in critical illness may limit the accuracy of the calculated values. Turbulent flow (as associated with anemia or hyperdynamic circulation) in the aorta may alter velocity measurement, leading to inaccurate results. Some nomograms assume a constant and circular aortic area, whereas changes in descending aortic diameter have been shown in patients with hypotension. The esophagus and the aorta may not run parallel, leading to deviation from the assumed angle of insonation of 45 degrees. Probe position can easily be lost, making consistent trend measurements difficult. Nasal and oral probes are available; however, the probe may be uncomfortable for nonsedated patients, which can limit its use. Nevertheless, when used appropriately to assess the immediate impact of a therapeutic intervention, the esophageal Doppler monitor is a precise and safe device that is relatively easy to use.

TRANSCUTANEOUS DOPPLER MONITORING

Using principles similar to those for the esophageal Doppler monitor, blood velocity in the ascending aorta can be calculated from data obtained with an ultrasound probe positioned in the suprasternal notch. With knowledge of the area of the aortic outflow tract, the flow in the ascending aorta can be calculated, thus allowing stroke volume and cardiac output to be measured. This method is noninvasive and allows measurements to be taken at the aortic root, which are therefore not affected by alterations distribution of cardiac output between the upper and lower body. Its use is limited by difficulties in identifying the aortic root, maintaining alignment of the ultrasound probe with the ascending aorta, and discomfort in nonsedated patients. These limitations predispose the system to a high degree of interobserver variability, so it is infrequently used as a monitoring tool in critical care.

ECHOCARDIOGRAPHY

Both transthoracic and transesophageal echocardiography techniques can be used to measure end-diastolic and end-systolic ventricular volumes for calculating left ventricular stroke volume. The use of these modalities for hemodynamic monitoring is limited by availability of equipment and trained operators. Because measurements can be made only intermittently, these techniques are not used for routine critical care monitoring.

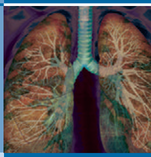
CRITICAL CARE RESPIRATORY MEDICINE



Chapter 36
Acute Respiratory Distress Syndrome

Jesús Villar • Demet S. Sulemanji • Robert M. Kacmarek

The acute respiratory distress syndrome (ARDS) is an inflammatory disease process of the lungs that is a response to both direct and indirect insults, characterized clinically by severe hypoxemia, reduced lung compliance, and bilateral radiographic infiltrates. Although much has evolved in the current understanding of its pathogenesis and factors affecting patient outcome, there is still no specific treatment for ARDS.

In 1967, Ashbaugh and colleagues published an article in *The Lancet* in which they described for the first time a clinical syndrome that they termed the "adult respiratory distress syndrome" for its similarity to the well-recognized infant respiratory distress syndrome. From a cohort of 272 patients who were receiving respiratory support, these investigators identified 12 patients with a constellation of specific pulmonary findings: The respiratory distress in these patients was defined as sudden and catastrophic and often associated with a multiorgan system insult that led to tachypnea, hypoxemia, decreased lung compliance, and bilateral pulmonary infiltrates on the chest radiograph, in the absence of cardiogenic pulmonary edema. In this study, respiratory support consisted of oxygen therapy delivered by nasal prongs or face mask and mechanical ventilation. The mortality rate was 58%, and on histopathologic examination, the lungs of the nonsurvivors were heavier than normal and exhibited atelectasis with interstitial and alveolar edema and hyaline membranes. Since that time, the hallmarks of this syndrome, now known as ARDS, have been recognized to consist of (1) a risk factor for the development of acute respiratory distress (e.g., sepsis, trauma, pneumonia, aspiration, pancreatitis), (2) severe hypoxemia despite a relatively high fraction of inspired oxygen (FIO_2), (3) decreased lung compliance, (4) bilateral pulmonary infiltrates, and (5) lack of clinical evidence of cardiogenic pulmonary edema. Acute lung injury (ALI) resulting in ARDS also can occur in the setting of left ventricular failure, but this is very difficult to diagnose without careful serial measurements of pulmonary artery and capillary (wedge) pressure. Although ALI/ARDS had been recognized for more than a century and was referenced in published data from the Second World War, it was not until the landmark paper by Ashbaugh's group that broad clinical interest in ARDS began to emerge. In the subsequent years, very few acronyms have received as much attention in critical care medicine.

ARDS usually occurs in previously healthy people. Characteristically, there is a latent period between the insult and the development of the full-blown clinical syndrome, which usually is 18 to 24 hours in duration. After this interval, tachypnea, labored breathing, and cyanosis are observed, and arterial blood gas analysis confirms hypoxemia. The abnormalities in lung mechanics and oxygenation are assessed once the patient is intubated and receiving mechanical ventilation. The chest radiograph classically shows diffuse, bilateral, interstitial alveolar infiltrates (Figure 36-1). Resolution of the infiltrates, if it occurs at all, is much slower than with cardiogenic pulmonary edema.

PATHOPHYSIOLOGY, HISTOPATHOLOGY, AND ETIOLOGY

ARDS is caused by an insult to the alveolar-capillary membrane that results in increased permeability and subsequent interstitial and alveolar edema. The mechanisms whereby a wide variety of insults can lead to this syndrome are not clear. ALI includes injury to both the pulmonary capillary endothelium and the alveolar epithelium. In the ARDS lung, an influx of protein-rich edema fluid into the air spaces occurs as a consequence of increased permeability of the alveolar-capillary barrier. The degree of alveolar epithelial injury is an important determinant and predictor of outcome. The normal alveolar epithelium has two types of cells. The type I cells make up 90% of the alveolar surface area and are easily injured. The type II cells make up the remaining 10% of the alveolar surface area and are more resistant to injury; their functions include surfactant production, ion transport, and proliferation and differentiation to type I cells after injury.

The loss of epithelial integrity in ARDS has several consequences. First, under normal conditions, the epithelial barrier is much less permeable than the endothelial barrier; thus epithelial injury can contribute to alveolar flooding. Second, the loss of epithelial integrity and injury to type II cells serve to disrupt normal epithelial fluid transport, impairing the removal of edema fluid from the alveolar space. Third, injury to type II cells reduces the production and turnover of surfactant. Fourth, loss of epithelial barrier can lead to sepsis in patients with bacterial pneumonia. Finally, in severe alveolar epithelium injury, pulmonary fibrosis can develop. Independent of the clinical disorders associated with ARDS (Box 36-1), it is useful to think of the pathogenesis of ARDS as a result of two different pathways: a direct insult to lung cells and an indirect insult occurring as a result of an acute systemic inflammatory response. The host's inflammatory response to the initial direct (pulmonary) or indirect (nonpulmonary) insult is a key factor in determining the development and progression of the acute injury to the lung. Despite ongoing elucidation of the role of cellular and humoral components of the inflammatory responses in the lung, the precise sequence of events leading to lung damage is still unknown. As with any form of inflammation, ALI during ARDS represents a complex process in which multiple cellular signaling pathways can propagate or inhibit damage to the lung.

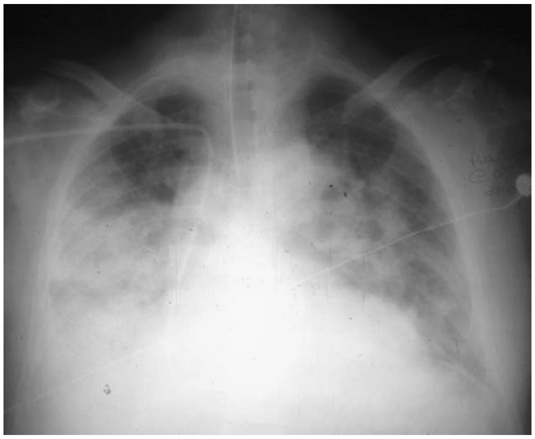


Figure 36-1 Chest radiograph showing diffuse, bilateral, interstitial, and alveolar infiltrates in a patient with acute respiratory distress syndrome (ARDS). The patient, a 54-year-old man, developed ARDS as a result of a severe bacterial pneumonia and required intubation and mechanical ventilation. His initial $\text{PaO}_2/\text{FIO}_2$ ratio was 113 mm Hg while he was receiving $\text{FIO}_2 = .6$ on PEEP of 10 cm H_2O. *PEEP*, positive end-expiratory pressure.

Box 36-1 Most Common Clinical Disorders Associated with Development of Acute Respiratory Distress Syndrome (ARDS)

Direct Lung Injury

Common Causes

- Pneumonia
- Aspiration of gastric contents

Less Common Causes

- Pulmonary contusion
- Near-drowning
- Inhalational injury
- Fat emboli
- Reperfusion pulmonary edema

Indirect Lung Injury

Common Causes

- Sepsis
- Multiple trauma

Less Common Causes

- Acute pancreatitis
- Drug overdose
- Cardiopulmonary bypass
- Transfusions of blood products

The typical histopathologic features of ARDS are collectively known as *diffuse alveolar damage*. The early phase of ALI—the exudative phase—is characterized by leakage of protein-rich edema fluid into the lung and inflammatory cellular alveolar infiltrates. During this phase, a cytokine storm and an array of inflammatory mediators are released into the interstitium and alveolar space, perpetuating inflammation and promoting the development of atelectasis and structural damage to the lung architecture. In addition, damage to the alveolar-capillary barrier enhances the difficulty in removing the excess of extravascular lung fluid. An important source of these inflammatory mediators is neutrophils, which play a key role in the pathogenesis and progression of ALI. Human and animal studies have demonstrated migration and activation of neutrophils in the lungs, where they cause cell damage through the production of free radicals, inflammatory cytokines, and proteases. It is well accepted, however, that a single mediator does not predominate, and that several parallel and simultaneously interacting mechanisms may be involved. Clinically, this initial phase is manifested as marked hypoxemia and reduced lung compliance. Eventually, these changes evolve to a fibroproliferative phase in which capillary thrombosis, lung fibrosis, and neovascularization take place. Most nonsurvivors of ARDS die during this phase, despite aggressive ventilatory support with high inspiratory concentrations of oxygen and positive end-expiratory pressure (PEEP). However, only a small proportion of patients with ARDS die of hypoxemia. Rather, lung injury appears to predispose patients to the development of a systemic inflammatory response that culminates in multiple system organ dysfunction. A plethora of evidence suggests that the development of multiple extrapulmonary organ dysfunction is due to alveolar epithelial-endothelial barrier disruption and the migration of cytokines produced in the lungs into the systemic circulation.

More than 50 specific conditions associated with the development of this syndrome are recognized. The risk for development of ARDS depends on the predisposing clinical condition (i.e., some events are more likely than others to progress to ARDS) but also increases with the number of predisposing factors. Sepsis, bacterial pneumonia, multiple trauma, and aspiration pneumonia are the most common predisposing factors, accounting all together for more than 70% of cases; infection is the most frequent cause. Many invading organisms can trigger host innate and acquired immune systems to initiate the inflammatory cascade. The risk for development of ARDS also depends on patient characteristics. For example, alcoholism is a predisposing factor, and new data suggest the possibility of a genetic predisposition. Overall mortality from ARDS has not decreased substantially since the publication of the 1967 report, and the current survival rate approximates to 45% in all major epidemiologic series. Sepsis-related ARDS is characterized by a higher overall disease severity, poorer recovery from lung injury, and higher mortality than non–sepsis-related ARDS. Among patients with ARDS associated with combined pulmonary and nonpulmonary sources of infection, mortality is even higher. Approximately 80% of all deaths in patients with ARDS occur within 2 to 3 weeks after the onset of the syndrome. Death traditionally has been attributed to the underlying disease, the presence of sepsis, and the failure of vital organ systems other than the lung.

DEFINITION, INCIDENCE, AND SEVERITY

Because it is difficult to measure changes in capillary and alveolar permeability at the bedside, diagnosis of ARDS is based on a combination of clinical, oxygenation, hemodynamic, and radiographic criteria. These criteria allow the inclusion of a highly heterogeneous group of critically ill patients, because various types of lung injury can lead to a similar pulmonary response. Despite general agreement on the overall criteria on which to base a definition of ARDS (i.e., severe hypoxemia, marked decreased of lung compliance), the specific values of these variables and the preferred conditions of measurement vary greatly among clinicians and scientists. Thus, the original description of ARDS has proved to be incapable of identifying a uniform group of patients. Several of the patients in the original report of Ashbaugh and co-workers would not be classified as having ARDS today, because fluid overload was an important etiologic factor in those cases. Some investigators have questioned whether ARDS is a distinct entity. Others have suggested that ARDS should not be considered a separate syndrome but should be seen as part of the multiple system organ dysfunction syndrome. From a clinical perspective, a strict definition of ARDS may not be required, because current management is supportive. From a therapeutic standpoint, however, a more precise definition probably is necessary, because the effects on outcome of certain ventilatory and adjunctive techniques may presumably vary depending on the degree of lung injury. In terms of prognosis, a number of investigators have examined whether various parameters of oxygenation and lung mechanics would be useful in predicting outcome. In the context of research on ARDS, a very strong argument can be made for a universal definition: It would help standardize experimental and clinical studies evaluating the natural history, incidence, pathophysiology, treatment, and outcome of ARDS. It also would help in the comparison of data among various clinical studies and centers.

A good example of the problems inherent in formulation of a definition for ARDS is the wide disparity in the literature on the incidence. Reported data in the United States suggest an occurrence rate greatly in excess of that expected from current clinical experience in Europe. The most common figure cited for the annual incidence of ARDS is 75 cases per 100,000 population. This is based on an American Lung Program Task Force of the National Heart and Lung Institute in 1972. This internal report suggested that there were about 150,000 cases per year of ARDS in the United States, a value similar to the number of all new cases of cancer. In 1988, Webster and colleagues in England estimated an incidence of 4.5 cases per 100,000 population, and in 1989, Villar and associates in Spain calculated the incidence as 3.5 new cases per 100,000 population per year. Most epidemiologic studies report an ARDS incidence ranging from 4 to 8 cases per 100,000 population per year.

In an attempt to overcome some of these problems, Murray and colleagues proposed an expanded definition of ARDS that takes into account various pathophysiologic features of the syndrome. Their definition uses a “lung injury score” (LIS) to characterize the acute pulmonary damage by considering four components: assessment of the chest radiograph, degree of hypoxemia (determined as the ratio of arterial partial pressure of oxygen to the fraction of inspired oxygen, PaO_2/FIO_2), level of PEEP, and the value of lung compliance, when available (Table 36-1). The final injury score is obtained by dividing the total score by the number of components that were used. A score of 0 indicates no lung injury, a score of 1 to 2.5 indicates mild to moderate lung injury, and a score greater than 2.5 indicates severe lung injury or ARDS. The LIS is not specific for ARDS, however, and has not been validated, because it is not clear whether patients with identical LIS have similar degrees of lung injury. Furthermore, patients with a major component of cardiogenic edema may be mislabeled as having ARDS, and a postoperative patient with moderate atelectasis and mild fluid overload may fit the LIS criteria for ARDS.

Table 36-1 Lung Injury Scoring System

Chest Radiograph Infiltration		*PEEP (cm H_2O)*	
Nil	0	≤5	0
1 Quadrant	1	6-8	1
2 Quadrants	2	9-11	2
3 Quadrants	3	12-14	3
4 Quadrants	4	≥15	4
Hypoxemia: PaO_2/FIO_2 (mm Hg)		***Compliance* (cm H_2O)***	
≥300	0	≥80	0
225-299	1	60-79	1
175-224	2	40-49	2
100-174	3	20-39	3
<100	4	≤19	4
Final score: Divide sum by number of components used.			
No lung injury		0	
Mild-moderate injury		0.1-2.5	
Severe lung injury (ARDS)		>2.5

*If measured.
ARDS, acute respiratory distress syndrome; *PEEP*, positive end-expiratory pressure.

Box 36-2 American-European Consensus Definitions for Acute Lung Injury (ALI) and for Acute Respiratory Distress Syndrome (ARDS)

- Acute onset
- Severe hypoxemia (PaO_2/FIO_2 <300 mm Hg for ALI OR ≤200 mm Hg for ARDS)
- Diffuse bilateral pulmonary infiltrates on frontal chest radiograph
- Absence of left atrial hypertension OR pulmonary artery wedge pressure <18 mm Hg if measured

Because severe hypoxemia is the hallmark of ARDS, it should be crucial to the assessment of the severity of ARDS, for predicting the development and evolution in any given patient, and for assessing the response to treatment. To better characterize the severity of lung damage, in 1994 an American-European Consensus Conference (AECC) defined ALI and ARDS as follows:

> (i) acute and sudden onset of severe respiratory distress; (ii) bilateral infiltrates on frontal chest radiograph and (iii) the absence of left atrial hypertension (a pulmonary capillary wedge pressure <18 mm Hg or no clinical signs of left ventricular failure; and (iv) severe hypoxemia (assessed by the PaO_2/FIO_2 ratio).

According to these guidelines, ALI exists when the PaO_2/FIO_2 ratio is 300 mm Hg or less regardless of the level of PEEP and FIO_2, and ARDS is present when the PaO_2/FIO_2 ratio is 200 mm Hg or less regardless of the PEEP setting and FIO_2 (Box 36-2). Although this definition formalized the criteria for the diagnosis of ARDS and is simple to apply in the clinical setting, it has been challenged over the years in several studies. Such definitions have limitations: The physiologic thresholds do not require standardized ventilatory support, and the use of PEEP can improve oxygenation indices sufficiently to convert the patient’s status from meeting the definition of ARDS to not meeting the ARDS definition and also can change the physiology in the lung such that the patient does not meet the criteria for ARDS. Therefore, the ARDS criteria may be met when the PaO_2 is measured with zero PEEP but not when

measured at a PEEP of 5 or 10 cm H_2O, making patient comparisons difficult. Furthermore, most of the randomized controlled studies did not use the same definition for ARDS, nor did they evaluate the same ventilatory approaches. Diversity among ARDS definitions is apparent in a large number of studies (Table 36-2).

GENETICS

Critical care physicians have long recognized that some patients progress despite therapy, whereas others do better than predicted. It is now well accepted that these responses may be related to variations in the genome. Little is known, however, about the genes that are responsible for susceptibility to and outcome of ARDS. The search for genetic variants determining susceptibility and predicting outcome is still a developing field. The identification of important associations between genotype and clinical outcomes will have an impact on the development of more efficient genotype- or phenotype-guided therapies for patients with ALI or ARDS. The current understanding is that the pathogenesis of ARDS has a fundamental inflammatory component eliciting a response similar to that observed against any pathogen. In addition, common genetic risk factors with modest effects may be associated with disease susceptibility. Many studies have searched for genetic variations underlying ARDS susceptibility. Owing to the impracticality of classical genetic approximation in ARDS, association studies comparing unrelated ARDS cases with controls for genetic variants at specified locations of the human genome represent the prevailing study design for detecting such loci. The genetic variants explored usually are single base changes in the DNA, known as single-nucleotide polymorphisms (SNPs), because they are the most common variants across the genome. The genetic studies of ARDS have focused largely on candidate genes involved in the response to external stimulus and cell signal transduction, because those genes are assumed to be important in the immune response.

Extensive cross-species gene expression pattern comparisons in experimental models of ALI/ARDS have revealed that IL-6, an acute-phase response cytokine with pleiotropic effects, is highly upregulated. This finding is consistent with clinical studies indicating that IL-6 and other cytokines are released from the lungs in patients with ARDS; increased IL-6 concentrations are found in the bronchoalveolar lavage fluid and serum of these patients. IL-6 levels have been correlated with clinical outcome and implicated in the development of multiple system organ failure. A G/C SNP located at position −174 of the promoter region of the IL-6 gene has been shown to functionally affect the activity of the IL-6 gene promoter in vitro. To date, assessing the SNP variation for virtually all common variants of the gene has allowed subsequent studies to reveal a consistent picture for the association of the IL-6 gene with ALI and ARDS.

In case-control studies of patients with severe sepsis and ARDS, several investigators have explored variants of the gene encoding the lipopolysaccharide-binding protein (LBP) and serial measurements of the LBP in serum to relate them with risk gene variants. It has been reported that (1) a four-SNP risk haplotype of the LBP gene is associated with mean serum LBP concentrations within the first week of the disease process; (2) LBP levels at 48 hours are much higher in patients with ARDS than in those with ALI; and (3) a subsequent increase of LBP levels at 48 hours is associated with a four-fold increase in mortality rate. A positive association with ARDS susceptibility and/or outcome has been reported for several other genes, including surfactant pulmonary-associated protein B (*SFTPB*), angiotensin-converting enzyme (*ACE*), tumor necrosis factor (*TNF*), vascular endothelial growth factor (*VEGF*), *IL-10*, pre-B cell–enhancing factor (*PBEF*), chemokine CXC motif ligand 2 (*CXCL2*), mannose-binding lectin-2 (*MBL2*), myosin

light chain kinase (*MLCK*), nuclear factor κ light polypeptide gene enhancer in B cells (*NFKB1*), coagulation factor V (*F5*), and type 2 deiodinase (*DIO2*) (Table 36-3). These genes are involved mainly in the response to external stimulus and cell signal transduction.

Altogether, significant progress has been made in the studies of genetic associations for ARDS. Because all studied candidate genes await repetitive validation in independent studies using larger samples, the search for genetic variants determining susceptibility and outcome in ARDS still needs to grow, to identify associations between genotype and clinical outcomes. The identification of genetic risk factors might allow the development of a new classification of patients and a more accurate determination of patient outcome.

VENTILATOR-INDUCED LUNG INJURY

Unequivocal evidence from both experimental and clinical research shows that mechanical ventilation can damage the lungs and initiate an inflammatory response, possibly contributing to extrapulmonary organ dysfunction. This type of injury, referred to as *ventilator-induced lung injury* (VILI), resembles the syndromes of ALI and ARDS. VILI can trigger a complex array of inflammatory mediators, resulting in a local and systemic inflammatory response. Substances produced in the lungs can be translocated into the systemic circulation as a result of injury to the pulmonary epithelium and to the capillary endothelium. This type of injury forms the basis for the use of low tidal volumes (in the range of 4 to 8 mL/kg of predicted body weight) during mechanical ventilation of patients with ALI or ARDS. The recognition of VILI has prompted a number of investigators to suggest that ALI and ARDS may in part be a product of efforts to mechanically ventilate patients, rather than representing progression of the underlying disease. On the other hand, current scientific evidence supports a link between VILI and the development of extrapulmonary organ dysfunction, in a manner similar to that in which severe cases of sepsis manifest clinically. In addition, functional genomic approaches using gene array methodology to measure lung gene expression have identified patterns of genes differentially expressed in animal models of VILI, similar to those gene pathways activated during experimental and clinical sepsis.

Ventilators are intended to deliver air or oxygen at tidal volumes and frequencies sufficient to provide adequate alveolar ventilation, to reduce the work of breathing, and to enhance oxygenation (see also Chapter 32). However, mechanical ventilation is a nonphysiologic process, and complications are associated with its application, including increased risk for pneumonia, impaired cardiac performance, and lung injury. During mechanical ventilation, pressures, gas volumes, ventilatory rates, and concentrations of inspired oxygen often are applied at levels that exceed those normally experienced by healthy lungs during spontaneous breathing. VILI is not a new concept—it is the designation historically applied to macroscopic injuries associated with alveolar rupture due to overdistention resulting from application of high inspiratory pressures. Clinical manifestations include interstitial emphysema, pneumothorax, pneumomediastinum, and pneumoperitoneum. The concept of VILI has shifted somewhat from pressure-induced (really volume-induced) injury to increased vascular permeability, accumulation of lung fluid, “atelectrauma,” and inflammation induced by mechanical ventilation.

In 1998 Tremblay and Slutsky coined the term *biotrauma* to describe the pulmonary and systemic inflammatory response triggered by lung cell distention, alveolar disruption, and/or necrosis after the application of mechanical ventilation. Although a Consensus Conference in 1994 recommended that plateau pressure generally should be limited to 35 cm H_2O, little change in ventilator practice occurred until publication of an ARDS Network study demonstrating that a lung-protective strategy using a tidal volume of 6 mL/kg of predicted body weight and moderate levels of PEEP decreased mortality in patients with ALI. This study confirmed that VILI was not just an interesting experimental entity but also was an important clinical entity. This recognition led to the widespread, albeit not universal, use of lung-protective strategies in patients with ALI. Unequivocal evidence from both experimental and clinical data has proved that mechanical ventilation can cause or aggravate ALI. Many of the pathophysiologic consequences of VILI mimic those of ARDS. A number of specific forms of injury caused by the trauma of mechanical ventilation have been identified: barotrauma, volutrauma, atelectrauma, and biotrauma. Current experimental and clinical evidence supports a link between VILI and the development of extrapulmonary organ dysfunction, by mechanisms similar to those whereby most severe cases of sepsis are clinically manifested (Figure 36-2).

PATHOPHYSIOLOGY OF VENTILATOR-INDUCED LUNG INJURY

Lung volumes for all mammals scale with a common function based on body mass. In spontaneously breathing mammals, tidal volumes are approximately 6 to 7 mL/kg of body weight (Figure 36-3), yet historically, tidal volumes of 12 to 15 mL/kg were used in mechanically ventilated patients with acute respiratory failure, and peak alveolar pressures were allowed to increase above 40 cm H_2O. This “one tidal volume fits all” approach was formulated in the 1960s, because anesthesiologists and critical care pioneers had demonstrated that ventilation with small tidal volume resulted in a gradual loss of lung volume (i.e., atelectasis) and hypoxemia. Large-tidal-volume ventilation was useful to prevent this negative physiologic consequence. Since the mid-1970s, experimental studies have

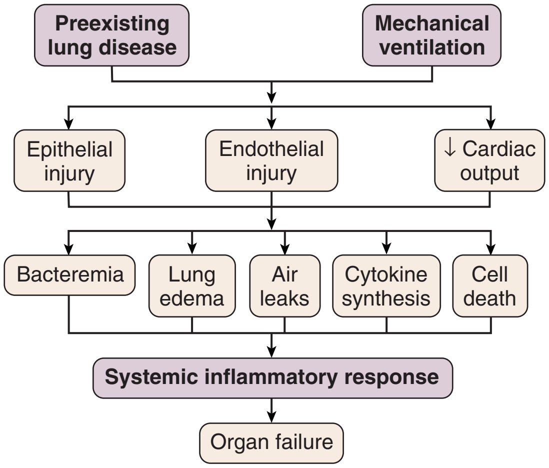

Figure 36-2 Mechanical ventilation and multiple system organ failure: Postulated mechanism by which mechanical ventilation with or without sepsis may contribute to multiple system organ failure.

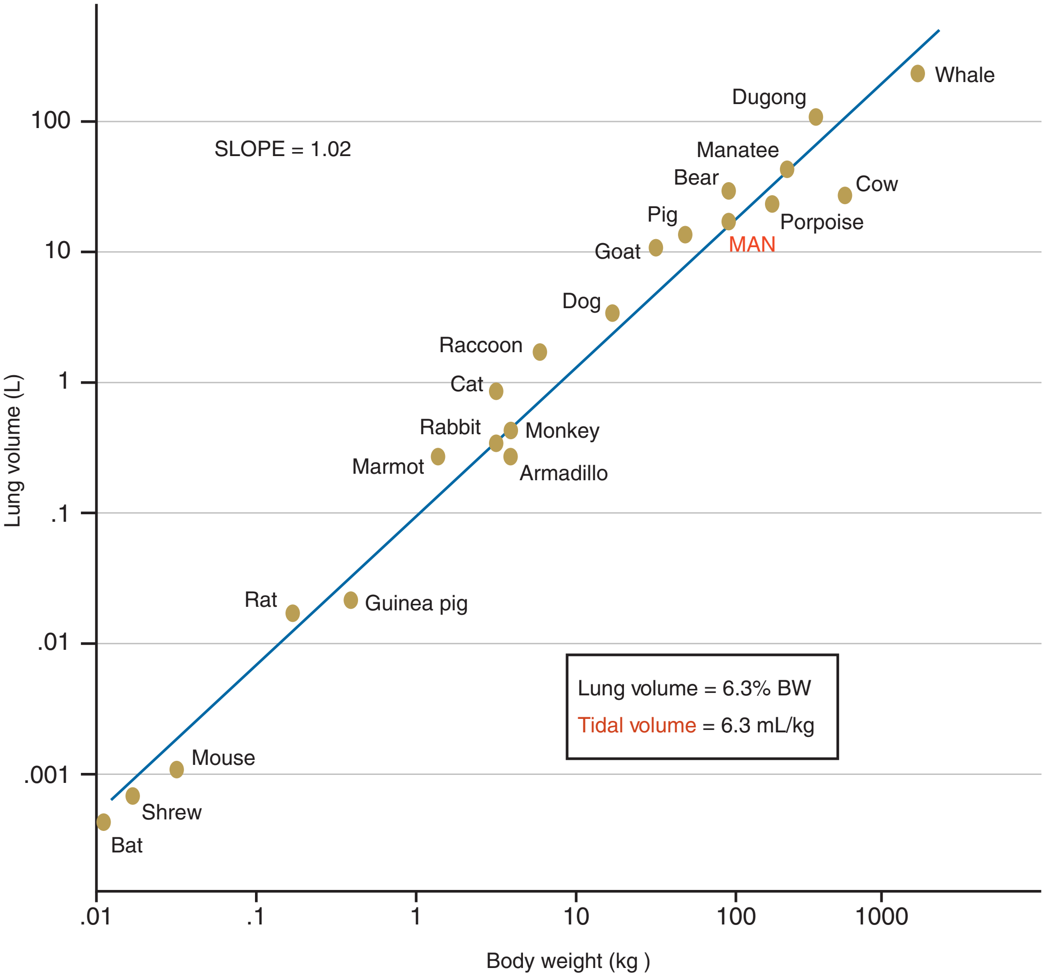

Figure 36-3 Scaling of the lung in mammals. *BW*, body weight. *(From Villar J, Kacmarek RM, Hedenstierna G: From ventilator-induced lung injury to physician-induced lung injury: why the reluctance to use small tidal volumes?* Acta Anaesth Scand *48:267–271, 2004.)*

described the onset of pulmonary edema in rats and larger mammals ventilated with high peak alveolar pressures.

Experimental evidence and advances in lung imaging techniques and bedside ventilator waveform analysis are providing support for the concept that any tidal volume, regardless of how small, has the potential to damage the preinjured lung. Limitation of tidal volume to 6 to 7 mL/kg and plateau pressure to a maximum of 30 cm H_2O represents the standard for mechanical ventilation in patients with ALI or ARDS. However, tidal hyperinflation may occur in some patients despite limiting tidal volume to 6 mL/kg and plateau pressure to 30 cm H_2O. Current evidence suggests that lung-protective ventilation strategies (in the absence of a priming pulmonary insult) cause significant gene expression in the lung. These changes can be detected even after 90 minutes of mechanical ventilation. In patients with ARDS, a further reduction of tidal volume to levels lower than 6 mL/kg in some instances minimizes tidal hyperinflation and attenuated pulmonary inflammation, as evaluated by pulmonary cytokines and computed tomography.

VILI is a dynamic process that is hard to capture at a single point in time. The damage observed in VILI reflects the primary injurious stimuli and the secondary complex interactions of inflammatory mediators on alveolar epithelial and capillary endothelial cells. Alveolar overinflation elicits a well-coordinated response that contributes to cellular proliferation and inflammation. As the epithelium is progressively stretched, a nonreversible opening of water-filled channels between alveolar cells occurs, resulting in free diffusion of small solutes and albumin across the epithelial barrier. The pulmonary endothelium is a metabolically active surface that provides a regulatory interface for the continual processing of blood-borne vasoactive molecules; it plays an active role in homeostasis and immunologic and inflammatory events, regulates vascular tone, and interacts with inflammatory cells and neighboring vascular cells. Mechanical forces originating within the alveolus can cause endothelial disruption and hemorrhagic injury, even in the absence of preexisting inflammation. Cell deformation by mechanical forces directly causes conformational changes in molecules within the cell membrane, leading to activation of downstream messenger systems. Mechanical ventilation can trigger a complex array of pro- and antiinflammatory mediators that may lead to either greater injury or enhanced lung healing and quicker restoration of pulmonary function. Some ventilatory strategies, however, can cause an acute imbalance in this normal stress response, altering lung cellular function and producing a local and a systemic response. Two mechanisms are believed to be responsible for this mechanical ventilation–induced cytokine release (biotrauma). The first is *direct trauma* to the cell with disruption of the membranes, resulting in translocation of cytokines into both the alveolar space and the systemic circulation. The second mechanism has been termed *mechanotransduction*. In vitro studies have shown that most pulmonary cells can produce cytokines in response to cyclic stretch. A large number of genes differentially expressed in the lung by mechanical ventilation have been identified in in vivo animal models of VILI, including genes involved in immunity and inflammation, stress response, metabolism, and transcription processes. However, the sensing mechanism of these physical forces and the translation into intracellular signals is largely unknown.

Mechanical ventilation with large tidal volumes results in extracellular matrix remodeling in patients. This effect suggests a potential contributory role of mechanical ventilation in causing lung fibrosis (Figure 36-4). In elective surgical patients, mechanical ventilation with a tidal volume of 12 mL/kg and no PEEP promote procoagulant changes, leading to fibrin deposition within airways; such changes can be prevented by use of low VT and high-level PEEP.

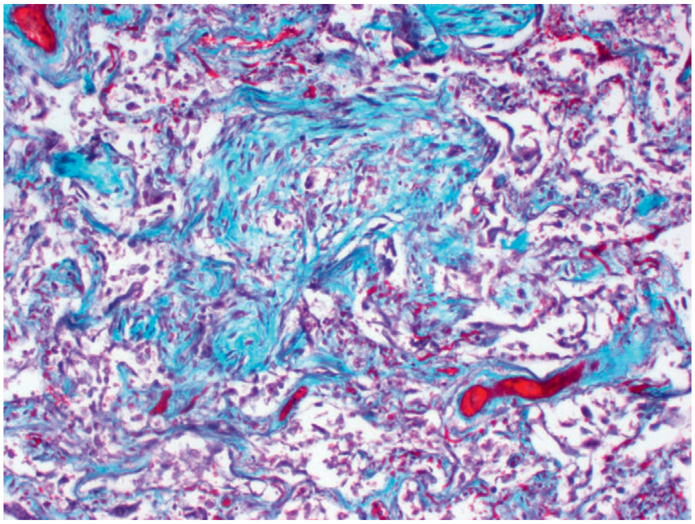

Figure 36-4 Fibrotic lung from a patient with acute respiratory distress syndrome after 10 days of mechanical ventilation. (Gomori trichrome staining technique: *blue* represents fibrosis, *purple* represents the nuclei of the cells (mostly fibroblasts), and red blood cells are stained in *red*.) 100× magnification.

MECHANICAL VENTILATION-INDUCED SEPSIS

Sepsis originating from pulmonary and nonpulmonary infections is the most frequent cause and complication of ARDS. First described by Hippocrates in 400 BCE, sepsis is a controversial topic eliciting various hypotheses for its immunopathophysiology. The controversy surrounding sepsis is a result of the way it is defined, because its etiology and pathogenesis remain unclear, and because it is defined by inflammation, regardless of the source.

Sepsis describes a complex clinical syndrome occurring as a result of a systemic inflammatory response to live bacteria or bacterial products. Sepsis develops when the initial, appropriate host response to an infection becomes amplified and is then deregulated. According to the current definition, sepsis represents a disease continuum that proceeds from infection to a systemic inflammatory response syndrome and finally to severe sepsis. The clinical management of sepsis remains very complicated because of the nonhomogeneous nature of patient populations and because of the difficulties in precise clinical classification of patients with the disorder. Whether the sepsis is treated or not, potential outcomes include multiple system organ dysfunction, shock, and death.

Because an all-encompassing single mechanism for sepsis remains elusive, mechanical ventilation–induced inflammation may be a root cause, by amplifying the sepsis cascade of microbial or nonmicrobial origin. Most pulmonary cells express a large repertoire of genes under transcriptional control that are modulated by biomechanical forces and bacterial infections. The highly integrated pulmonary defense system is capable of initiating rapid and intense immune responses to invading microbes or cell debris, resulting in profound local and systemic inflammation. Healthy experimental animal and human lungs ventilated with small, moderate, and large tidal volumes evoke early inflammatory responses similar to those evoked by endotoxin or those seen during infections (activation of nuclear factor κB [NFκB] and cytokine release). Gene expression profiles obtained from microarrays across different experimental models of VILI also suggest that the response triggered by alveolar overdistention might mimic an innate immune inflammatory response against pathogens. Mechanical ventilation enhances lipopolysaccharide (LPS)-induced expression of TNF-α. When used with moderate tidal volumes, it augments the innate immune response to bacterial products in the lung and may play a role in the perpetuation of a septic state. Ventilator-associated pneumonia is a frequent complication of mechanical ventilation and an important contributor to morbidity and mortality in critically ill patients. Endotracheal intubation may be the most important factor leading to pneumonia, because the endotracheal tube directly interferes with the barrier between the oropharynx and the lower respiratory tract, by preventing glottic closure, leading to an ineffective cough mechanism. It is not surprising that pulmonary bacterial colonization and infection are associated with a higher risk for development of ARDS, because the lung, with the largest epithelial surface area of the body, is repeatedly exposed to airborne particles and microorganisms.

As with the association of bacteria and their products translocating from the gut and leading to sepsis, injurious mechanical ventilation may be responsible for translocation of bacteria and their products from the alveoli into the bloodstream and be a major factor in the development of systemic infection and multiple organ dysfunction. In the absence of a pulmonary infection, however, mechanical ventilation–induced epithelial and endothelial damage could be responsible for the translocation of soluble mediators derived from pathogens or tissue other than bacteria or endotoxin. In some cases, those pathogen-associated molecules could come from pathogens that are colonizing rather than infecting the airway.

VILI and sepsis involve more mediators than was previously thought. Essential components of the innate immune system are the Toll-like receptors, which recognize not only microbial products but also degradation products released from damaged tissue, providing signals that initiate inflammatory responses. Toll-like receptor agonists circulate in the bloodstream both attached to microorganisms and also separately. Because the pulmonary epithelial and endothelial barriers are damaged during ALI, lung cytokines and bacterial products can be trafficked from the alveoli and the interstitium into the systemic circulation, leading to inter- or intracellular signaling impairments in the functional metabolic properties of those populations of cells. It has been found that mechanical ventilation, in the absence of infection, can induce upregulation of the Toll-like receptor-4 signaling pathway (a receptor related to endotoxin signal transduction), resulting in an increase in proinflammatory cytokine levels in the lungs and in the systemic circulation.

MULTIPLE SYSTEM ORGAN DYSFUNCTION: A COMMON END FOR VENTILATOR-INDUCED LUNG INJURY AND SEPSIS

Approximately 80% of all deaths in patients suffering from ARDS occur within 2 to 3 weeks after its onset. The exact cause of death remains elusive; no autopsy studies have revealed why patients with ARDS die. Death has traditionally been attributed to the underlying disease, the presence of sepsis, and/or the failure of vital organ systems other than the lung. The association of ARDS with multiple system organ dysfunction is not inevitable, but it certainly is common.

The relationship of ARDS with multiple system organ dysfunction is complex, with at least three possible pathophysiologic models: (1) Although sepsis may cause similar local injury (e.g., increased capillary leak), the functional implications of this injury in the lung are greater because of the exquisite susceptibility of the gas exchange apparatus of the lung to edema; (2) local injury to the lungs (trauma, aspiration, gas inhalation) may set up a secondary diffuse inflammatory response resulting in damage to other organs; or (3) infection and sepsis set off the chain of events leading to ARDS and multiple system organ dysfunction. Among those three models, the classic accepted scenario is that ARDS is complicated by sepsis, which results in multiple system organ dysfunction. A fourth possibility has emerged in light of current evidence on VILI: Ventilator-induced inflammatory response may alter cellular pathways that are important for the normal function of tissues and organs.

Multiple system organ dysfunction is a cumulative sequence of organ dysfunctions in patients suffering from the same diseases often found in patients with ARDS. Still to be resolved is why in most studies on sepsis, at least a third of the patients do not have a truly identified source of the septic process. Among several possible reasons, one of the most frequently offered is that antibiotics, administered early, have suppressed the growth of bacteria, as borne out by results of blood culture. It is plausible that mechanical ventilation could be partially responsible for the development of sepsis or a sepsis-like syndrome in critically ill patients, even if blood cultures are negative. Several investigators have suggested that the mechanical ventilation–induced inflammatory response may be a contributing factor in multiple system organ dysfunction by initiating or propagating a malignant, systemic inflammatory response (see Figure 36-2). ARDS and acute kidney injury are frequent complications in critically ill patients with multiple system organ dysfunction. Although the functional changes seen in septic patients are known to affect primarily the lungs, the cardiovascular system, and the kidneys, the gut has long been established as an important component of the immune barrier. An emerging consensus implicates the gut flora in the pathogenesis of sepsis. The gut is a reservoir of pathogens and pathogen-associated molecular patterns from microbes, and translocation of these molecular patterns and toxins other than endotoxin also induces a systemic inflammatory response (probably through Toll-like receptors and NFκB signaling pathways), contributing to the development of a systemic infection and multiple organ dysfunction in critically ill patients.

IMPLICATIONS OF THE SEPSIS–VENTILATOR-INDUCED LUNG INJURY CONNECTION

What conclusions can be drawn from the VILI story? First, the available evidence strongly indicates that patients with ARDS must be ventilated with a tidal volume of 4 to 8 mL/kg of predicted body weight. Second, although data are too limited to support the conclusion that all critically ill patients must be ventilated with a tidal volume of 4 to 8 mL/kg, using small tidal volumes in patients without ARDS may be a reasonable strategy, with little risk for harm, if clinical issues related to maintenance of sufficient PEEP, and possibly the respiratory acidosis that may arise, are addressed appropriately. Third, in view of the relationship between mechanical ventilation and lung injury, an increasingly pertinent consideration is that ARDS may be a consequence of clinical efforts to ventilate the patient, rather than of progression of the underlying disease.

Injurious ventilatory strategies have been shown to increase alveolar-capillary leak, to worsen oxygenation, to cause pulmonary infiltrates, to decrease lung compliance, and to cause an increase in lavage fluid and systemic cytokines—all hallmarks of ALI and ARDS. In the context of increased alveolar-capillary leak, use of excessive intravenous fluids—often administered to treat shock in patients at risk for ALI—can cause increased lung water and likewise impair pulmonary mechanics and gas exchange, leading to worse clinical outcomes. It may not be a coincidence that ARDS was first described in the late 1960s, at the time of the Vietnam conflict, when it was called “Da Nang lung” or “shock lung,” in the setting of aggressive resuscitation in the battlefield. Finally, endotracheal intubation affects host defense and can lead to development of colonization or pneumonia, a predisposing factor for ALI and ARDS. Thus, ALI-ARDS may be largely a “man-made” syndrome, arising as a consequence of the aggressive regimens adopted to treat acutely treat patients. If this is so, an inflection point is needed in which ALI-ARDS is no longer a syndrome that must be treated but an iatrogenic illness that should be prevented.

VENTILATORY MANAGEMENT FOR ACUTE RESPIRATORY DISTRESS SYNDROME

Ventilation is an essential function of life and also one of the first to be replicated by artificial means. Mechanical ventilation is the second most frequently performed therapeutic intervention after treatment of cardiac arrhythmias in the intensive care unit (ICU), and it is the most important aspect of the supportive care of patients with respiratory failure. As part of the therapy for the underlying disease, patients with ARDS invariably require endotracheal intubation and mechanical ventilation to decrease the work of breathing and to improve oxygen transport. An improvement in oxygenation can be obtained in many patients with ARDS by an increase in PEEP. To date, the only proven, widely accepted method of mechanical ventilation for ARDS is protective lung ventilation using a low-tidal-volume strategy (4 to 8 mL/kg of predicted body weight) and medium to high PEEP to keep alveoli open throughout the ventilator (respiratory) cycle.

Early interest in low-tidal-volume ventilation was prompted by animal studies in the 1970s showing that mechanical ventilation with large tidal volumes and high peak alveolar pressures resulted in the development of ALI characterized by formation of hyaline membranes and inflammatory infiltrates. Although tidal volumes of 10 to 15 mL/kg had traditionally been used in a majority of patients with respiratory failure, it was recognized in the mid-1980s that ARDS resulted in a significant reduction in the amount of normally aerated lung tissue. The ARDS “baby lung” concept—in which only a small portion of the lung is actually available for ventilation—describes marked overdistention by high tidal volumes.

The effect of different lung-protective ventilatory strategies in patients with ALI or ARDS has been investigated in randomized controlled trials. In the late 1990s, four such trials were conducted to evaluate the benefit of low tidal ventilation in ARDS patients compared with traditional tidal volume ventilation (Table 36-4). Only one of these trials, performed in Brazil by Amato and colleagues, showed a significant reduction in mortality in the experimental treatment group. Patients randomized to receive tidal volumes of 6 mL/kg of actual body weight or lower and driving pressures of less than 20 cm H_2O were significantly less likely to die during the 28-day study period than were patients randomized to receive the traditional 12 mL/kg of actual body weight tidal volumes and unlimited driving pressures. Because all four studies had limited statistical power owing to small sample sizes, a large trial was needed to definitively determine the effect of low-tidal-volume ventilation in patients with ARDS.

In response to this need, the National Heart, Lung, and Blood Institute ARDS Network enrolled 861 patients at 10 institutions between 1996 and 1999 in a randomized controlled trial known as the Respiratory Management in Acute Lung Injury/ARDS (ARMA) trial. This study compared a ventilatory protocol using tidal volumes of 4 to 8 mL/kg of predicted body weight and maintaining plateau pressures of 30 cm H_2O or less with conventional mechanical ventilation using 12 mL/kg of predicted body weight tidal volumes. The lower tidal volume protocol in the ARMA study achieved more pronounced differences between the intervention and control groups in tidal volume (6.2 versus 11.8 mL/kg of predicted body weight) and plateau pressure (25 versus 33 cm H_2O) than those achieved in previous studies. The hospital mortality rate was significantly reduced in the low-tidal-volume group, with a nearly 9% reduction in the absolute risk of death from that the control group (31% versus 39.8%; $P = .007$). Although it has been postulated that the mortality benefit demonstrated in the ARMA study was attributable to a high mortality rate in the control group resulting from tidal volumes that were higher than the standard of care, several observational studies performed later indicated that no uniform standard of care existed at the time of the ARMA trial.

Therefore, it is recommended that critical care physicians utilize the ventilation protocol outlined by the Acute Respiratory Distress Syndrome Clinical Network (ARDSNet) investigators. This protocol involves the following principles:

1. High tidal volumes and high plateau pressures are to be avoided.
2. Tidal volume size should be based on *predicted* body weight, calculated from gender and height—50 + 0.91 × (height in cm − 152.4) for men and 45.5 + 0.91 × (height in cm − 152.4) for women—rather than on actual body weight.
3. Tidal volumes should be systematically adjusted (from 4 to 8 mL/kg of predicted body weight) to maintain a plateau pressure of 30 cm H_2O or less.
4. The respiratory rate should be titrated as needed (over a range of 10 to 35 breaths/minute) to maintain a pH of 7.3 to 7.45.
5. An appropriate combination of F_{IO_2} and PEEP should be used to achieve adequate oxygenation (Pa_{O_2} of 55 to 85 mm Hg, or Sp_{O_2} of 90% or greater).

Since the publication of ARMA, however, despite the statistically significant decrease in mortality rates, widespread use of this therapy remains elusive. Significant barriers to the implementation of low-tidal-volume mechanical ventilation include unwillingness to accept or lack of knowledge of the published data, failure to recognize patients as having ARDS, perceived contraindications to low-tidal-volume ventilation, concerns regarding patient discomfort, and presence of hypercapnia or acidosis.

THE USE OF POSITIVE END-EXPIRATORY PRESSURE IN ACUTE RESPIRATORY DISTRESS SYNDROME

PEEP has become an essential component of the care of many critically ill patients who require ventilatory support. The

rationale for the use of PEEP in ALI coincides with the theoretical basis for loss of lung volume and compliance in patients with ARDS. With the application of PEEP, the baseline end-expiratory pressure in mechanically ventilated patients is elevated above atmospheric pressure. The application of PEEP is expected to improve lung mechanics and gas exchange, because it maintains recruited lung volume open. PEEP should be utilized in patients with ARDS to decrease the proportion of nonaerated lung, resulting in improved oxygenation. PEEP prevents complete alveolar collapse and improves oxygenation by increasing functional residual capacity, probably by preventing airway closure and keeping open the previously recruited unventilated alveoli. Conversely, the increase in functional residual capacity also may increase lung compliance. In general, PEEP is applied to improve oxygenation, which usually is not observed except with a concomitant increase in functional residual capacity. The application of PEEP is expected to increase Pao_2 and to decrease intrapulmonary shunt, alveolar-arterial O_2 pressure difference, and arteriovenous O_2 content difference because greater lung volumes are recruited. Four mechanisms have been proposed to explain the improved pulmonary function and gas exchange with PEEP: (1) increased functional residual capacity; (2) alveolar recruitment; (3) redistribution of extravascular lung water; and (4) improved ventilation-perfusion matching. The increase in lung volume is the result of three separate effects. First, PEEP increases lung volume as a result of distention of already patent airways and alveoli by an amount dependent on system compliance.

Table 36-5 **Oxygenation Scale for Application of Positive End-Expiratory Pressure (PEEP)***

Low PEEP

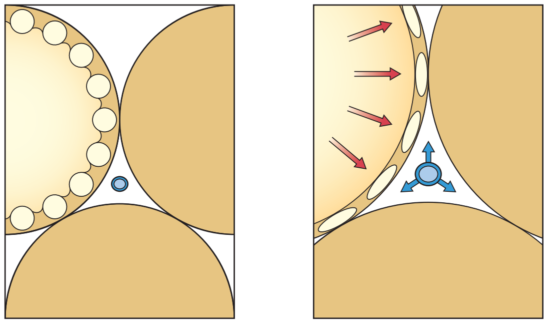
*Note: These tables were used for the first time in the ALVEOLI study but lack a physiologic basis because the data are based on surveys of clinicians' practice.
ALVEOLI, Assessment of Low Tidal Volume and Elevated End-Expiratory Pressure to Obviate Lung Injury; *FIO_2*, fraction of inspired oxygen.
Data compiled for Brower RG, Lanken PN, MacIntyre N, et al; National Heart, Lung, and Blood Institute ARDS Clinical Trials Network: Higher versus lower positive end-expiratory pressures in patients with the acute respiratory distress syndrome, *N Engl J Med* 351:327, 2004.



A Low lung volume B High lung volume

Figure 36-5 As a result of increasing lung volume with PEEP **(B),** alveolar capillaries are stretched and compressed (*arrows*). Extraalveolar and corner vessels between alveoli are expanded, which increases the flux of fluid into the interstitial space. Without PEEP **(A),** these changes are reversed. *PEEP*, positive end-expiratory pressure. *(From Kacmarek RM: Positive end-expiratory pressure. In Pierson DJ, Kacmarek RM, editors:* Fundamentals of respiratory care, *New York, 1992, Churchill Livingstone, pp 891–920.)*

Therefore, the stiffer the system, the smaller the volume change. Second, application of PEEP prevents alveolar collapse during expiration. Dependent, small airways tend to collapse at low lung volumes. Third, PEEP levels above 10 cm H_2O recruit collapsed alveoli in the acutely injured lung. Alveolar recruitment describes reinflation of previously collapsed alveoli. The application of PEEP allows recruitment of flooded alveoli and improves oxygenation without diminishing lung water content, supporting the conclusion that PEEP redistributes lung water from alveoli to the perivascular space. In general, by increasing intraalveolar pressure, PEEP moves fluid from the interstitial space of alveolar vessels to the interstitial space around extraalveolar vessels. In addition, PEEP increases the transmural pressure across corner (in the peribronchial area) and extraalveolar vessels, thereby increasing flux into the interstitial space (Figure 36-5).

Although PEEP is well recognized to improve oxygenation in selected patients, its beneficial effects on morbidity and mortality have not been conclusively demonstrated. Early observations that PEEP greatly improves oxygenation in patients with ARDS led to its widespread use in such patients, but the level of PEEP needed to achieve maximum benefit with minimal complications has never been established. Traditionally, PEEP values of 5 to 12 cm H_2O have been used in the ventilation of patients with ARDS. In the ARMA trial, PEEP levels in both the experimental and control groups were adjusted according to the required FIO_2 and ranged between 5 cm H_2O (when FIO_2 was 0.3) and 18 to 24 cm H_2O (when FIO_2 was 1.0) (Table 36-5). On average, patients in the low-tidal-volume ventilation group were treated with levels of PEEP that were no different than those utilized in the high-tidal-volume group. However, it remains unclear whether these values are ideal because randomized controlled trials have not clearly shown that higher levels of PEEP lead to a reduction in mortality rate.

Several randomized controlled trials have evaluated the efficacy of high levels of PEEP in the treatment of ARDS. Thus far, a total of seven published randomized controlled trials have examined the effects of higher levels of PEEP in patients with ALI or ARDS, or both. Those trials have tested higher versus lower PEEP strategies during low-tidal-volume ventilation and lower tidal volume and PEEP titrated to above the lower inflection point of the individual pressure volume curve versus higher-tidal-volume ventilation and lower PEEP (see Table 36-4). At first look, the pooled results of a metaanalysis of these trials suggest that the application of either low or high PEEP levels in patients with ALI or ARDS does not influence outcome. However, this is not what the data show. First, because the ALI-ARDS population was not homogeneous in all the trials, the benefit of higher levels of PEEP could not be appropriately evaluated. Second, in some trials, a PEEP level of 5 cm H_2O was a permissible setting in the higher PEEP group. Therefore, a patient with a PaO_2 of 60 mm Hg on a FIO_2 of 0.3 and 5 cm H_2O of PEEP satisfied the AECC inclusion criteria. It is difficult to accept that in these patients there is a need to test the effects of high levels of PEEP. Finally, some trials (e.g., the Assessment of Low Tidal Volume and Elevated End-Expiratory Pressure to Obviate Lung Injury [ALVEOLI] and Expiratory Pressure [ExPress] trials) (see Table 36-4) included patients with ALI (without ARDS), who did not benefit and more often experienced adverse effects from higher levels of PEEP, suggesting that both trials failed to focus on the patients at highest risk. If the subjects in a trial have a very low risk for the condition that the intervention is hypothesized to prevent, the trial—regardless of sample size—will not verify the value of the experimental intervention under study. In the study of a protective ventilation strategy by Amato and Villar and their respective colleagues, PEEP was significantly higher in the intervention group than in the control group (13 to 14 cm H_2O versus 9 cm H_2O, respectively). Although both trials reported a significantly lower mortality in the intervention group, these findings cannot be solely attributed to higher levels of PEEP, because the intervention strategies in these trials also included both low tidal volumes and high levels of PEEP.

To determine the isolated benefit of high levels of PEEP in patients with ARDS, the ARDSNet conducted a large randomized controlled trial known as the ALVEOLI trial. Patients ventilated with low tidal volumes (4 to 8 mL/kg of predicted body weight) were randomized to a ventilator protocol utilizing high levels (12 to 24 cm H_2O) or low levels of PEEP (5 to 24 cm H_2O). In the first 7 days of ventilator support after initiation of treatment, patients in the high PEEP group received 13 to 15 cm H_2O of PEEP and patients in the low PEEP group, 8 to 9 cm H_2O of PEEP. Although patients in the high PEEP group experienced better improvement in oxygenation, the duration of mechanical ventilation and hospital mortality were similar in the two groups.

The speculation of many investigators regarding the lack of expected benefit from higher PEEP in the ALVEOLI, Lung Open Ventilation (LOV), and ExPress trials (see Table 36-4) is that in a substantial proportion of patients in those trials, the severity of lung injury was modest. In two other trials, Amato and colleagues and Villar and associates enrolled only patients with severe, established ARDS, and both groups found that the application of higher levels of PEEP was associated with a better outcome. By contrast, in the rest of the trials, the investigators studied an unselected, mixed population of ALI and ARDS and, as a result, missed the opportunity to test whether the use of higher levels of PEEP is beneficial in patients with persistent ARDS. Patients in the ALVEOLI, LOV, and ExPress trials had similar PaO_2/FIO_2 ratios at study entry (about 140 ± 50 mm Hg). It is conceivable, however, that a disproportionate number of patients meeting ALI criteria on standard ventilatory settings ended up in the control group, negating the beneficial effect of the treatment because of a lower mortality rate (20% or less in most series). A critical review of the two most recently published trials on the effects of PEEP in ARDS leads to an alternative interpretation. In both trials (the LOV study and the ExPress trial), patients who received higher PEEP were less likely to require rescue therapy. In addition, a lower PEEP was associated with significantly fewer ventilator-free and organ failure-free days, which may be the reason for a 4% mortality difference in favor of the high PEEP groups (*P* = .10).

Of note, current published metaanalyses including some or all of the available trials reported conflicting results and are biased because they do not deal with all comparisons between tidal volume and PEEP (**Table 36-6**). The first metaanalysis from Oba and colleagues, which considered five trials (reported by Amato, Brower, Meade, Mercat, and Villar and their co-workers), showed a decrease in in-hospital mortality (*P* = .03) and a trend toward significance for the 28-day mortality (*P* = .06) with higher PEEP and without an increase in barotrauma. A second meta-analysis, by Phoenix and colleagues, included an additional study (by Ranieri and co-workers) and showed a reduction in mortality (pooling together the in-hospital and the 28-day mortality rates, *P* = .007) with higher PEEP. In a subsequent metaanalysis, Putensen and colleagues analyzed the five trials included in the Oba metaanalysis. Data from three of these trials—those reported by Brower, Meade, and Mercat and their co-workers—were pooled together for comparison of lower versus higher PEEP at low tidal volume ventilation. The remaining two studies (by Amato and Villar and their co-workers) were used for the comparison of higher tidal volume and lower PEEP versus lower tidal volume and higher PEEP. Despite opposite results from the two previous metaanalyses, the comparison between lower and higher levels of PEEP at low tidal volume ventilation showed similar hospital mortality rates (*P* = .08). However, the risk of in-hospital mortality was reduced only with the combination of a lower tidal volume and higher PEEP, compared with higher tidal volume and lower PEEP (*P* = .005). Thus, the beneficial effect of PEEP

Table 36-6 Metaanalysis of Data From Randomized Controlled Trials Comparing Lower and Higher Levels of Positive End-Expiratory Pressure (PEEP) in Patients With Acute Lung Injury (ALI) or Acute Respiratory Distress Syndrome (ARDS)

Study Feature	**Oba et al: *Respir Med* 103:1171, 2009**	**Phoenix et al: *Anesthesiology* 110:1098, 2009**	**Putensen et al: *Ann Intern Med* 151:566, 2009**	**Briel et al: *JAMA* 303:865, 2010**
Trials included in the metaanalysis*	Amato et al, 1998 Brower et al, 2004 Villar et al, 2006 Meade et al, 2008 Mercat et al, 2008	Amato et al, 1998 Ranieri et al, 1999 Brower et al, 2004 Villar et al, 2006 Meade et al, 2008 Mercat et al, 2008	Amato et al, 1998 Brower et al, 2004 Villar et al, 2006 Meade et al, 2008 Mercat et al, 2008	Brower et al, 2004 Meade et al, 2008 Mercat et al, 2008
High PEEP, no. deaths/no. patients (%)	408/1215 (33.6)	415/1233 (33.6)	429/1163 (36.9) at low VT (Brower et al + Meade et al + Mercat et al) 30/79 (38) (Amato et al + Villar et al)	374/1136 (32.9) 324/951 (34) for ARDS 50/184 (27.2) for ALI
Low PEEP, no. deaths/no. patients (%)	464/1232 (37.6)	482/1251 (38.5)	378/1136 (33.3) at low VT (Brower et al + Meade et al + Mercat et al) 42/69 (60.9) (Amato et al + Villar et al)	409/1163 (35.2) 368/941 (39) for ARDS 44/220 (19.4) for ALI
Overall effect	*P* = .038	*P* = .007	*P* = .08 high vs. low PEEP at low VT P = .005 high PEEP + low VT vs. low PEEP + high VT	*P* = .25 (hospital mortality) *P* = .01 (ICU mortality) *P* = .049 (beneficial for ARDS only) *P* = .07 (harmful for non-ARDS)

*See Tables 36-2 and 36-4 for publication information on cited studies.
ICU, intensive care unit; *VT*, tidal volume.

may have been due to a simultaneous reduction in the tidal volume and an increase in the level of PEEP. Finally, a fourth metaanalysis from Briel and colleagues (see Table 36-6) was performed on the individual data for 1136 patients (with higher PEEP) and 1163 patients (with lower PEEP) from trials that compared lower and higher PEEP values at a low-tidal-volume ventilation. The individual data analysis showed that a nonsignificant difference was found in hospital mortality rates between the higher and lower PEEP groups (32.9% versus 35.2%; $P = .25$). In conclusion, these metaanalyses of individual patient data suggest that higher levels of PEEP may be associated with lower mortality in patients who meet ARDS criteria, whereas such a benefit is unlikely in patients who have less severe lung injury.

RESCUE STRATEGIES FOR REFRACTORY HYPOXEMIA

A number of alternative techniques (currently available worldwide or under evaluation) can be used to improve oxygenation and ventilation in patients with ALI or ARDS who have refractory hypoxemia. Today, refractory hypoxemia is rare and an infrequent cause of death (accounting for less than 15% of ARDS-related deaths). There is no standard definition for refractory hypoxemia in terms of a predetermined $\mathrm{PaO_2}$ value under a specific oxygen concentration ($\mathrm{FIO_2}$) and applied PEEP level for a specific period of time. In most reports, it has been defined as having a $\mathrm{PaO_2}$ below 60 mm Hg on an $\mathrm{FIO_2}$ 0.8 to 1.0 and PEEP 10 to 20 cm H_2O for more than 12 to 24 hours.

RECRUITMENT MANEUVERS

As described previously, ARDS is characterized by collapsed and consolidated alveoli. Recruitment maneuvers are intended to reopen these alveoli and to attenuate the injurious effects of the repetitive opening and closing of the alveolar unit. In general, a recruitment maneuver is defined as applying a pressure higher than that applied during a normal breath either intermittently (for 2 to 3 minutes) or sustained for a short period of time (up to about 40 seconds). A recruitment maneuver usually improves oxygenation and may influence ventilation by reducing $\mathrm{PaCO_2}$. Recruitment occurs during the whole period of inspiration, and the amount of recruited lung area correlates with the inspiratory pressure applied. The amount of potentially recruitable lung tissue seems to correlate well with the severity of ARDS. With respect to hemodynamics, the acute and substantial increase in intrathoracic pressure during the recruitment maneuver often induces a decline in cardiac output and tissue oxygenation. Therefore, it is essential to stabilize the patient hemodynamically before a recruitment maneuver procedure. Although the potential for barotrauma is a concern during a recruitment maneuver, when recruiting pressures are maintained at or below 50 cm H_2O peak alveolar pressure, barotrauma has been rarely reported.

The ALVEOLI trial also evaluated the safety and efficacy of recruitment maneuvers in the first 80 patients randomized to receive high-level PEEP. Continuous positive airway pressure (CPAP) of 35 to 40 cm H_2O was applied for 30 seconds, and the results were compared with those of a sham recruitment maneuver. Because the interventions resulted in only small and transient increases in oxygenation, they were discontinued. Such maneuvers have been associated with transient hypotension and hypoxemia, and their long-term benefit remains unproved. In a metaanalysis of seven clinical trials involving 1170 patients with ALI/ARDS, there was no significant difference in survival between groups receiving an "open lung" ventilatory strategy that included recruitment maneuvers and groups given standard ventilatory care. The main limitation of that systematic review, however, was the design of the trials, in that they either did not isolate recruitment maneuvers from other variables or assessed only short-term outcomes, and few of these trials determined the patient-specific PEEP level (by decremental trial) after the recruitment maneuvers—a key to the successful use of such maneuvers. Most recent data suggest that a recruitment maneuver performed in the early phase of ARDS might be more effective than in late-stage ARDS.

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO) is a technique that originally was applied in patients with acute respiratory failure of such severity that it was impossible to provide adequate oxygenation by conventional mechanical ventilation. To supplement gas exchange, a portion of the cardiac output must go through the ECMO circuit. During ECMO, CO_2 is removed by the extracorporeal circuit, but this technique usually is supplemented with conventional mechanical ventilation at low ventilatory rates, high PEEP levels, and tidal volumes adequate to maintain a plateau pressure below 30 cm H_2O. Most long-term adult ECMO procedures are performed using the venovenous approach. Access for both blood removal and return is by way of the femoral, saphenous, or jugular vein. Despite the excitement generated by earlier reports of success, the results of ECMO trials led to a loss of enthusiasm for its use in acute respiratory failure. Some investigators, however, believe that there exists a role for ECMO in young adult patients with single organ system failure who are deemed to have potentially reversible pulmonary dysfunction when all other conventional modalities have failed.

Recently a large multicenter adult ECMO trial was completed. Referred to as the CESAR trial (Conventional Ventilatory Support versus Extracorporeal Membrane Oxygenation for Severe Adult Respiratory Failure), this randomized controlled trial assessed the effectiveness of extracorporeal lung assist in 180 patients with severe ARDS. The findings of this study represent the first positive results for adult ECMO application in severe respiratory failure. Survival at 6 months or absence of severe disability was achieved in 63% of the patients on ECMO, compared with 47% of the control group ($P = .03$). However, a number of major concerns and limitations with this study have been identified: First, patients allocated to conventional management (control group) were treated with conventional mechanical ventilation or with high-frequency ventilation. Second, patients in the control group were ventilated with a nonstandardized protocol; to ensure the collaboration of participating centers, physicians were allowed to choose any ventilatory strategy. Third, 30% of patients in the control group were not ventilated with a lung-protective strategy. Fourth, no data regarding ventilatory parameters at study entry and during the mechanical ventilation period are presented. Fifth, all patients receiving ECMO were treated in the same center. Sixth, the ECMO center did not treat patients randomized to the conventional management group. Seventh, many patients randomized to receive ECMO did not receive ECMO. In fact, 103 patients who were screened for eligibility were excluded because a bed was unavailable for ECMO, and 22 patients (25%) assigned to be transferred to the ECMO center never received ECMO (16 of these improved with conventional management). Finally, a more critical analysis of outcomes data for patients who actually received ECMO (68 of 90) compared with those who were treated with mechanical ventilation for whom information about mortality was available (87 plus 22) showed that the mortality rates were similar in both groups (48.5% for ECMO versus 43.1% for mechanical ventilation) ($P = .64$, by our own calculations). In addition, the length of ICU stay and hospital stay was more than twice as high in the ECMO group.

The highly specialized equipment and knowledge required to provide ECMO make this technique available only in specific medical centers.

HIGH-FREQUENCY OSCILLATORY VENTILATION

Some clinicians have proposed that high-frequency oscillatory ventilation (HFOV) is an ideal mode of ventilation for patients with ARDS, because it is the natural culmination of low-tidal-volume ventilation. Current understanding of the mechanisms and importance of ventilator-induced lung injury has advanced considerably over the past 3 decades. HFOV should theoretically be an ideal mode to ventilate patients with severe lung damage, because it achieves gas exchange by delivering very small tidal volumes that typically are 1 to 3 mL/kg (often less than the anatomic dead space) at frequencies ranging from 3 to 10 Hz around a relatively constant mean airway pressure. HFOV is not a difficult technique. In fact, it is easier than conventional mechanical ventilation: It incorporates fewer and simpler controls that are not interrelated as they are in conventional mechanical ventilators. Recent prospective, observational studies have reported that HFOV is a feasible and efficient method of ventilation that results in rapid and sustained improvement in oxygenation in patients with severe ARDS. However, a critical examination of randomized controlled trials comparing HFOV with conventional ventilation demonstrates that there is equivalence between conventional ventilation and HFOV. Specifically, there is no evidence that conventional mechanical ventilation with low tidal volumes, high-level PEEP, and limited plateau pressures is more harmful that HFOV. All of the randomized controlled trials to date have compared HFOV with a less-than-optimal approach to conventional ventilation. Several ongoing trials, however, are comparing HFOV with low-tidal-volume ventilation.

PRONE POSITIONING

Changes in posture can have profound effects on the pulmonary function of patients with severe respiratory failure. Most changes in pulmonary physiology with posture occur as a consequence of the influence of gravity and chest wall shape on the mechanical properties of the lung. By tradition, patients with respiratory failure are cared for supine. In critically ill patients, the supine posture is associated with a fall in functional residual capacity to below closing capacity, resulting in ventilation-perfusion mismatching and a drop in $\mathrm{PaO_2}$. During acute respiratory failure, a reduction of functional residual capacity results in supine hypoxemia regardless of age. Because most lung infiltrates in patients with ARDS are seen in dependent lung regions, it was postulated that prone positioning of patients redistributes blood flow and ventilation to the least affected areas of the lung, promotes secretion clearance, and shifts the weight of the mediastinal contents anteriorly, to assist in the recruitment of atelectatic regions. Thus, the proposed mechanisms by which prone positioning improves oxygenation include an increase in functional residual capacity, a change in regional diaphragm motion, redistribution of perfusion to better-ventilated lung units, redistribution of ventilation to better-perfused lung units, and improved secretion clearance.

Since 1974, prone positioning has been proposed as a technique to improve oxygenation. The practice of turning prone seems to be inexpensive and safe, with the possible exception of an increased risk of regurgitation or inadvertent extubation. However, the act of turning is labor-intensive; at least four experienced staff members are required for this maneuver to avoid the loss of vascular accesses or the airway during turning. Meticulous care must be used in positioning the patient. Placing a neck roll or a pillow under the patient's shoulders and turning the head to one side constitutes the recommended way to support the patient when prone. In addition, prone positioning may be associated with an increased need for sedation. Automated prone positioning uses special devices operated by one nurse, and therapy can be individualized in accordance with the patient's needs and responses. Most complications, such as skin injury, facial edema, catheter removal or compression, hypotension, arrhythmias, and inadvertent extubation, are associated with manual positioning. The risk of developing pressure ulcers is ever-present, as the patient is immobile and pressure on bony prominences may be prolonged. If the patient's tongue becomes edematous to the point of the teeth cutting into it, a dental mouth prop should be used to prevent injury. Facial edema, although only temporary, can be very disturbing for the patient's family to view and can be minimized with application of ice packs.

Although sufficient data have accumulated to permit the conclusion that oxygenation frequently improves when patients with ARDS are turned prone (in about 70% of patients), prone positioning is still not widely implemented. Three recent systematic reviews and metaanalysis in patients with ALI or ARDS have shown that in general, prone positioning does not reduce mortality or duration of mechanical ventilation despite improved oxygenation and a decreased risk of pneumonia. By stratifying patients according to their $\mathrm{PaO_2/FIO_2}$ ratio, however, the most recent metaanalysis has found that in patients with severe ARDS, as defined by a $\mathrm{PaO_2/FIO_2}$ ratio less than 100 mm Hg, prone positioning was able to cause a significant reduction (16% decrease in the relative risk) of all-cause mortality. Thus, prone positioning should be considered to represent a rescue maneuver, and it should be reserved only for patients with severe acute hypoxemic failure in the early phase of the disease process. In such circumstances, the potential for life-threatening complications of prone positioning, including accidental dislodgment of the endotracheal tube or central venous catheters and endotracheal tube obstruction, should be weighed against the short-term benefit of improved oxygenation. Unfortunately, no recommendations can be offered on the optimal timing or duration of prone positioning until large randomized controlled trials in patients with severe hypoxemia provide more information. Extended prone positioning seems to be most beneficial when maintained 18 to 20 hours daily.

INHALED VASODILATORS

Antiinflammatory agents and vasodilators have been tried experimentally in animals and humans for prophylaxis or treatment of ARDS. Prostaglandins, ibuprofen, pentoxifylline, inhaled nitric oxide (iNO), inhaled prostacyclin, almitrine, and corticosteroids all have been tried. None of them have shown any major benefit on outcome in large randomized human trials, even though significant improvements of oxygenation have been observed with some of these agents.

Nitric oxide (NO) is important for the regulation of pulmonary vascular smooth muscle tone. NO appears to be pivotal in acute and chronic hypoxic pulmonary vasoconstriction. Pulmonary hypertension is a typical feature of ARDS and is a bad prognostic factor in respiratory failure. Inhaled NO selectively dilates pulmonary vasculature without systemic effects. Over the past two decades, an increasing number of clinical studies have been published assessing different aspects of inhaled NO in patients with ARDS and addressing the ability of NO to attenuate ALI. Despite the fact that many clinicians consider inhaled NO to be a useful rescue treatment for patients with ARDS, no randomized controlled trial has demonstrated an outcome benefit. A systematic review and metaanalysis of 12 randomized controlled trials including a total of 1237 patients with severe ALI or ARDS found that overall, NO is associated with limited improvement in oxygenation at 24 hours of therapy, has no effect on duration of ventilation, does not confer mortality benefits, and may cause harm.

IMPLICATIONS OF RESCUE THERAPIES FOR CLINICAL PRACTICE

Use of rescue therapies carries a number of implications for clinical practice. First, not enough evidence from well-performed randomized controlled trials has been accumulated to support routine use of ECMO for rescue therapy in adults with severe ARDS. Second, no specific ventilatory mode (including high-frequency oscillatory ventilation) has been proved to be superior to limiting end-inspiratory plateau pressures and tidal volumes and appropriately setting PEEP. Third, although altering body position is part of routine clinical care in most patients with respiratory failure, evidence to support the routine use of prone positioning is lacking. However, prone ventilation seems to reduce mortality in patients with severe acute hypoxemic respiratory failure. Fourth, none of the pharmacologic therapies evaluated in patients with ALI or ARDS, including inhaled vasodilators, have been shown to reduce morbidity or mortality when compared with placebo or conventional treatment. The good news is that none of these therapies that improve oxygenation significantly increase morbidity or mortality. Accordingly, when conventional therapy fails, all such interventions may be tried. Nevertheless, clinicians should consider that the only thing these therapies may accomplish is increasing cost.

SUPPORTIVE TREATMENT

SEDATION

Patients with ARDS who are being ventilated with low tidal volumes should be managed with the same sedation strategies recommended for all critically ill mechanically ventilated patients. Specifically, sedation protocols using standardized sedation scales and sedation goals have been proved to reduce the duration of mechanical ventilation. Preference should be given to the daily interruption of sedation and the use of intermittent boluses, rather than continuous infusions, when tolerated.

MUSCLE PARALYSIS

Neuromuscular blocking agents have commonly been used in clinical practice for patients with marked ventilator asynchrony and in a large but highly variable proportion of patients with ARDS. Current guidelines indicate that neuromuscular blocking agents are appropriate for facilitating mechanical ventilation when sedation alone is inadequate, most notably in patients with severe gas exchange impairment. The mechanisms by which these agents may benefit patients with ARDS are not completely understood but presumably involve improvement in patient-ventilator synchrony and limiting of excessive airway pressures. Prevention of barotrauma is another mechanism by which neuromuscular blockade may improve outcome.

Previous publications suggesting that the use of neuromuscular blockade agents may lead to increased incidence of ICU-acquired weakness or other complications raised concerns about long-term side effects with routine use of paralytic agents for ARDS. However, the latest information on the use of neuromuscular blockade in the treatment of patients with severe ARDS showed promising results. In a multicenter, double-blind trial conducted in France, 340 patients with severe ARDS within the previous 48 hours were randomly assigned to receive, for 48 hours, either the neuromuscular blocking agent cisatracurium besylate (178 patients) or placebo (162 patients). Severe ARDS was defined as a PaO_2/FIO_2 ratio less than 150 mm Hg, with a PEEP of 5 cm H_2O or less and a tidal volume of 6 to 8 mL/kg of predicted body weight. The primary outcome was death either before hospital discharge or within 90 days after study enrollment, as reflected in the 90-day in-hospital mortality rate. The hazard ratio for death at 90 days in the cisatracurium group, as compared with the placebo group, was 0.68 ($P = .04$) after adjustment for both the baseline PaO_2/FIO_2 and plateau pressure. The crude 90-day mortality rate was 31.6% in the cisatracurium group and 40.7% in the placebo group ($P = .08$); the mortality rate at 28 days was 23.7% with cisatracurium and 33.3% with placebo ($P = .05$). In addition, treatment with the neuromuscular blocking agent cisatracurium for 48 hours early in the course of severe ARDS increased the numbers of ventilator-free days and days outside the ICU, and decreased the incidence of barotrauma during the first 90 days. The rates of ICU-acquired neuromuscular weakness did not differ significantly between the two groups. Additional work is needed to determine whether the use of neuromuscular blocking agents for only 48 hours is beneficial in selected patients. The beneficial effect of the neuromuscular blocking agent on survival was confined to the two thirds of patients with a PaO_2/FIO_2 ratio below 120 mm Hg.

FLUID MANAGEMENT IN ACUTE RESPIRATORY DISTRESS SYNDROME

Until recently, the optimal strategy for fluid management in patients with ARDS was unclear. Animal and human data suggest that when lung capillary permeability increases, lung water accumulates to a greater degree than usual at lower pulmonary artery occlusion pressures. Human trials show improved physiologic end points with various diuretic approaches to reduce lung water, including diuresis without vascular pressure measurements, intravascular pressure–targeted diuresis, and diuresis guided by direct measurements of lung water. Abundant data suggest that prompt resuscitation of hemodynamically unstable patients improves outcome, whereas the same resuscitative efforts given later may not be helpful and may potentially be harmful.

The ARDSNet published in 2006 the results of a large randomized trial comparing two fluid management strategies in 1000 patients with ALI or ARDS. Subjects were randomized to management with either a conservative (−136 ± 491 mL) or a liberal (6992 ± 502 mL) approach. In other words, the conservative fluid management group had a net fluid balance of about zero over the first 7 days of the protocol, whereas the liberal fluid management group had an average daily fluid gain of approximately 1 L. Fluid and diuretic management was dictated by a highly protocolized regimen, and all patients received respiratory support using a low-tidal-volume, plateau pressure–limited ventilation strategy. Although no significant difference was noted in the primary outcome of 60-day mortality, the conservative approach improved lung function and shortened the duration of mechanical ventilation and ICU stay without increasing the rate of nonpulmonary organ failure. These data provide reassurance and support for the use of a conservative fluid management strategy in patients with ARDS.

CORTICOSTEROIDS

Corticosteroids would seem to be an ideal therapy for ALI, in view of their potent antiinflammatory and antifibrotic properties. Several clinical trials have evaluated the utility of corticosteroids in preventing ARDS and in treating either early-stage (inflammatory) or late-stage (fibrotic) ARDS. None of them have demonstrated a mortality benefit. Despite failed studies of prevention or early treatment, great interest remains in the use of corticosteroids for so-called salvage therapy in patients with persistent ALI. The ARDSNet performed the largest randomized, blinded trial of methylprednisolone versus placebo in patients with ARDS of at least 7 days' duration. No survival benefit was noted in the steroid group (29.2% versus 28.6%); however, methylprednisolone increased the number of ventilator-free days, shock-free days, and ICU-free days during the first month. Also, it was associated with a significant increase in 60-day and 180-day mortality rates among patients enrolled after 13 days from onset of ARDS. This study argues against the use of corticosteroids to treat patients with ARDS. However, a metaanalysis of selected trials showed that prolonged administration of systemic steroids is associated with favorable outcomes and a survival benefit when given before day 14 after onset of ARDS. The latter finding prevailed when data for subgroups from the ARDSNet were reanalyzed according to time of treatment initiation. Nevertheless, the questionable benefit of steroids in patients with ARDS should not preclude the use of a low-dose regimen in acutely ill patients with sepsis, including those with ARDS.

PROGNOSIS AND LONG-TERM SURVIVAL

Prognosis with ARDS depends primarily on the underlying cause of lung injury. In an analysis of the ARDSNet database, survival to home discharge was lowest in patients with sepsis, intermediate in patients with pneumonia, and highest in patients with trauma and ARDS.

Very few studies have evaluated the long-term outcome of patients with ARDS. Patients who are treated for this condition often face long-term physical and psychological complications that result from their prolonged hospitalization. Studies have considered long-term outcomes in patients with ARDS in terms of respiratory function, exercise tolerance, loss of muscle mass, and cognitive effects. In 2001, a 1-year follow-up study of patients with ARDS in the United States found that a significant percentage of deaths occurred between day 28 and 4 months, which raised the potential for longer monitoring in the evaluation of new interventions or therapies. One-year predictors of death were advanced age and the premorbid functional status. Anxiety, depression, and posttraumatic stress disorder were frequent in that study.

Patients with ARDS lose a significant amount of body weight during their hospital stay. Most patients gradually recover this weight but still remain below admission weight after 12 months. In addition, most patients complain of proximal muscle weakness, with a decrease in distance covered on the 6-minute walk test. A long-term prospective study from Canada found that patients exhibited impairment on pulmonary function testing, seen as a mild restrictive pattern, with subsequent clinical improvement over the course of a year to near-normal levels. No patients required oxygen at rest after 12 months, and only 6% of patients required oxygen with ambulation. Similarly, marked impairment in exercise tolerance is typical; with the reestablishment of muscle mass, however, this impairment levels off by the end of 1 year, but no significant gains were made in the second year. Radiographic abnormalities were present in 80% of cases at 12 months. Of note, half of all patients who contracted ARDS had returned to work by 1 year, with most returning to their original employment position.

On the basis of this cumulative evidence, a patient surviving hospitalization for ARDS can be expected to return to a similar lifestyle over the course of a year, with some lingering physical and psychological challenges. Therefore, in the absence of significant comorbid conditions, the long-term outcome data are sufficient to warrant aggressive treatment for ARDS.

CONTROVERSIES AND PITFALLS

In patients with acute coronary syndromes, the working diagnosis is based on the presence of acute chest pain that is accompanied by abnormalities on the electrocardiogram (ECG) and the biomarker troponin. Troponin is the biomarker for detection of heart injury, and troponin levels serve as the basis for risk stratification and therapeutic interventions in patients with coronary artery disease. By contrast, pathognomonic laboratory or clinical features are lacking in patients with ARDS. There are no data that link a particular PaO_2/FIO_2 ratio to predictable structural changes in the alveolar-capillary membrane, probably because ARDS represents a common pathway of diverse events and disease entities. Also, current guidelines for ARDS management do not follow a strict stratification, as used in patients with coronary artery diseases. Stratification of respiratory and ventilatory variables at the onset of ARDS could be a useful strategy for identifying and selecting patients for clinical trials with various levels of mortality risk. Using demographic, pulmonary, and ventilatory data collected at ARDS onset, a simple prediction model based on a stratification of variables into low, intermediate, and high categories of risk assists in predicting patient outcome. Tertile distribution for age, plateau airway pressure, and PaO_2/FIO_2 ratio at ARDS onset is able to identify subgroups with markedly different mortality rates.

Lack of specific knowledge of the molecular mechanisms responsible for ARDS represents the most important obstacle to the successful diagnosis and treatment of affected patients. In comparing the management of acute chest pain with ARDS, the former is based on an emergency medical model of awareness of a life-threatening condition and the importance of adherence to predefined decision algorithms. No comparable awareness and emergency decision algorithms are available for the care of patients with ARDS. It is plausible that a new definition based on specific biochemical criteria of lung

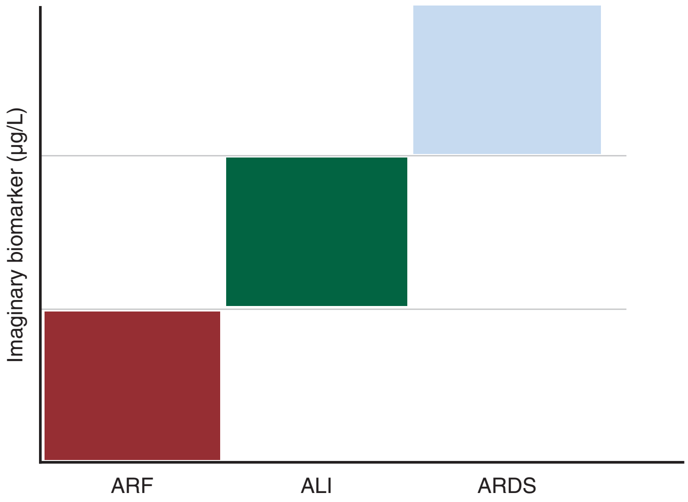


Figure 36-6 Use of a hypothetical biomarker for the diagnosis of ARDS. *ALI*, acute lung injury; *ARDS*, acute respiratory distress syndrome; *ARF*, acute respiratory failure.

inflammation, rather than on clinical parameters, is likely to provide clinicians with a better stratification and identification of a more homogeneous population of patients with ALI and ARDS. Thus, stratification of patients with ARDS should be linked to two measures of severity: one that specifically quantifies the severity of ALI and ARDS and another that quantifies the overall physiologic response along with comorbidity and premorbid health. Adding objective measures, such as levels of biologic markers, could facilitate recognition of ALI and ARDS.

The use of simple thresholds for the diagnosis of disease processes of increasing prevalence in the general population is common. This is the case with the use of blood sugar for diabetes and hemoglobin for anemia. It appears improbable that in the case of ARDS, a biomarker alone will resolve this issue. Instead, a clinical prediction model or a combination of such a predictor model with a biomarker would provide a better definition of ALI and ARDS (Figure 36-6). Ideally, such a biomarker should be (1) 100% sensitive, (2) 100% specific, (3) easy to measure in blood, exhaled air, or any other biologic sample, (4) affected by treatment, and (5) cost-effective. There have been recent efforts to identify biologic markers in pulmonary edema fluid and in blood collected from patients with and without ARDS. It has been postulated that owing to increased permeability of the alveolar-capillary barrier, proteins leak into the circulation. Patients at risk for ARDS who have higher levels of interleukin-8 in bronchoalveolar lavage fluid subsequently progress to ARDS. Serial LBP measurements may offer a clinically useful biomarker for identification of patients likely to experience the worst outcomes and with the highest probability for development of sepsis-induced ARDS. A combination of biologic markers that reflect endothelial and epithelial pulmonary injury, inflammation, and coagulation will be superior to clinical predictors or biomarkers alone for predicting mortality or stratifying patients with ALI or ARDS. Finally, serial elevation of plasma levels of functionally relevant cell proteins (above a critical threshold) could be used for the differential diagnosis for ALI and ARDS. The measure of those biomarkers may inform clinicians of the development of ALI or ARDS.

An interesting direction for research would be identification of reliable biomarkers that are specific for the noninfectious, septic-like syndrome of VILI. It is hoped that the rapidly evolving sciences of genomics, proteomics, and computational biology can be used to model VILI and to tailor mechanical ventilation strategies to create an ideal inflammatory environment for minimal injury, tissue repair, cell regeneration, and organ function. Such a strategy would not only mitigate VILI but also decrease the incidence of other ventilator-induced complications.

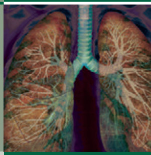
AIRWAY DISEASES



Chapter 37

Upper Airway Disease: Rhinitis and Rhinosinusitis

Glenis K. Scadding • Harsha H. Kariyawasam

UPPER AIRWAY

The upper airway is a continuous structure that extends from the nasal vestibule to the alveolar units of the lung. Although the airway traditionally has been divided into upper and lower segments by an arbitrary line drawn at the level of the vocal cords, airway disease does not restrict itself to such specific anatomic regions. In fact, upper and lower airway disease frequently coexist, and upper airway manifestations of disease often can precede lower airway involvement. Such recognition has led to the sobriquet "the United Airway," with an emphasis on approaching patients with disease from a combined perspective on both the upper and lower airways.

RHINITIS

Rhinitis is defined as the presence of two or more symptoms of nasal discharge (anterior or posterior), blockage with sneeze, or itch for more than 1 hour on most days. It is an umbrella term that encompasses multiple diseases with distinct immunopathogenic mechanisms and correspondingly specific diagnostic and treatment strategies (**Figure 37-1**). Although rhinitis is subdivided into two broad categories of allergen-induced rhinitis and nonallergic rhinitis, disease overlap is common. Thus, a careful history and directed investigations are required to establish the exact diagnosis. In practice, inflammatory changes usually are continuous from nasal to sinus mucosa (see Figure 37-1); therefore, the designation *rhinosinusitis* is more accurate, although its use may lead to clinical confusion with the separate group of diseases that are historically classified under *sinusitis*. Apart from viral colds, allergic rhinitis (AR) is the most common cause of nasal symptoms.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOPHYSIOLOGY

Allergic Rhinitis

Up to 30% of adults and 40% of children are affected, and worldwide the prevalence of AR continues to increase (**Figure 37-2**). The condition has marked effects on quality of life and is responsible for reduced school and workplace attendance (by 3% to 4%) and performance (by 30% to 40%). The resulting economic burden is high, and rhinitis and related AR are common. It is estimated that nearly 500 million people worldwide have AR, and it is one of the most common reasons for attendance with a primary care practitioner.

The predisposition to develop AR is both genetic and environmental. Identical monozygotic twins demonstrate a 40% to 50% concordance rate, whereas dizygotic twins have a 25% concordance rate. Thus, persons with an affected parent or sibling are at increased risk but as-yet undefined environmental factors must interact with genetic predisposition for disease occurrence. Western lifestyle seems to be associated with an increased prevalence of allergic disorders in general, including asthma and eczema. Studies to identify the exact genes involved are still limited in AR, and the findings have been difficult to interpret because of lack of replication in separate population cohorts. As in asthma, multiple genes are involved, many of which code for epithelial molecules concerned with innate immunity, suggesting that an impaired mucosal barrier is relevant to development of AR, as is now confirmed in eczema.

The key immunologic event that initiates AR is binding of allergen to specific IgE on mast cells found in the nasal mucosa. Cross-linking of two or more high-affinity IgE molecules in response to allergen binding leads to mast cell activation and degranulation with release of mediators, initiating an immune cascade (**Figure 37-3**). This is termed the immediate response. With the release of histamine, leukotrienes, prostaglandins, bradykinin, and other mediators (platelet-activating factor, substance P, tachykinins) comes the immediate onset of symptoms of sneezing, itching, and "running," typically seen in instances of intermittent allergen contact—for example, with hay fever. An additional immunologic event in up to 70% of affected persons is a further influx of inflammatory cells consisting predominantly of eosinophils, basophils, and T cells expressing T_H2 cytokines such as interleukin (IL)-4 (B cell IgE class switching) and IL-13 (mucus hypersecretion). Clinically this process is characterized by further obstruction, decreased olfaction, and mucosal irritability with immunopathologic changes similar to those seen in chronic asthma (see Figure 37-3). Local mucosal allergen–specific IgE production by nasal B cells is now confirmed and leads to local (skin prick test–negative) rhinitis. Emerging evidence also indicates that activated nasal epithelium–derived cytokines such as thymic stromal lymphopoietin (TSLP), IL-25 (i.e., IL-17E), and IL-33 can further promote disease through initiation, enhancement, and maintenance of T_H2 inflammation at the mucosal surface where allergen deposition and sampling occur. In addition, the potential for innate mucosal immune mechanisms such as Toll-like receptor (TLR) signaling system to drive or skew T_H2 responses is increasingly recognized.

Common aeroallergens that can initiate AR include plant pollen, house dust mite, fungal spores, cockroach aeroallergens, and dander from domestic pets. AR was formerly categorized as seasonal, perennial, and occupational; however, the World Health Organization (WHO) Allergic Rhinitis and Impact in Asthma (ARIA) guidelines suggest that intermittent and persistent rhinitis are better subdivisions, because they are globally applicable, even in geographic regions that lack specific seasons.

In the United Kingdom and other North European countries, symptoms in the spring are frequently caused by allergy to tree pollens. The peak period for tree pollens ranges from mid-February for alder to early April. Silver birch, oak, ash, elm, willow, and poplar release pollen from late March or early April to the middle of May. Pine trees pollinate from late April to early July. In late spring and early summer—the classic hay fever season—AR results from allergy to grasses such as rye, timothy, and cocksfoot. In late summer, weed pollens, such as nettle and mugwort, are responsible, whereas in autumn, the fungi *Cladosporium* spp., *Alternaria* spp., and *Aspergillus* spp. provoke symptoms. In the United States, ragweed pollen allergy is a common cause of rhinitic symptoms, usually from mid-August to mid-September. Grass pollen is the most common seasonal allergen in the United Kingdom, and symptoms correlate with the presence of high airborne pollen counts.

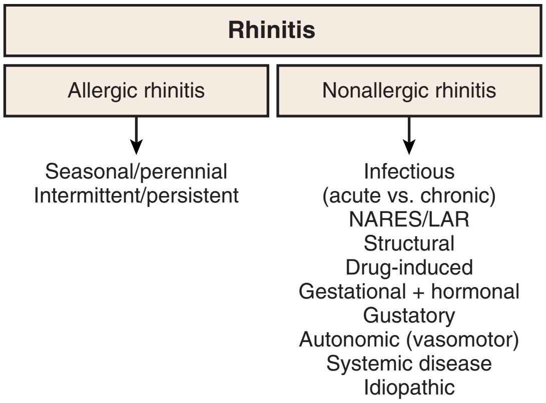


Figure 37-1 Classification of rhinitis. *NARES/LAR*, nonallergic rhinitis with eosinophilia syndrome/local allergic rhinitis.

Perennial rhinitis—in which symptoms occur throughout the year—in the United Kingdom most commonly is caused by allergy to the fecal pellets of the house dust mite (*Dermatophagoides pteronyssinus*), which flourishes in warm, humid environments and lives in bedding and soft furnishings. The major house dust mite allergen *Der p 2* is now recognized as demonstrating molecular mimicry to the mammalian lipid-binding protein (LBP) MD-2. This feature allows *Der p 2* to bind bacterial lipopolysaccharide (LPS) airway TLR-4 signaling complex, which is highly expressed on epithelium, and facilitates TLR signaling. Such signaling is important for the development of allergen-driven $\text{T}_{\text{H}}2$ signaling pathways. Allergy to dander from domestic pets (such as cats, dogs, rabbits, and hamsters) can account for perennial rhinitis, whereas allergens encountered in the workplace are responsible for occupational rhinitis. Examples are sensitization to latex, flour, and grain (bakers); allergies to small mammals among laboratory workers; and allergy to wood dust, biologic products (such as antibiotic powder and enzyme-enhanced detergents), and rosin (colophony) from solder flux.

Constant or very-high-level allergen contact produces chronic obstructive symptoms, with reduced olfaction and nasal hyperreactivity, the allergic nature of which may not be recognized, because hyperreactivity to nonspecific irritants, such as inhaled fumes, dusts, and cold air, may lead to an erroneous diagnosis of "vasomotor" rhinitis. True food allergy is rarely the cause of isolated rhinitis but may be relevant in small children with multisystem allergy.

Infectious Rhinitis

The nasal and sinus mucosa can be infected by all types of organisms: viruses, bacteria, fungi, and protozoa. Of such infections, viral infections are the most frequent.

Figure 37-3 Immunopathogenesis of allergic rhinitis. 1, Allergen impaction on the mucosal surface leads to its solubilization and diffusion to sites of mast cell (MC) residence, where cross-linking of two or more high-affinity (FcεRI) IgE receptors lead to MC activation and subsequent degranulation and release of mediators, such as histamine and leukotrienes, that initiate the immediate rhinitis symptoms (acute inflammation). Dendritic cells (DC) also take up allergen and present processed allergen peptide in the context of MHC class II to naive T cells, which then undergo activation, leading (*2*) to the release of T_H2 cytokines. IL-5 in particular is essential for the maturation, release, and trafficking of eosinophils from the bone marrow. *3*, Intense cellular infiltration characterizes the late nasal response, which leads to (*4*) chronic inflammation of the epithelium and submucosa with structural cell activation, edema, and neural hyperreactivity. TLR signaling and epithelial activation, along with TSLP, IL-17, and IL-33 signaling, will further promote T_H2 signaling. The Common Cold (Acute Coryza)

Most people have approximately three colds per year, but small children have from six to eight. Humans spend 2 years of their lives with colds, of which 50% result from rhinoviruses, a further 20% from coronaviruses, and a further 20% from influenza virus, parainfluenza virus, adenoviruses, and respiratory syncytial virus; the remainder are caused by other viruses, including enteroviruses. Viral invasion occurs at the point of infection, usually in the posterior nasopharynx, and results in transient vasoconstriction of the mucous membrane, followed by vasodilatation and edema with mucus production. A leukocytic inflammatory infiltrate develops, followed by desquamation of mucous epithelial cells. Initially, a clear watery secretion is produced, but this is followed by epithelial desquamation with opacification of secretions—not necessarily an indication of bacterial infection, which complicates only approximately 2% of colds. Resolution occurs in a few days in uncomplicated viral infections; however, compared with nonatopic persons, allergic patients have more colds of greater severity. With rhinovirus infections in asthmatic children exposed to allergens to which they are sensitized, the odds ratio for hospitalization with asthma approaches 20.

Nonallergic Rhinitis

Nonallergic, Noninfectious Rhinitis

By definition, patients with nonallergic rhinitis (NAR) are skin prick–negative for common aeroallergens. NAR occurs in around 25% of persons with rhinitis symptoms. However, mixed rhinitis (a combination of allergic and nonallergic forms) can occur in up to 44% to 87% of patients. NAR incidence is higher in women. The nonallergic form of rhinitis incorporates a very heterogeneous group of conditions, and it is possible to further subclassify NAR into etiologic subtypes: a group for which the etiology is known and one for which it cannot be established, termed idiopathic rhinitis. The latter type is a diagnosis of exclusion, and approximately 60% of NAR cases will

fall into this category. A summary of considerations in the differential diagnosis for NAR is presented in Box 37-1. An essential division is between NAR with eosinophilic inflammation in the upper airway and that without.

Nonallergic Rhinitis with Eosinophilia Syndrome

Nonallergic rhinitis with eosinophilia syndrome (NARES) was described in 1981. The presence of eosinophils in nasal smears (more than 5% to 25%, according to different authorities) characterizes NARES, which probably is the counterpart of intrinsic asthma and may precede nasal polyposis and aspirin sensitivity. It typically is rapidly responsive to topical nasal corticosteroids. Recent progress in identifying local airway mucosal production of allergen-specific IgE has implications for future disease classification, and an entity termed *local allergic rhinitis* (LAR) has been described recently. What overlap NARES will have with LAR is not yet defined, but it is likely that with further investigation of these two NAR subtypes, common disease mechanisms will be found and the classification terminology will change further.

Aspirin hypersensitivity, or aspirin-exacerbated respiratory disease (AERD), develops usually in adult life in patients with rhinitis (often NARES), with subsequent development of nasal polyps and asthma. Mast cell and eosinophil degranulation are seen in biopsy specimens, and polyclonal local IgE production stimulated by superantigens from staphylococci has been described. Cyclooxygenase-1 (COX-1) inhibition by aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs) promotes leukotriene production, while inhibiting that of prostaglandins, including PGE_2, a bronchodilator. Leukotrienes cause bronchoconstriction, mucosal swelling, and excess mucus production, and sensitivity to their effects is high in aspirin sensitivity, probably because of increased numbers of specific receptors. The clinical picture often is one of aggressive eosinophilic polyposis, severe asthma with life-threatening reactions to aspirin and other NSAIDs, and frequent need for oral corticosteroids. A subgroup reacts also to “E number” foods (i.e., additives and preservatives, such as sulfites in wine), as well as high-salicylate foods such as some herbs, spices, dried fruit, and jams.

Nonallergic Rhinitis Without Eosinophilia

Autonomic Rhinitis The nasal mucosa receives a rich efferent innervation from both the parasympathetic and sympathetic nervous system. Nasal glandular secretion is largely mediated by the parasympathetic fibers, the main postganglionic neurotransmitter being acetylcholine (ACh) acting through muscarinic receptors (predominantly the M_3 subtype). The sympathetic fibers mediate vascular tone and can regulate nasal airflow by potent effects on venous erectile tissue. The primary neurotransmitter is norepinephrine (noradrenaline). In autonomic rhinitis, there is no evidence of nasal inflammation, but of autonomic dysfunction or imbalance. Nasal and, in some patients, cardiovascular reflexes are abnormal, and there may be association with the chronic fatigue syndrome. Topical ipratropium is useful in decreasing watery rhinorrhea; capsaicin applications also may relieve symptoms for several months after a few weeks of treatment. Epinephrine (adrenaline) and other sympathomimetics lead to vasoconstriction of the nasal mucosa, with increased nasal patency. Both α- and β-adrenergic blockers increase nasal resistance and can produce symptoms of nasal stuffiness (Box 37-2). Stimulation of the parasympathetic system leads to an increase in nasal secretions. However, patients who have this condition also have increased responsiveness to both histamine and methacholine, which results in nasal blockage and rhinorrhea. It also is associated with hypertrophy of the inferior turbinates, and nasal polyps are sometimes present. Certain stimuli such as cold air, exercise, mechanical or thermal factors, and humidity changes result in rhinorrhea and other symptoms of rhinitis, and a period of nasal

hyperresponsiveness often follows viral infection. This observation is consistent with general neuronal dysregulation leading to excessive and troublesome neural hyperreactivity and imbalance with certain environmental exposures.

Drug-Induced Rhinitis

The main drugs implicated in pharmacologic rhinitis are listed in Box 37-2. This entity is mostly noninflammatory—for example, antihypertensives, particularly beta blockers, can cause nasal obstruction by abrogation of the normal sympathetic tone, which maintains nasal patency. Exogenous estrogens in oral contraceptives or hormone replacement therapy also evoke rhinitis in some patients. Overuse of α-agonists results in rhinitis medicamentosa: a tachyphylaxis of α-receptors to extrinsic and intrinsic stimuli. The mucosa becomes swollen and reddened. Aspirin hypersensitivity is an inflammatory form of drug-induced rhinitis (see earlier).

Hormonal Rhinitis

Hormonal rhinitis is seen in pregnancy, occasionally in relation to menstruation, and at puberty. Rhinitis is more common in the later stages of pregnancy and may be more frequent in women who smoke. The exact pathogenesis is unknown, but the effects of estrogens on nasal mucosal homeostasis in relation to vascular tone and glandular secretion are relevant, with the potential for effects on nasal tissue remodeling as well. The symptoms disappear soon after the affected woman gives birth. Chronic nasal obstruction is associated with hypothyroidism and acromegaly.

Food-Induced Rhinitis

Gustatory Rhinitis

Rapid induction of nasal hypersecretion in relation to consumption of food, particularly spicy food, is termed gustatory rhinitis. Although the exact mechanism is uncertain, the stimulation of afferent neural fibers—for example, by capsaicin—leads to excessive efferent activation of parasympathetic nasal neural pathways. Thus, intranasal blockade of acetylcholine with an ipratropium spray before eating often is effective.

Food Allergen-Induced Rhinitis

Much rarer than is popularly supposed, food allergy rarely causes isolated rhinitis. In early infancy, milk or egg allergy can cause rhinitis as part of a spectrum that can include atopic dermatitis, gut symptoms, asthma, and failure to thrive. AR is sometimes accompanied by the oral allergy syndrome, in which sensitization to pollen results in oral reactivity to the same components in fresh fruit and vegetables. In Northern Europe, the reactions usually are mild, typically consisting of itching of the lips, mouth, and throat on consumption of the offending food; cooked food is tolerated without reaction, because the major allergen involved is heat-labile profilin. Southern Europeans, however, in whom the immune system recognizes lipid transfer proteins, can experience more severe reactions, including anaphylaxis. Allergy to food may be confused with food intolerance (in which IgE-mediated mechanisms are not involved). Some foods are rich in histamines (e.g., cheese, some fish, some wines) that may result in flushing, headache, and rhinitis and the same may occur with tyramine-rich foods (e.g., bananas). Food additives and coloring agents (such as sulfites, benzoates, and tartrazine) also may provoke reactions, especially in aspirin-sensitive subjects. Finally, alcohol or spicy, hot food containing capsaicin may irritate C fibers, thereby nonspecifically provoking rhinitic symptoms.

Atrophic Rhinitis

Atrophic rhinitis is characterized by atrophy of mucosa plus the bone beneath. The nose is widely patent, but crusting and an unpleasant odor are characteristic. *Klebsiella ozaenae* has been found in many patients, and cure with long courses of ciprofloxacin has been reported. Uncertain, however, is whether this condition is primarily infective. It may follow extensive surgery, radiation therapy, chronic granulomatous disease, or trauma. Possibly the primary problem is failure of normal mucociliary clearance mechanisms.

Granulomas/Vasculitis

A number of granulomatous diseases may involve the nose and sinuses as part of the generalized disease, and nasal symptoms may be the first manifestation. These include Wegener granulomatosis, Churg-Strauss syndrome, and sarcoidosis, particularly in persons of Afro-Caribbean ancestry. Mucous membrane infiltration and thickening with granulomas may be present and may involve the septum, inferior turbinates, and occasionally the sinuses. Nasal congestion is a prominent symptom, sometimes with epistaxis and marked crusting. Sufferers feel unwell, with fatigue and malaise. Infective granulomatous disease may involve the nose and sinuses; examples are tuberculosis, leprosy, syphilis, blastomycosis, histoplasmosis, and aspergillosis.

Occupational Rhinitis

Occupational rhinitis can be allergic or nonallergic, with the former nearly always preceding or developing concurrently with occupational asthma.

Idiopathic or Intrinsic Rhinitis

Idiopathic or intrinsic rhinitis is a diagnosis of exclusion, with no evidence for any of the aforementioned causes. Symptoms tend to be perennial, and local allergy has been suggested as a cause, on the basis of histologic findings of mast cells and eosinophils in resected turbinates and on positive responses to local nasal allergen challenge in a subgroup of patients. Direct release of mediators from mast cells or neurogenic mechanisms may be involved here. Finally, emotional factors may play a part, ranging from stress to sexual arousal that compounds nasal blockage and discharge to emphatic or consistent complaints of gross nasal symptoms, despite the absence of abnormal findings on examination. Such effects may be mediated through autonomic dysfunction. Gastroesophageal reflux extending above the vocal cords is thought to be a cause of rhinitis, especially in small children. Chronic exposure to dry air or occupational irritants—for example, those found in the shipbuilding industry—can lead to nasal mucosal changes, often with squamous cell abnormalities.

DIFFERENTIAL DIAGNOSIS FOR RHINITIS

A summary of considerations in the differential diagnosis for rhinitis is provided in Box 37-1. Neoplasms, foreign bodies, and trauma all can produce obstruction, pain, purulent discharge, and epistaxis. In adults, the possibility of neoplasm should always be considered in patients who have persistent symptoms, particularly if these are unilateral. In children, the presence of a foreign body should be considered if the nasal discharge is unilateral and foul-smelling. Local disease in the pharynx and larynx also may involve the nose and paranasal sinuses (e.g., enlarged adenoids), as may dental disease (e.g., maxillary dental root infection), which may spread to the maxillary sinus.

RHINOSINUSITIS

Evolutionary developments in humans have meant that the head is now held upright, so that sinuses, which reach down to the level of the top jaw, drain at the level of the nasal bridge, against gravity. This process is dependent on efficient mucociliary clearance and a patent ostiomeatal (sinus drainage point) complex and is easily compromised by mucosal swelling or mucociliary failure from any cause. The sinus drainage pathways are illustrated in Figure 37-4.

Rhinosinusitis, which means inflammation of the lining of the nose and sinuses, is another umbrella term that incorporates a large and heterogeneous group of upper airway disorders. It is a common condition, affecting up to 15% of the population in Western countries, and is associated with significant morbidity as well as substantial socioeconomic and health care costs.

The 2007 European position paper (EP$_3$OS-2007) defines rhinosinusitis as inflammation of the nose and paranasal sinuses characterized by two or more symptoms, one of which should be nasal obstruction (blockage, congestion) or nasal discharge (anterior or posterior), together with either facial pressure or pain or reduction in or loss of smell. Sinus and nasal examination accomplished by endonasal inspection or CT scanning is important to confirm the diagnosis. Sinusitis is subclassified as acute or chronic disease. *Chronicity* is arbitrarily defined by the persistence of symptoms beyond 12 weeks. Chronic rhinosinusitis (CRS) is further broadly subdivided into CRS without nasal polyps (CRSsNP) and with nasal polyps (CRSwNP).

Acute Rhinosinusitis

Acute rhinosinusitis (ARS) is common. It can be mild, moderate, or severe. Whereas a simple upper airway viral infection often will resolve after 5 days, with ARS the symptoms worsen by then or persist beyond 10 days. In the absence of confounding factors such as allergic inflammation or anatomic abnormalities, for example, full resolution is expected within a month.

Although the nose harbors bacteria, the sinuses normally are largely sterile, possibly because of the nitric oxide (NO) concentrations therein and continuous mucociliary clearance. ARS rarely occurs directly after trauma, dental infections, and diving into polluted water but usually arises from a bacterial infection secondary to the common cold. The mucous membranes of the nose and sinuses become swollen, which leads to blockage of the ostiomeatal complex and bacterial infection of the sinuses, particularly with *Haemophilus influenzae* and *Streptococcus pneumoniae,* with other causative bacteria identified as *Staphylococcus aureus, Moraxella catarrhalis, Streptococcus pyogenes,*

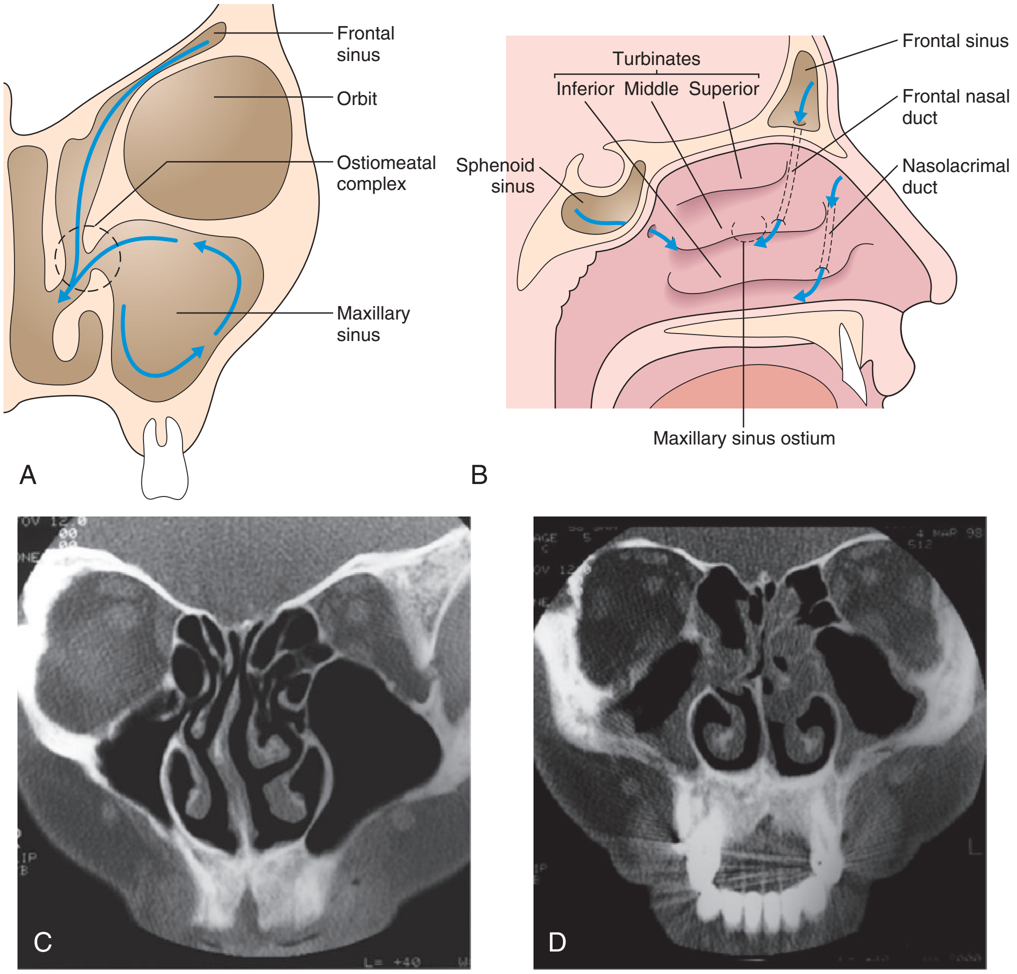

Figure 37-4 Sinus drainage pathways. **A** and **B,** In these diagrams, the ostiomeatal complex is seen to drain the frontal, anterior ethmoid, and maxillary sinuses. **A,** Coronal section. **B,** Lateral view. **C** and **D,** Computed tomography (CT) scans. **C,** On a coronal image, the paranasal sinuses are clear in a patient with a deviated nasal septum. **D,** On a lateral view, significant thickening of the mucosal lining is evident. CT changes do not correlate well with nasal symptoms but do relate to eosinophil counts in blood and sputum and to pulmonary function in accompanying asthma. *(**C** and **D,** Courtesy Ian Mackay.)*

and gram-negative bacteria such as *Klebsiella* and *Pseudomonas*. Anaerobic organisms also may be involved.

Chronic Rhinosinusitis

Failure to correctly subclassify the different subtypes of CRS has prevented confirmation of their exact incidence and prevalence, but CRS without nasal polyps (CRSsNP) accounts for a majority of cases seen.

Although CRS probably occurs after failure of resolution of ARS with the same bacterial pathogens involved, other factors often are present, such as eosinophilic inflammation (in both allergic and nonallergic forms of rhinosinusitis), immune deficiency (innate or adaptive), or structural abnormalities; the role of pathogens is disputed. One possibility is persistence of organisms as a biofilm that continually stimulates a damaging mucosal immune response.

Immune Defects

Panhypogammaglobulinemia is a severe condition with variable absence of all classes of immunoglobulin; it manifests with bacterial and other infections at many sites. Initial presentation may be to the otorhinolaryngologist with symptoms of recurrent acute or chronic rhinosinusitis. It is important to make the diagnosis early before irreversible damage occurs at other sites (the lungs) and so that appropriate immunoglobulin therapy can be instituted.

Total or relative *absence of IgA* may be present in the absence of any obvious clinical disease. However, IgA deficiency is now known to be associated in some patients with IgG2 subclass deficiency, and such persons may be more prone to episodes of sinusitis caused by encapsulated bacteria such as *H. influenzae* and *S. pneumoniae.*

Acute, chronic, and recurrent forms of sinusitis are common in persons with human immunodeficiency virus infection, the most common causative organisms being *S. pneumoniae* and *H. influenzae*. A tendency to chronicity and to relapse has been described, and in addition, fungal (*Cryptococcus* spp., *Alternaria* spp., and *Aspergillus* spp.) and viral (cytomegalovirus) sinusitis may occur.

Mucus Clearance Defects

The nose and paranasal sinuses are lined with ciliated epithelium, which in a coordinated fashion moves a mucus blanket toward the nasopharynx. This mucus is important for the entrapment and removal of particulate material and toxic substances, which include bacteria and allergens. The integrity of the mucociliary clearance pathway is vital to the appropriate drainage and ventilation of the paranasal sinuses and the nose (see Figure 37-4). Primary ciliary dyskinesia is inherited as an autosomal recessive trait and is characterized by the presence of sinusitis, bronchiectasis, situs inversus (Kartagener syndrome, present in 50% of these patients), and male infertility that results from dyskinetic sperm. Various ciliary structural defects have been described (e.g., absence of inner or outer dynein arms or both), but some cilia appear normal (Young syndrome). Recent work suggests that deficiency of inducible nitric oxide synthase (iNOS) may be the common underlying abnormality. Presentation is with chronic sinusitis, bronchiectasis or bronchitis, and obstructive azoospermia.

Secondary ciliary defects may arise after viral or bacterial infections. A number of mechanisms are involved:

- Mucous membranes become swollen and inflamed, which may result in blockage of the sinus ostia, thus preventing clearance (this is particularly critical at the ostiomeatal complex).
- If viruses or bacteria damage the epithelial cell layer, the integrity of cilial clearance is destroyed.
- Some bacteria produce toxins that inhibit cilial clearance mechanisms.
- Mucus during infection becomes thick and difficult to clear.

Chronic Rhinosinusitis With Nasal Polyps

Chronic rhinosinusitis with nasal polyps (CRSwNP) represents a more distinct immune phenotype with better characterization. Nasal polyps (**Figure 37-5**) result from prolapse of the mucous membranes lining the nose and on examination are seen as pale, grapelike swellings arising predominantly from the middle meatus. These lesions are insensitive to pain but cause blockage and hyposmia and often are associated with asthma and aspirin hypersensitivity. They also may be infection-related, being common in persons with cystic fibrosis. Classification of polyps is similar to that of rhinitis (**Box 37-3**).

Nasal polyposis demonstrates a strong heritable component, with a relative risk of 18 times the normal rate of 4% in the population and 6 times the normal rate with an affected father and mother, respectively. A strong association of AERD with CRSwNP is recognized. A number of genes have been found to be associated with AERD (e.g., leukotriene C4 synthase promoter region); these vary among different populations. HLA-DQB1 is associated with allergic fungal sinusitis. The genetics of cystic fibrosis are discussed in Chapter 46; heterozygotes for cystic fibrosis are overrepresented in the chronic rhinosinusitis population. Primary ciliary dyskinesia is also genetic, with an incidence of approximately 1 in 20,000. Various structural ciliary defects have been described, but one

common defect—a lack of iNOS in nasal mucosa—has recently been found.

CLINICAL FEATURES

Allergic Rhinitis

AR manifests in two major patterns: (1) watery discharge, sneezing, or itching and (2) nasal blockage. Affected persons have been called "runners" (or "sneezers" or "itchers") and "blockers," respectively.

Running/Sneezing/Itching

With the "running/sneezing/itching" pattern of AR, symptoms tend to be intermittent and changeable and often are closely related to allergen exposure during the day. Severity varies, with symptoms ranging from trivial to extremely disabling. In addition, itching and injection of the conjunctivae may occur, with watery discharge and conjunctival swelling, and itching in the mouth, oropharynx, and ears. This form of AR tends to be a disorder of children and young adults, and up to one third of patients have associated asthma.

Blockage

The nasal passages are chronically obstructed, with little in the way of immediate allergic symptoms. Other symptoms may include facial ache, headache, nasal hyperreactivity, and loss of sense of smell. Examination of the nose reveals pale or bluish mucosa, which is boggy and swollen, and a watery discharge may be present. Careful clinical inspection of the nose is important to exclude the concomitant presence of polyps, septal deviation, prominent turbinates, and evidence of other systemic disease and tumors.

Secondary symptoms may include disturbed sleep, pharyngitis, poor concentration, cough, and exacerbation of lower respiratory tract problems.

Considerable overlap between causes of rhinitis is not uncommon, adding to the usual rhinitic symptoms; for example, AR characterized by sneezing, itching, and watery discharge results in considerable mucosal swelling, which may result in reduced sinus drainage and contribute to development of secondary infection. Both allergic and infective forms of inflammatory rhinosinusitis may be exacerbated by the presence of anatomic and mechanical defects, such as a deviated nasal septum or enlarged turbinates. It also is important to consider the possibility of serious underlying conditions, early recognition of which may be necessary to prevent later damage (e.g., defects of immunity, impaired cilial motility, vasculitic and granulomatous disease).

Rhinosinusitis frequently is associated with lower respiratory disease; for example, approximately one third of patients who have bronchiectasis also have chronic sinusitis, and patients who have cystic fibrosis invariably have sinusitis and frequently have nasal polyps develop. Rhinitis is practically ubiquitous in asthmatic persons, with 10% of adults with late-onset asthma exhibiting aspirin hypersensitivity, often with nasal polyps (Samter's triad). Most asthma exacerbations begin with rhinitis, either infective or allergic, or both.

Nonallergic Rhinitis

Infection

Acute Coryza (The Common Cold) The prodrome of the common cold typically consists of a feeling of dryness, itching, and heat in the nose, which may last for a few hours and often is followed by a dry, sore throat; sneezing; watery nasal discharge; and constitutional symptoms of fever and malaise. This phase is followed in a day or so by symptoms of nasal obstruction and mucopurulent discharge, which along with the fever and malaise, may continue until resolution after 5 to 10 days. The initial symptoms of AR and coryza may be difficult to distinguish from each other.

NONINFECTIVE RHINITIS

Symptoms of noninfective rhinitis are similar to those of the blockage pattern of AR, as mentioned previously. Differentiation from AR depends on skin prick or other allergy testing.

Clinical Presentations That Warrant Physician Referral

Patients with unilateral symptoms, bloody discharge, polyps manifesting for the first time, or systemic illness should be seen by an otorhinolaryngologic surgeon. Orbital cellulitis and sinusitis with severe headache or vomiting warrant urgent referral.

Acute Rhinosinusitis

Acute maxillary rhinosinusitis is characterized by facial pain, localized to the cheek, but also present in the frontal area or around the teeth, that is made worse by stooping down or straining. The pain can be unilateral or bilateral, and tenderness may be elicited over the sinus. Acute frontoethmoidal sinusitis may cause pain around the eye and in the frontal region, with overlying tenderness and erythema of the skin. There is usually fever, and toxemia may occur. The differential diagnosis for facial pain is wide in scope and includes dental disease and the numerous causes of headache. Recently, all of the clinical signs and symptoms described here have been shown to be unreliable as diagnostic aids to identify acute sinusitis; instead, the combination of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) is the best guide.

Chronic Rhinosinusitis

CRS frequently is pain-free and manifests with a sensation of congestion, poor concentration, tiredness, and malaise. Other signs and symptoms of CRS include purulent nasal discharge (often postnasal), sore throat, and a productive cough, especially in children, in whom misdiagnosis of asthma is not uncommon. Loss of the sense of smell and halitosis are additional features.

DIAGNOSIS, EVALUATION, AND TESTS

EXAMINATION

It frequently is possible to arrive at a diagnosis of rhinitis and rhinosinusitis on the basis of a good detailed history. Physical examination should never be omitted, and it is vitally important that chronic symptoms be appropriately investigated. Observation of the patient's face may reveal an allergic crease or salute, deviation of the nose from midline, or more sinister collapse of the nasal bridge.

Anterior rhinoscopy performed with use of a bright light or head mirror along with a Thudicum speculum allows simple examination of the anterior nasal cavity. In addition, the mucous membrane can be viewed, and the presence of nasal polyps and disorders of the anterior part of the nasal septum can be ascertained.

Nasal endoscopy performed using either a rigid or a fiberoptic flexible endoscope allows more detailed examination and assessment. Congenital defects such as cleft palate and atresia, septal deviation and perforation, abnormalities of the turbinates, compromised state of the mucous membranes, presence of purulent secretions, polyps, neoplasms, and foreign bodies can be identified with this examination.

Coryza

Coryza normally is diagnosed on the basis of the patient's history, and further investigations are rarely required. Viral culture or immunofluorescent techniques can identify specific viruses.

Acute Rhinosinusitis

On examination, red, swollen nasal mucous membranes are present, and pus may be seen in the middle meatus. Endoscopy, together with imaging techniques, allows assessment of the severity and extent of involvement (diagnostic antral puncture and lavage are now rarely required). Middle meatal swabs provide material for bacteriologic culture. Immunoglobulin classes and subclasses are checked in cases of recurrent or chronic sinusitis.

IMAGING TECHNIQUES

Radiography is rarely needed for diagnosis, unless a tumor is suspected. A high incidence of imaging abnormalities in the general population has been recognized: One third of unselected adults and 45% of children will have such abnormalities. After a cold, computed tomography (CT) scans show changes for at least 6 weeks. The role of imaging is largely to provide a road map for the surgeon after failure of medical treatment.

Since the advent of CT, plain sinus radiographs now have only a very limited role in the diagnosis of acute rather than chronic sinusitis, because opacification or a fluid level may be seen in a sinus or gross soft tissue swelling may be evident. The imaging investigation of choice is CT, which is the best technique to demonstrate mucosal disease and underlying anatomic abnormalities (see Figure 37-4). The detailed anatomy of both bone and soft tissue is well delineated, and axial and coronal sections can be obtained. The coronal cuts provide views of the ostiomeatal complex, important for planning surgery for acute and chronic sinusitis (**Figure 37-6**). Preoperatively, coronal sections at 3 to 4 mm give maximal anatomic detail, whereas axial views provide vital information regarding the relation of the optic nerve to the posterior ethmoidal and sphenoid sinuses. Magnetic resonance imaging (MRI) is of very limited value, because bone is not well imaged. MRI is useful, however, in distinguishing one type of soft tissue from another and has the advantage of avoiding irradiation.

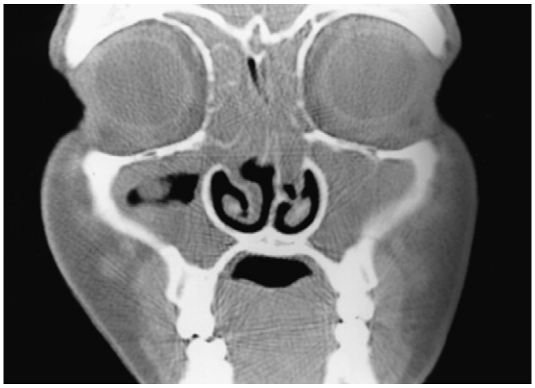

Figure 37-6 Computed tomography scan of paranasal sinuses. This coronal image shows almost complete opacification of maxillary and ethmoid sinuses with polyps that obstruct the ostiomeatal complex. *(Courtesy Ian Mackay.)*

MUCOCILIARY FUNCTION TESTING

For the simplest test, known as the saccharin clearance test, one quarter of a grain of saccharin is placed on the lateral nasal wall, 1 cm behind the anterior end of the inferior turbinate. A sweet taste is detected within 20 minutes if cilial function is normal—that is, the mucociliary mechanism is able to transport the particle to the nasopharynx and the pharynx, where taste is detected. If cilial function is abnormal, more sophisticated tests of cilial activity in cells detached by brushings taken from the turbinate can be undertaken with use of phase contrast microscopy. Significant abnormalities on this test constitute an indication for electron microscopic examination of cilia. Confirmation of reports of very low nasal NO in primary ciliary dyskinesia means that a nasal NO concentration of greater than 250 parts per billion (ppb) excludes this diagnosis with 95% sensitivity.

NASAL AIRWAY TESTS

Dynamic tests include nasal inspiratory peak flow measurement (for which the patient, wearing a mask attached to a peak flow meter, sniffs hard with a closed mouth) and rhinomanometry. The latter technique is used to assess nasal airway resistance by measuring airflow across a pressure gradient with use of a pneumotachograph and face mask. Acoustic rhinometry uses a sound pulse to measure the nasal cross-sectional area.

Nasal airway resistance can change very dramatically within a few minutes. Congestion is produced by engorgement of venous erectile tissue within the nose; the mucous membrane receives dense, autonomic innervation. Nasal resistance falls with administration of epinephrine and other sympathomimetic drugs but also with exercise, rebreathing, and adoption of the erect posture. Nasal resistance increases in rhinitis and, in some persons, with ingestion of alcohol, aspirin, and other drugs, as well as when the supine posture is adopted.

EVALUATION FOR SUSPECTED ALLERGIC RHINITIS

The diagnosis usually is obvious from a careful history and examination but can easily be missed in chronic blockers; thus, skin prick tests should be performed in all patients presenting to the rhinitis clinic. Skin tests that use allergen extracts to elicit IgE-mediated immediate hypersensitivity responses can be used to confirm or exclude atopy. If all of the skin test results are negative, the history may still suggest local nasal allergen-specific IgE driven disease. However, positive results on skin testing do not confirm the diagnosis, because many asymptomatic persons exhibit a positive response to common allergens. Correlation between skin prick tests and history should be sought, because occasionally it is possible to identify an allergen that can be avoided. Measurement of total IgE is not helpful; however, measurement of specific IgE levels to common aeroallergens by means of immunologic testing may be useful, and the results show a good correlation with skin test results. Occasionally, particularly where occupational rhinitis may be a possibility, nasal challenge and provocation tests (with the offending allergen, histamine, aspirin, or methacholine) may be required.

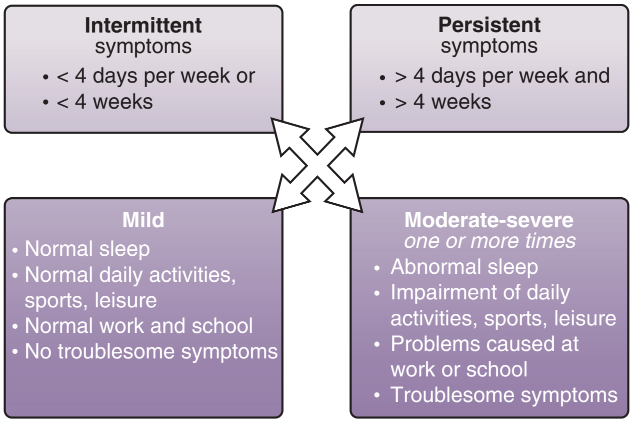

Figure 37-7 Classification of rhinitis by frequency and severity. *(From Bousquet J, Van Cauwenberge P, Khaltaev N, et al: Allergic rhinitis and its impact on asthma,* J Allergy Clin Immunol *108[suppl]:S147–S334, 2001.)*

NASAL CYTOLOGY

It may be of value to determine the presence or absence of eosinophils in patients who have perennial rhinitis and negative results on skin testing and who are not atopic. Subsets of these patients have nasal eosinophilia and are more likely to demonstrate allergic features such as sneezing and congestion; they are more likely to respond to topical corticosteroids.

TREATMENT

ALLERGIC RHINITIS

Treatment for AR has five major components:

- Allergen avoidance
- Pharmacotherapy
- Immunotherapy
- Surgery (rarely)
- Patient education (vital)

Identify and Avoid Allergens

In practice, the identification and avoidance of allergens may be extremely difficult. House dust mites are responsible for much perennial AR. Mites flourish at temperatures of approximately 15°C and 60% to 70% relative humidity, conditions present in many homes that contain central heating. They flourish particularly in soft furnishings, mattresses, pillows, and bed covers, as well as in carpets. Allergen avoidance and measures to reduce the load (i.e., wooden floors rather than carpets, regular vacuum cleaning, and barrier covers for mattresses and pillows) effectively reduce rhinitic symptoms. Acaricides that kill the mites do not eliminate the antigen, which is present in the fecal pellets. Removal of a pet may not abolish symptoms, because allergens may persist in rooms for many months, if not years. Avoidance of pollen is difficult, but vacationing away from pollen areas or, failing that, staying indoors when the pollen count is high, closing windows, shutting car windows, and avoiding open grassy spaces may help.

Medical Suppressive Therapy

The classification system and treatment plan for AR according to ARIA are shown in Figures 37-7 and 37-8, respectively. Intermittent rhinitis is defined as that accompanied by symptoms for fewer than 4 days per week or fewer than 4 weeks in total. Persistent symptoms are defined as those present for more than 4 days per week and lasting more than 4 weeks in total duration. Classification of disease severity as mild, moderate, or severe is based on effects on day-to-day well-being and ability to sleep or work. Thus, the diagnosis takes into account severity of disease in terms of effects on quality of life, as well as disease duration, which in turn guides pharmacotherapy and immunotherapy intervention. However, in view of the spectrum of respiratory diseases (i.e., NAR) that can manifest with rhinitis symptoms and the possible need for use of allergen-specific immunotherapy, the key concept of *seasonality* is very useful in the diagnostic algorithm and has been retained by several guidelines and standards of care documents such as that from the British Society for Allergy Clinical Immunology (BSACI).

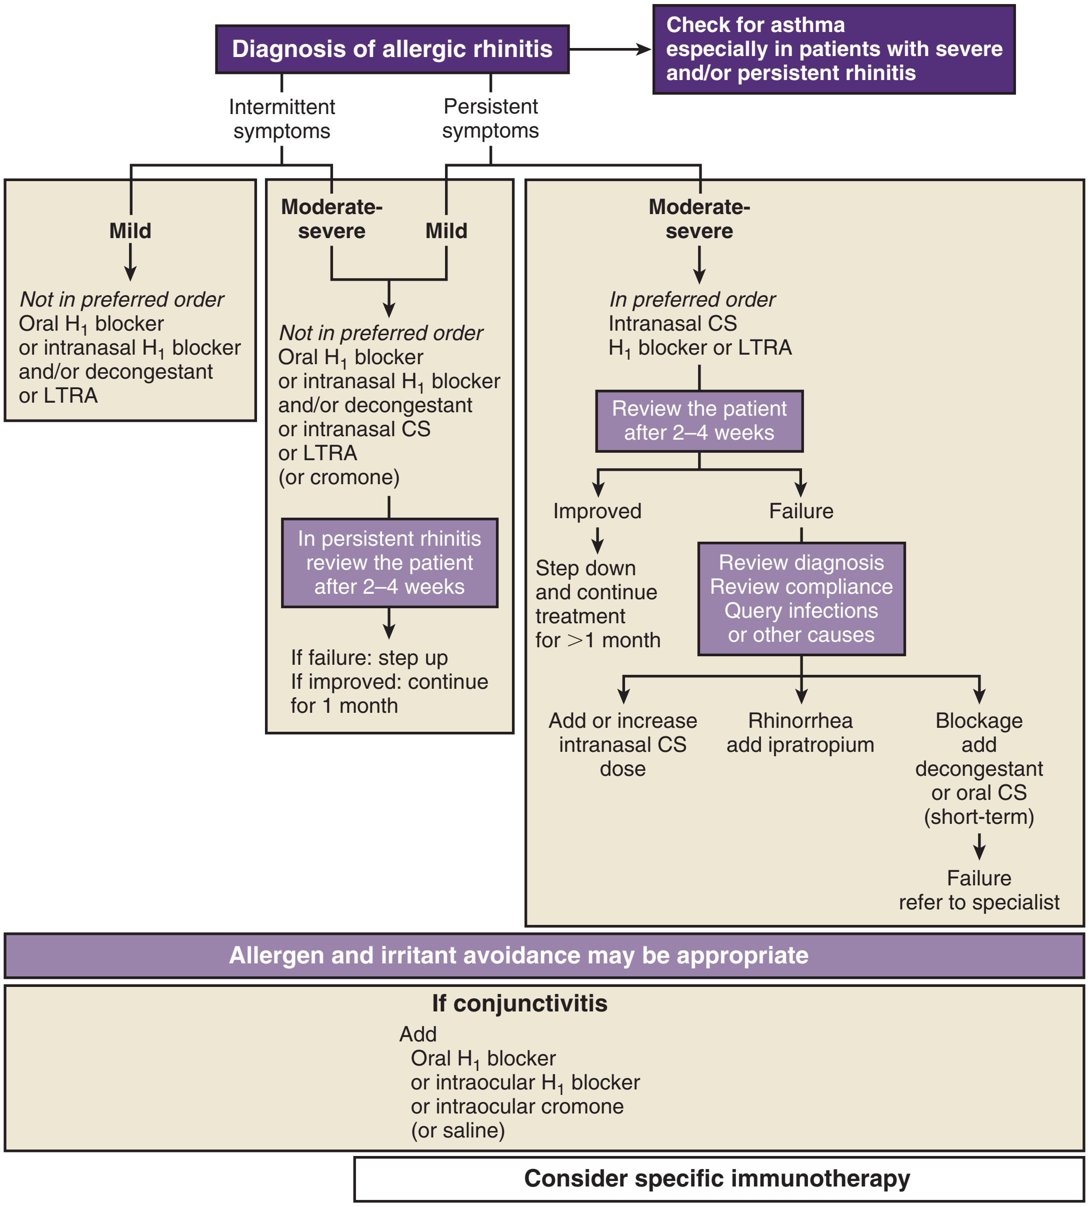
Topical Corticosteroids

Metaanalysis has shown that topical corticosteroids constitute the most effective treatment for AR. Regular use is needed, and preseasonal dosing reduces development of seasonal rhinitis symptoms. For polyps or marked nasal blockage, betamethasone drops or oral corticosteroids for the first 2 weeks of therapy may be needed, followed by a nonabsorbable drop formulation of fluticasone propionate (Flixonase Nasule), particularly in the long term for polyp management (Figure 37-9). Side effects of topical corticosteroids include local irritation and minor epistaxis. Systemic steroid absorption is low except with betamethasone and dexamethasone, which should be reserved for only short-term use.

Sodium cromoglycate is less effective when given nasally but may be suitable for small children, whereas severe conjunctival symptoms are best treated with sodium cromoglycate or nedocromil sodium. Corticosteroid eye drops are to be avoided.

Antihistamines

Antihistamines provide excellent relief of sneezing, itching, and rhinorrhea, but not congestion; oral ones have the advantage of being effective for mouth and eye symptoms. Chlorpheniramine is best avoided because it is sedating and reduces driving ability and academic performance. Newer histamine H_1 antagonists are largely nonsedating. Certain molecules—terfenadine, astemizole, and diphenhydramine in particular—can produce QT prolongation and fatal cardiac arrhythmias, especially with high blood levels from overdosing or combination of an antihistamine with another hepatically metabolized drug. Fexofenadine, cetirizine, levocetirizine, and desloratadine seem safe



Diagnosis of allergic rhinitis
Check for asthma especially in patients with severe and/or persistent rhinitis
Intermittent symptoms
Persistent symptoms
Mild
Not in preferred order
Oral H_1 blocker
or intranasal H_1 blocker
and/or decongestant
or LTRA
Moderate-severe
Mild

Oral H_1 blocker
or intranasal H_1 blocker
and/or decongestant
or intranasal CS
or LTRA
(or cromone)
In persistent rhinitis review the patient after 2–4 weeks
If failure: step up
If improved: continue for 1 month
Moderate-severe
In preferred order
Intranasal CS
H_1 blocker or LTRA
Review the patient after 2–4 weeks
Improved
Failure
Step down and continue treatment for >1 month
Review diagnosis
Review compliance
Query infections or other causes
Add or increase intranasal CS dose
Rhinorrhea add ipratropium
Blockage add decongestant or oral CS (short-term)
Failure refer to specialist
Allergen and irritant avoidance may be appropriate
If conjunctivitis
Add
Oral H_1 blocker
or intraocular H_1 blocker
or intraocular cromone
(or saline)
Consider specific immunotherapy

Figure 37-8 Approach to treatment of rhinitis based on the classification shown in Figure 37-7. *CS*, corticosteroids; *H_1*, histamine receptor type H_1; *LTRA*, leukotriene receptor antagonist. *(From Bousquet J, Khaltaev N, Cruz AA, et al: Allergic Rhinitis and Its Impact on Asthma [ARIA] 2008 update [in collaboration with the World Health Organization, GA[2]LEN and AllerGen],* Allergy *63[Suppl 86]:8–160, 2008.)*

in this respect and possess some measurable nasal unblocking activity. Azelastine and levocabastine are useful topical antihistamines. Rupatadine can block both histamine and platelet-activating factor.

Other Agents

Vasoconstrictors are useful in the short term for relief of marked congestion, but long-term use must be avoided because of the risk of rhinitis medicamentosa. Anticholinergics such as ipratropium bromide may be useful if extensive, watery secretion is a major problem. Antileukotrienes are similar in efficacy to antihistamines for treatment of AR, with no major benefits from a combination of the two. In some patients with polyps, however, these agents can reduce symptoms and polyp size when used with a topical steroid. Douching the nose with isotonic saline can reduce AR symptoms and improve endoscopic appearance and quality of life in chronic rhinosinusitis.

Immunotherapy

Immunotherapy is the only treatment that has been shown to influence the course of disease. Three years of treatment reduces symptoms for several years thereafter. In children with rhinitis, subcutaneous immunotherapy reduces progression to asthma as determined by follow-up evaluation at 3, 5, and 10 years. Reduction in the rate of new allergic sensitization also has been noted.

Desensitization involves the administration of increasing doses of relevant allergen extract by subcutaneous injection over a period of months and has been shown to effectively diminish symptoms of allergic seasonal rhinitis in response to grass pollen, ragweed pollen, and birch pollen. Some studies also suggest efficacy with house dust mite and some animal danders. Desensitization has largely been superseded by the success of effective medical therapy in the suppression of allergic inflammation and is therefore reserved for nonresponders

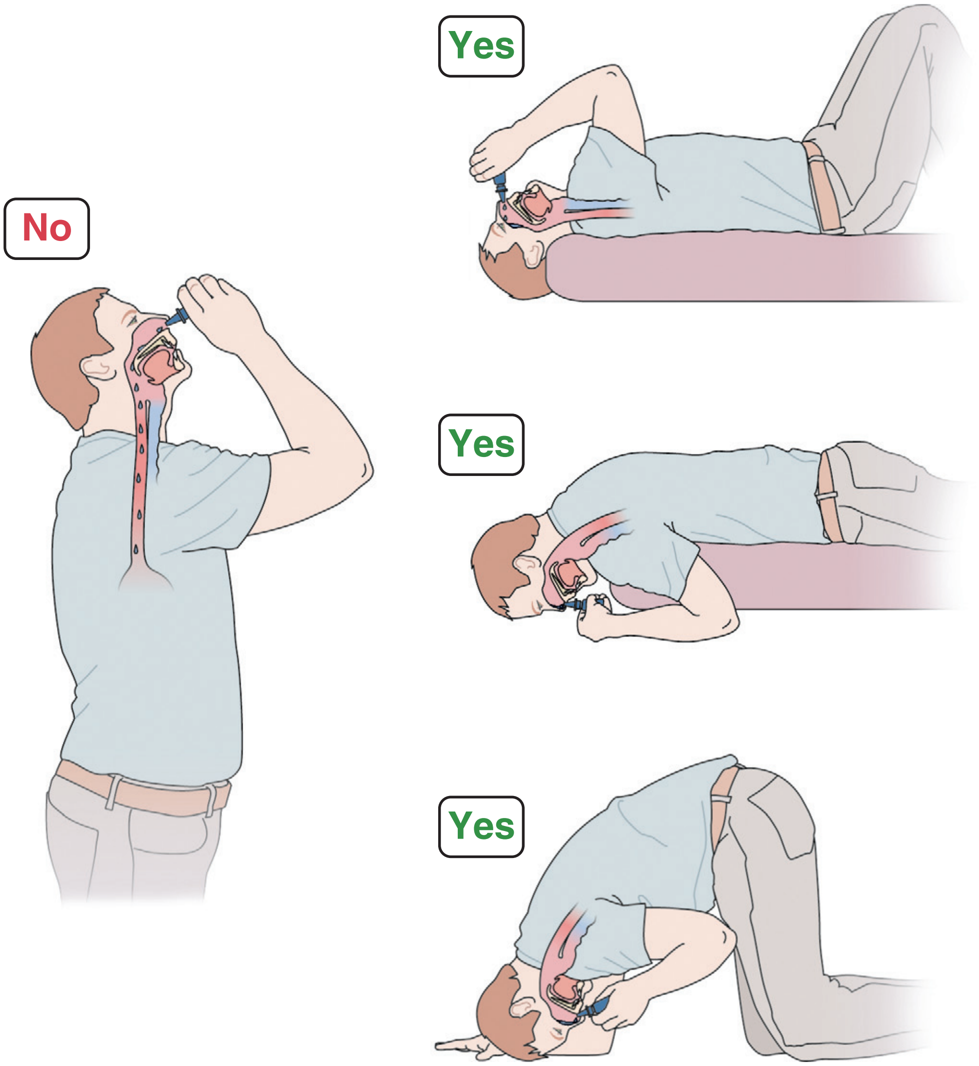

Figure 37-9 Correct instillation of nasal drops. *(Modified from Scadding GK, Durham SR, Mirakian R, et al: BSACI guidelines for the management of allergic and non-allergic rhinitis,* Clin Exp Allergy *38:19–42, 2008.)*

with severe disease. It is not always effective, and concerns have been raised regarding occasional anaphylactic reactions and deaths after the procedure, so it must be undertaken by well-trained personnel in a hospital setting with cardiorespiratory resuscitation facilities at hand.

Safer sublingual approaches have now been demonstrated to be effective, and grass pollen tablets are now available; trials with house dust mite sublingual preparations are ongoing. The first sublingual dose needs to be given under medical supervision; thereafter, each dose is taken every day at home. Eight weeks of preseasonal therapy followed by continuation throughout the pollen season is suggested, with subsequent continuation of this treatment for 3 years. However, pre- and co-seasonal therapy repeated over 3 years may suffice. The benefits of grass pollen sublingual immunotherapy last for at least 2 years after cessation of treatment.

Surgical Intervention

When medical treatment is only partly successful, a full otorhinolaryngologic assessment is performed, because correction of a deviated nasal septum or reduction of hypertrophied mucosa may help relieve the symptoms. With coexistent chronic sinus infection, functional endoscopic sinus surgery (FESS) techniques may be necessary to facilitate sinus drainage, aeration, and access for medications, although a recent study showed that medical therapy with corticosteroids and long-term macrolides was equally effective. Both resulted in improved control of concomitant asthma.

INFECTIONS

Acute Coryza (The Common Cold)

Treatment is essentially symptomatic, with analgesics, antipyretics, rest, and broad-spectrum antibiotics if secondary infection is present. Oral or topical nasal zinc may decrease symptoms and their duration.

NONINFECTIOUS CAUSES

Intrinsic Rhinitis

Anticholinergics (e.g., ipratropium bromide) are useful for troublesome rhinorrhea (i.e., intrinsic rhinitis) (Figure 37-10), particularly when eosinophils are absent from nasal secretions. When eosinophilia is present, a response to topical corticosteroid therapy is usual. α-Agonist decongestants, such as pseudoephedrine and xylometazoline, should be used sparingly. Surgical procedures may help if nasal obstruction is predominant.

†VAS = Visual analogue scale. This is a continuous horizontal line of 100 mm where 0 mm indicates no complaints, 100 mm indicates severe complaints. The patient is asked to evaluate his or her complaints over the past 14 days. (Blom HM, van Rijswijk JB, Garrelds IM, et al: *Clin Exp Allergy* 27:796–801, 1997.)

Structural Defects

Occasionally, topical corticosteroid therapy may ameliorate rhinitis secondary to structural defects, but normally surgical correction is required.

Immune Defects

Therapy of immune-related rhinitis is directed toward correction of the underlying defect.

Mucus Clearance Defect

It is not possible to correct the underlying mucus clearance defect, so therapy relies on regular douching, improved drainage and aeration, and prevention of secondary infection.

Granulomas

Appropriate, specific antimicrobial therapy is required for infectious causes of granulomatous disease. Sarcoidosis that involves the nose responds to either local or systemic glucocorticoid therapy. Each case will require a specific targeted approach.

Drug-Induced Disease

A careful drug history must be taken and the incriminated drug excluded.

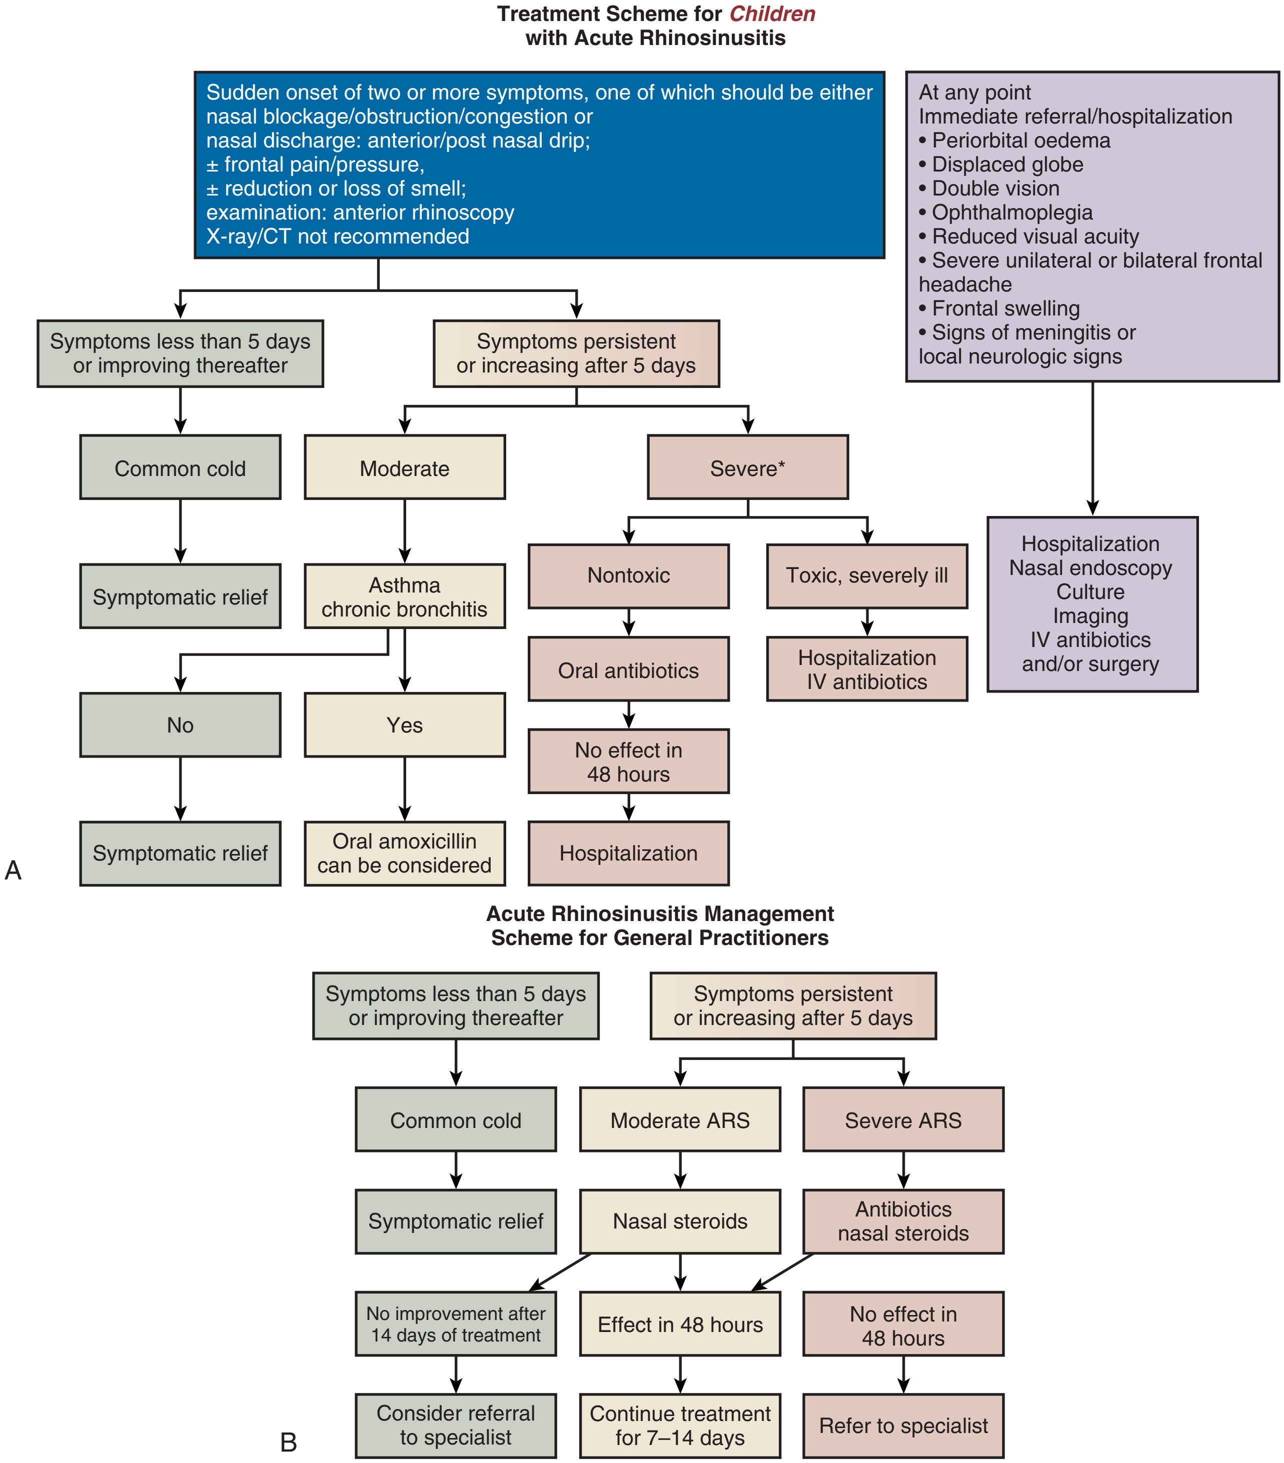
ACUTE RHINOSINUSITIS

Most cases of ARS resolve spontaneously. Analgesics and antipyretics provide symptomatic relief, but aspirin must be avoided in persons who may be hypersensitive. Acetaminophen (paracetamol) and codeine are satisfactory alternatives. Decongestants such as oxymetazoline and xylometazoline reduce edema but compromise mucociliary activity and are not recommended. Broad-spectrum antibiotics are appropriate for severe disease with a number needed to treat of 8. These antimicrobials must have activity against the most common pathogens, namely *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Agents such as amoxicillin, trimethoprim-sulfamethoxazole (co-trimoxazole), or a macrolide such as clarithromycin are appropriate. Amoxicillin-clavulanate has the added advantage of activity against *S. aureus* and penicillin-resistant *H. influenzae*. If anaerobic infection is suspected, a combination of amoxicillin-clavulanate and metronidazole or clindamycin may be used.

Recent evidence suggests that topical nasal corticosteroids help, either in conjunction with antibiotics or alone, to reduce symptom severity and hasten recovery. There is no suggestion that they lead to more recurrences or to more adverse events. In a number of rhinosinusitis scenarios, acute intervention will be required, as shown in the EPOS guidelines (**Figure 37-11**, *A* and *B*).

CHRONIC RHINOSINUSITIS

With CRS, the aims of treatment are to remedy any underlying cause (e.g., immunologic defect, anatomic abnormality that prevents drainage) and to restore the integrity of the mucous



Treatment Scheme for Children
with Acute Rhinosinusitis
Sudden onset of two or more symptoms, one of which should be either nasal blockage/obstruction/congestion or nasal discharge: anterior/post nasal drip; ± frontal pain/pressure, ± reduction or loss of smell; examination: anterior rhinoscopy X-ray/CT not recommended

membranes to allow normal ventilation of the sinuses and drainage. Nasal douching with saline relieves symptoms and improves the endoscopic appearance. Topical corticosteroids may help to reduce mucous membrane swelling and improve drainage. Initially, betamethasone drops taken in the head-down position (see Figure 37-9) are briefly used, but nonabsorbed fluticasone propionate (Flixonase Nasule) is safer for long-term use. Prolonged courses of macrolide antibiotics produced improvements equivalent to those achieved with FESS, possibly because of their antiinflammatory activity. Amphotericin douching is ineffective.

SURGICAL INTERVENTIONS FOR ACUTE AND CHRONIC RHINOSINUSITIS

Major changes have occurred in recent years as a result of the advent of high-resolution CT scans and FESS. Better demonstration of the nasal and sinus anatomy is achieved with CT scans, as well as of the important ostiomeatal complex, the vital region in which sinus drainage by mucociliary clearance occurs. Obstruction in this zone is very important in the generation of chronic sinus disease. The main aim of FESS is to restore adequate drainage for the frontal, maxillary, and ethmoidal sinuses (see Figure 37-4). When this fails, more radical sinus surgery may be needed, but complete investigation for underlying medical factors (e.g., immune deficiency) should be undertaken first.

Nasal Polyps

Unilateral nasal polyps (**Figure 37-12**) warrant appropriate investigation to exclude transitional cell papilloma, squamous cell carcinoma, encephalocele, or other pathologic conditions. In the absence of contraindications and clinical suspicion regarding the nature of the polyp, a medical polypectomy accomplished with use of prednisolone (0.5 mg/kg, enteric-coated) plus betamethasone drops (two in each nostril three times a day with the head upside down) for 5 days, up to 14 days as indicated by clinical need, can be as effective as surgery and is superior with respect to control of concomitant asthma. This should be followed by long-term corticosteroid drops—

initially betamethasone for 2 weeks, then almost nonabsorbed fluticasone propionate. Subsequently, a trial of a leukotriene receptor antagonist should be undertaken for 2 to 4 weeks, with continuation if beneficial. Other measures being evaluated include regular saline douching and topical lysine aspirin in patients sensitive to this on nasal challenge. Failure of medical treatment is an indication for surgery.

Patients with aspirin-exacerbated respiratory disease should be warned to avoid all COX-1 inhibitors and to watch for exacerbation by similar substances: “E number” foods, preservatives, high-salicylate foods. Most patients can tolerate paracetamol 500 mg or a COX-2 inhibitor.

CLINICAL COURSE AND PREVENTION

RHINITIS

Allergic Rhinitis

The clinical course in AR is variable. With good compliance, allergen avoidance, and regular pharmacotherapy, symptoms usually are minimal. Understandably, patients want a cure. Immunotherapy remains of limited value, but with development in understanding of the mechanism of generation of IgE responses and of ways in which this can be modulated, it may become more useful.

Infections

Coryza: The Common Cold

Unfortunately, avoidance of the common cold is virtually impossible, and prevention by immunization has thus far been a failure. Colds are self-limiting, however, and normally last approximately 5 days. Clinical trial data support the value of zinc in reducing the duration and severity of symptoms of the common cold when administered within 24 hours of the onset of common cold symptoms.

Most asthma exacerbations (80% in children and 60% in adults) start with a viral upper respiratory tract infection. Synergy among allergen sensitization, exposure, and rhinoviral infection leads to an almost 20-fold likelihood that an asthmatic child will require hospitalization. Other complications include acute sinusitis, pharyngitis, otitis media, mastoiditis, and tonsillitis. The common cold frequently leads to lower respiratory infection, including laryngotracheitis, bronchitis, and occasionally pneumonia. Patients who have other cardiorespiratory diseases may also experience exacerbations.

Intrinsic Rhinitis

Intrinsic rhinitis often has an onset in middle age or later and frequently is refractory to treatment. Combinations of therapy may prove helpful.

RHINOSINUSITIS

Acute Bacterial Rhinosinusitis

Before the antibiotic era, acute bacterial rhinosinusitis carried significant morbidity and mortality associated with spread of bacterial sepsis beyond the sinuses. Osteolysis of the sinus wall was common, with abscess formation and direct spread to neighboring structures, in addition to local spread and thrombophlebitis. Local complications include orbital cellulitis with or without abscess formation, cavernous sinus thrombosis, sagittal sinus thrombosis, intracranial abscess formation, meningitis and encephalitis, osteomyelitis, and septicemia. Complications are now rarely seen, because severely affected patients are prescribed broad-spectrum antibiotics.

Chronic Rhinosinusitis

With CRS, the clinical course is again variable, depending on the subtype of disease present. Often addressing any underlying contributing or exacerbating factor will decrease the frequency and severity of exacerbations, but complete resolution of disease is not common.

CONTROVERSIES AND PITFALLS

- Not all patients who have nasal symptoms have AR—neoplasm or foreign body may be the cause.
- Unilateral discharge in children probably indicates the presence of a foreign body, but in adults it may be a sign of carcinoma.
- Unilateral lesions must be biopsied to exclude malignancy.
- Nasal decongestants should be used sparingly, if at all.
- Most medical treatment failures result from poor compliance; once-daily treatment is best, if possible.
- The common cold, a cause of widespread morbidity, remains a major research challenge.
- Intrinsic rhinitis can be troublesome to treat, and further research is required.
- Turbinates and polyps can be difficult to distinguish from one another; in general, however, turbinates are rigid and pain-sensitive, whereas polyps are mobile and insensitive to irritating or painful stimuli.
- Facial pain in the absence of nasal symptoms is rarely caused by sinus disease, so other causes such as migraine, dental problems, and temporomandibular joint syndrome should be considered.
- Chronic refractory sinusitis should stimulate investigation for underlying immune or other defects.
- CT scan is the investigation of choice—plain radiography or magnetic resonance imaging has a limited role.
- Treatment of rhinosinusitis benefits asthma.

Section 7
AIRWAY DISEASES

Chapter 38
Asthma: Epidemiology, Pathophysiology, and Risk Factors

Borja G. Cosio • Jaime Rodríguez Rosado • Federico Fiorentino Rossi

Asthma has been described throughout time, beginning with ancient Egyptians. The Georg Ebers Papyrus, found in Egypt in the 1870s, contains prescriptions written in hieroglyphics for more than 700 treatments for the disorder. The inhalation of fumes extracted from the heating of herbs in bricks was one of the remedies available. The term *asthma* comes from the Greek word *aazein*, meaning “to pant, or breathe with the mouth open.” Between the 1930s and 1950s, asthma was considered to be a psychosomatic illness. During the 1960s, the emergence of the inflammation theory refuted a psychological origin and proved that asthma is a physical disease. Nonetheless, an association between psychological conditions (e.g., anxiety, depression) and difficult-to-treat asthma has been recognized since that time.

Nowadays, asthma is defined as a chronic inflammatory process characterized by reversible and variable airflow obstruction due to bronchial responsiveness secondary to multiple external stimuli in which genetic factors interact with environmental factors. The Global Initiative for Asthma (GINA) gives an operational description of asthma, as follows:

> . . . a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction within the lung that is often reversible either spontaneously or with treatment.

At present, much research is directed at elucidation of the underlying causes of asthma, which remain unknown. The risk for development of asthma is supported by evidence for a mixture of genetic, environmental, and lifestyle factors. Asthma does not respect age or gender, affecting both children and adults from kindergarten and school through work to retirement. For the moment, there is no cure for this condition, so preventive strategies are being effectively applied at the community level to prevent onset of the condition and to control worsening of asthma symptoms in the future. Nevertheless, some of these approaches have failed to reach the entire spectrum of the community population, for various reasons, such as limited access to information, personal beliefs, religious practices, and ethnicity within emigrational cohorts. Moreover, clinical practice guidelines and their distribution are basic for acute asthma diagnosis, treatment, and control.

EPIDEMIOLOGY

The World Health Organization (WHO) estimates that 300 million people have asthma worldwide, producing significant morbidity and interfering with daily activities and quality of life. During the year 2009, 250,000 people died from this condition in low- to middle-income countries. Furthermore, asthma is the most frequent chronic respiratory condition among children worldwide, and its prevalence is increasing. The Centers for Disease Control and Prevention (CDC) has estimated a significant rise in asthmatic patients of 12.3% since 2001 in the United States. Statistical figures for 2009 show that 24.6 million people had asthma, compared with 20.3 million at the beginning of the decade. This increase has come with a cost to society of $56 billion dollars in medical expenses and lost productivity. No clear explanation for this increased prevalence, however, has emerged, especially in view of the overall reduction in smoking and in second-hand smoke exposure with the implementation of laws banning smoking. The same situation is described outside the United States. From a metaanalysis of data obtained through routine statistics and population surveys, Anderson and co-workers concluded that asthma prevalence increased in the United Kingdom from 1955 to 2004.

Despite a large number of research studies, the reasons for why some people develop asthma and others do not and why asthma has emerged as a public health problem in some populations earlier than in others are not well understand. The main problem in focusing on the epidemiology of asthma is to address a proper operational definition in an attempt to unify the large conclusions of many epidemiologic studies from different areas of the world. The need to derive a practical and tangible definition of asthma for use in large-scale questionnaire-based epidemiologic research has led to a focus on asthma symptoms and their highly subjective expressions as part of the results. In questionnaire surveys, the presence of asthma often is defined on the basis of responses to questions about symptoms of wheeze in the past weeks or months, “wheeze ever,” and doctor-diagnosed asthma. This approach has been shown to have good short-term repeatability but may lack specificity, particularly in children, because other causes of wheezing illness, such as viral infection, may be misdiagnosed as asthma. With a focus on symptoms, the most common clinical presentation is one of breathlessness, wheezing, chest tightness, and cough, especially at night, coexisting with asymptomatic periods. Because of the nonspecificity and variability inherent in personal perception of respiratory difficulty, implementation of vital patient educational programs and pharmacologic treatment of asthma symptoms may be delayed. Clinical symptoms vary from one person to another, so a severe asthma exacerbation that necessitates urgent medical attention may not be recognized at first, and consequent delay in getting required treatment may lead to a poorer outcome.

Reported prevalence rates for asthma are widely variable. Despite the difficulty in obtaining a consensus on epidemiologic data, several studies have shown that asthma prevalence is increasing worldwide, with at least 7% to 10% of the population affected. Inclusion of data obtained using nonstandardized methods (questionnaires versus definition agreement) in a majority of the epidemiologic studies to determine asthma prevalence underlies the notable differences in global rates published in contemporary literature. This particular finding has no significance for geographic distribution of asthma, rates for which remain very low in many rural villages, in contrast with data reported for Western populations. Pollution in industrialized civilizations acts like a silent predator on the susceptible airway, leading to asthma in persons with certain respiratory diseases. A “hygiene hypothesis” has been proposed to explain an increased risk in children for the development of asthma that may reflect reduced microbe exposure in early life.

In a morbidity and mortality report from the CDC for the period 2006 to 2008, asthma prevalence was estimated as 7.8% for the U.S. population (**Table 38-1**). Current asthma prevalence was higher among the multiracial (14.8%), Puerto Rican Hispanics (14.2%), and non-Hispanic blacks (9.5%) than among non-Hispanic whites (7.8%). Current asthma prevalence also was higher among children (9.3%) than among adults (7.3%), among females (8.6%) than among males (6.9%), and among the poor (11.2%) than among the near-poor (8.4%) and nonpoor (7.0%).

With respect to the worldwide variability in reported prevalence rates for asthma, different studies have examined the impact on asthma care in two of the most ethnically diverse nations, such as the United Kingdom and the United States. Emigrational cohorts of Mexican Hispanics have demonstrated a lower rate of asthma than that in U.S.-born Hispanics. Moreover, in a comparison of U.K.-born persons of the same ethnic group with those already settled after emigration, the second group demonstrated a lower rate of physician visits for asthmatic symptoms. Nevertheless, Westernization does not explain this variance, and the inequalities also may be influenced by differences in genetics, environmental risk factors, and social activities.

One of the main objectives of the European Community Respiratory Health Survey (ECRHS) was to estimate the variation in prevalence of asthma, asthma-like symptoms, atopic sensitization, and bronchial hyperreactivity, predominantly in Western Europe and many other countries (**Figure 38-1**). The highest rates in Europe were in the United Kingdom (15.2%), and the lowest were in Georgia (0.28%). Another important ongoing multicenter study, the International Study of Asthma and Allergies in Children (ISAAC), had as its main aim to determine the asthma prevalence in children. A comparative survey conducted in Canadian children between 2 and 7 years of age showed an asthma prevalence of 9.8% overall, with a 4.6% higher rate in boys than in girls (**Figure 38-2**). GINA embraced the results of both of these valuable studies in the Global Burden of Asthma report and estimated that by 2025, 400 million people around the world will have a diagnosis of asthma. In the same way, this increase in prevalence is directly related to the augmented rates of rhinitis, eczema, and other atopic disorders.

In relation to mortality, asthma accounts for an estimated 250,000 annual deaths worldwide. Statistical data show large differences between countries, and asthma death rates do not parallel prevalence rates (**Figure 38-3**). Mortality seems to be high in countries where access to essential drugs is low. According to the WHO, many asthma-related deaths are preventable, being a result of suboptimal long-term medical care and delay in obtaining help during the final, fatal attack. In many areas of the world, people with asthma do not have access to basic asthma medications and health care. Nations with the highest death rates are those in which controller medications are not available. In many countries, deaths due to asthma have declined recently as a result of better asthma management. Considerable evidence points to an overall trend of decreasing mortality. For instance, mortality rates in Australia registered by the Australian Institute of Health and Welfare decreased by approximately 70% between 1989 and 2006. Persons older than 65 years of age and people of lower socioeconomic status were at higher risk for dying from asthma, mainly secondary to respiratory infections during winter. Overall, asthma-related mortality in Australia remains uncommon, accounting for 402 (0.30%) in the year 2006 of all deaths (Australian Centre for Asthma Monitoring: *Asthma in Australia 2008*, AIHW Asthma Series no. 3, Cat. no. ACM 14, Canberra, Australian Institute of Health and Welfare, 2008) (**Figure 38-4**).

It is worth emphasizing that many of the deaths secondary to asthma are preventable, and that the high economic costs attributable to this disease can be diminished. The elevated prevalence and mortality rates are associated with not inconsideable consumption of health-related resources, placing an additional economic load on health care services.

PATHOGENESIS

Asthma is an inflammatory disorder of the airways in which multiple mediators and several types of inflammatory cells are involved. This pattern of inflammation is strongly associated with airway hyperresponsiveness and classic asthma symptoms of wheezing, breathlessness, chest tightness, and coughing.

A genetic predisposition to develop specific immunoglobulin E (IgE) antibodies directed against common environmental allergens, or *atopy,* is the strongest identifiable risk factor for the development of asthma. Intrinsic abnormalities in airway smooth muscle and airway remodeling in response to injury and inflammation add to the effects of airway inflammation in creating the clinical presentation of asthma (**Figure 38-5**).

AIRWAY INFLAMMATION IN ASTHMA

Despite the highly heterogeneous clinical expression of asthma, the presence of airway inflammation remains a consistent feature. Although airway inflammation in asthma is persistent even though symptoms are episodic, no clear relationship between the severity of asthma and the intensity of inflammation has been discovered. The inflammation affects all airways, including in most patients the upper respiratory tract and nose, but its pathophysiologic effects are most pronounced in medium-sized bronchi. The pattern of inflammation in the airways appears to be essentially the same in all clinical forms of asthma, whether allergic, nonallergic, or aspirin-induced, and at all ages.

Table 38-1 **Prevalence of Current Asthma Among Children and Adults by Sex, Race/Ethnicity, and Economic Status–Poverty Level***

	Prevalence Rate (%)†		
Characteristic	**Children**	**Adults**	**Total**
Race/Ethnicity			
White, non-Hispanic	8.2 (7.6-8.9)	7.7 (7.3-8.0)	7.8 (7.5-8.1)

Inflammatory Cells

Studies using bronchoalveolar lavage and bronchial biopsies have demonstrated that a variety of cells and mediators are involved, with IgE and mast cells implicated in the acute response and eosinophils and eosinophil granule proteins in the late response, with T cells, particularly T_H2 cells, orchestrating these responses through their production of cytokines such as the interleukins IL-4, IL-5, IL-9, and IL-13. Stromal and epithelial cells also are involved in the inflammatory response, as shown by the ability of these cells to respond to T_H2 cytokines with the production of chemokines that initiate and perpetuate tissue inflammatory reactions. As a result, a pathogenetic construct for atopic asthma (and possibly other forms of asthma) has been proposed in which (1) T_H2 cells play a central role in the recognition of antigens and the initiation and perpetuation of inflammation; (2) eosinophils are important

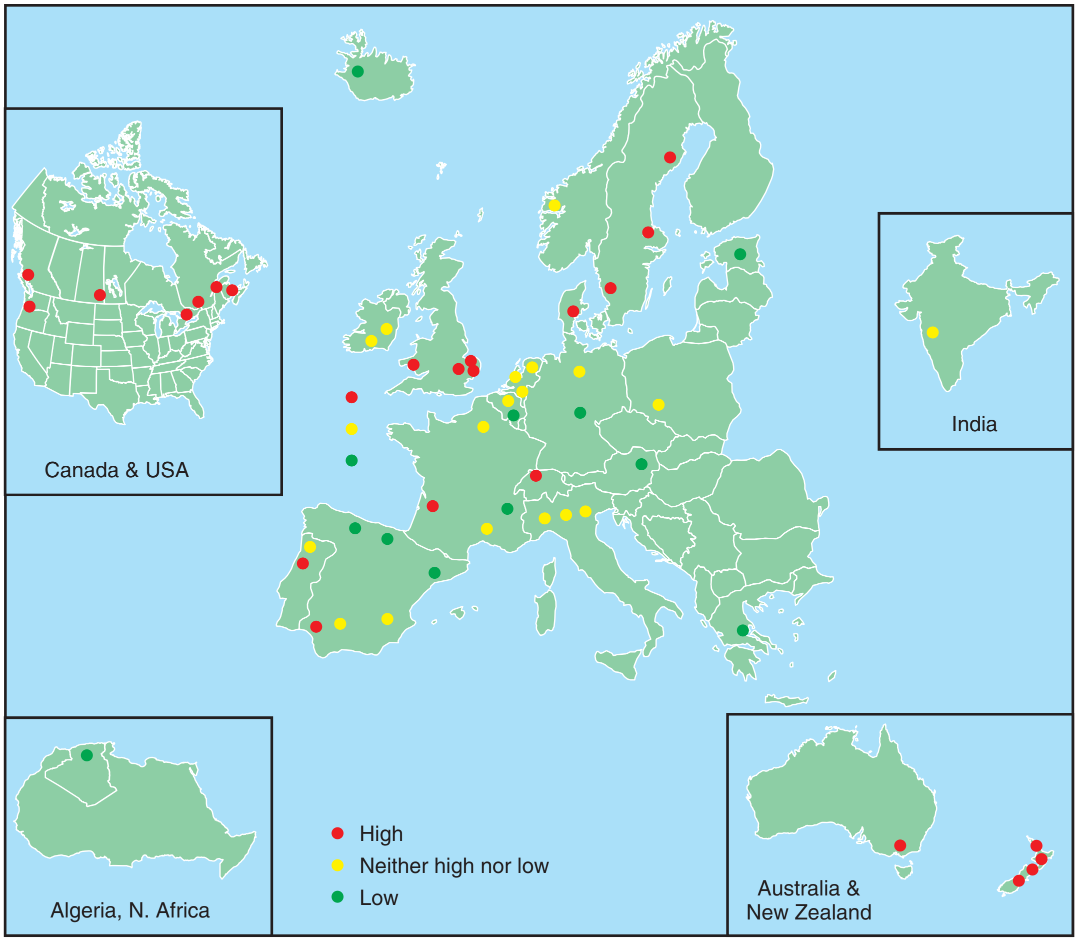

Figure 38-1 Prevalence of asthma in Europe. *(Courtesy European Community Respiratory Health Survey I Centers. Available at: http://www.ecrhs.org/ECRHS%20I.htm.)*

proinflammatory and epithelium-damaging cells; and (3) a variety of cells, including mast cells, epithelial cells, basophils, fibroblasts, smooth muscle cells, and macrophages, contribute through the secretion of cytokines that generate tissue inflammation or influence T_H2 lymphocyte or eosinophil function.

Implicit in the "inflammation theory" of asthma is the belief that inflammation is both necessary and sufficient to account for the complex features of asthma. Although inflammation is undoubtedly a cornerstone of asthma, it is now clear that the asthmatic response is more complex. Also clear from pathologic investigations is that structural alterations exist in the asthmatic airway. Mathematical modeling studies have provided evidence that these alterations contribute to the symptoms and physiologic dysregulation seen in asthma. As a result, it has been proposed that the chronic inflammation that is characteristic of the asthmatic airway leads to a remodeling response, and that the structural alterations induced by this response play an important role in generating the manifestations of the disorder. This conceptual evolution predicts that an enhanced understanding of asthma pathogenesis can be expected when asthma is studied in the context of paradigms of injury and wound healing, as well as the traditional paradigms relevant to the interface of inflammation and airway physiology. It also suggests that studies utilizing this new perspective will identify novel targets against which therapies can be directed and will help to elucidate the biologic basis for the patient-to-patient variability encountered in clinical practice.

Inflammatory Mediators

More than 100 different mediators are now recognized to be involved in asthma and to mediate the complex inflammatory response in the airways. Chemokines are expressed mainly in airway epithelial cells and are important in the recruitment of inflammatory cells into the airways. Eotaxin is relatively selective for eosinophils, whereas macrophage-derived chemokines (MDCs) recruit T_H2 cells.

Cytokines such as IL-1β and TNF-α, which amplify the inflammatory response, and granulocyte-macrophage colony-stimulating factor (GM-CSF), which prolongs eosinophil survival in the airways, orchestrate the inflammatory response in asthma and determine its severity. T_H2-derived cytokines include IL-5, which is required for eosinophil differentiation and survival; IL-4, which is important for T_H2 cell differentiation; and IL-13, needed for IgE formation.

Cysteinyl leukotrienes are potent bronchoconstrictors that act as proinflammatory mediators mainly derived from mast cells and eosinophils. Their inhibition has been associated with an improvement in lung function and asthma symptoms.

The prostaglandin PGD_2 is a bronchoconstrictor derived predominantly from mast cells and is involved in T_H2 cell recruitment to the airways.

Histamine is released from mast cells and contributes to bronchoconstriction and to the inflammatory response.

Nitric oxide (NO) has been associated with the presence of eosinophilic inflammation in asthma. It is produced

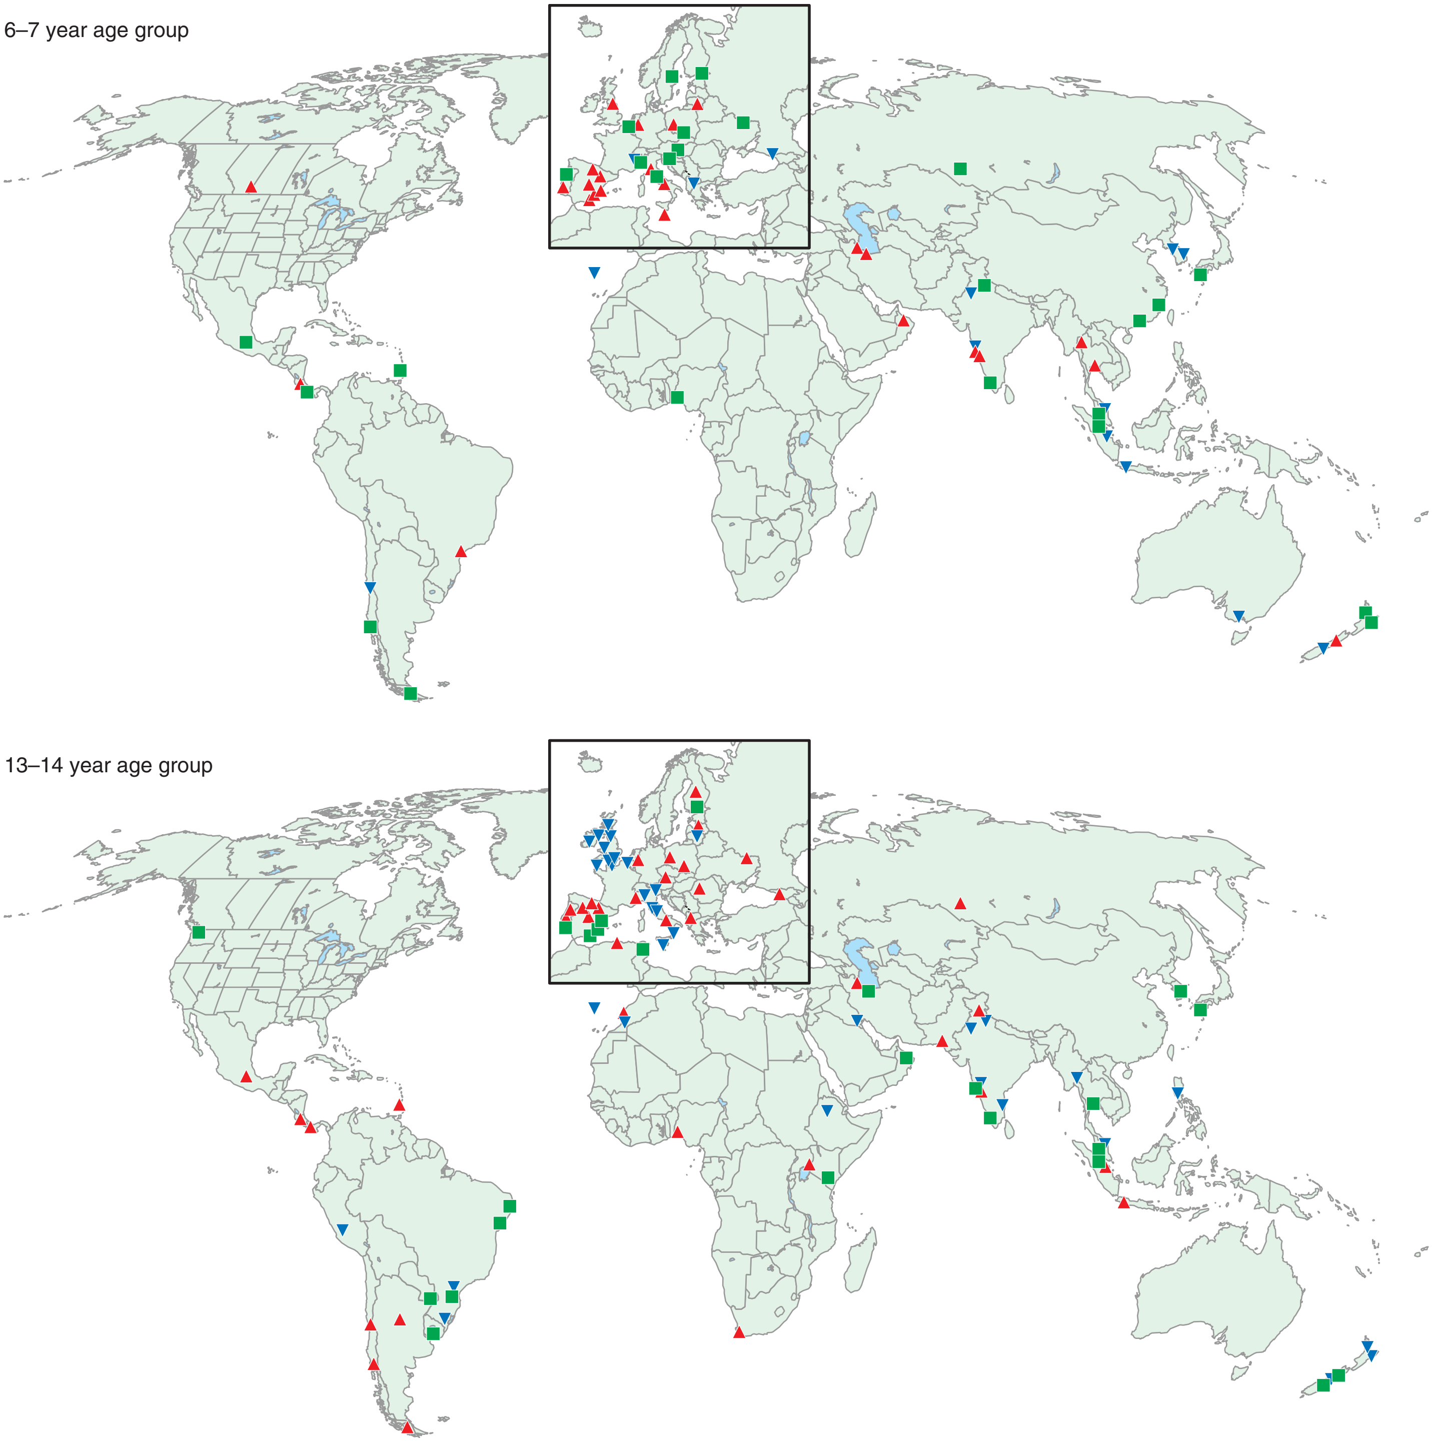

Figure 38-2 Annual changes in worldwide prevalence of asthma symptoms among children 6 to 7 years of age and those 13 to 14 years of age, over a mean of 7 years after phase I of the International Study of Asthma and Allergies in Childhood (which in most participating countries was conducted between 1991 and 1993). *Blue triangles*, locations where prevalence was reduced by at least 1 standard error (SE) per year; *green squares*, locations where there was little change in prevalence (i.e., change of less than 1 SE per year); *red triangles*, locations where prevalence increased by at least 1 SE per year. *(From Subbarao P, Mandhane PJ, Sears MR: Asthma: epidemiology, etiology and risk factors,* CMAJ *181:E181–E190, 2009.)*

predominantly from the action of inducible nitric oxide synthase (iNOS) in airway epithelial cells. Exhaled NO concentration is increasingly being used to diagnose asthma in the context of a compatible clinical history and to monitor the effectiveness of asthma treatment.

PATHOPHYSIOLOGY

Airway narrowing is the final common pathway leading to symptoms and physiologic changes in asthma. As discussed next, several factors contribute to the development of airway narrowing in asthma (Figure 38-6).

Bronchoconstriction Bronchoconstriction is an abnormal contraction of airway smooth muscle that was presumed to be due to an intrinsic abnormality in the airway myocytes. Nervous system dysfunction with cholinergic and/or tachykinin excess also was proposed as an important pathogenic process. Autonomic dysfunction decreases in response to β-agonist and increases in response to α-agonist activity.

Airway Edema Airway edema is due to increased microvascular leakage occurring in response to inflammatory mediators. This pathomechanism may be particularly important during acute exacerbations.

Airway Remodeling In addition to the inflammatory response, characteristic structural changes, often described as airway remodeling, are observed in the airways of asthma patients. Some of these changes are related to the severity of the disease and may result in relatively irreversible narrowing of the airways. These changes may represent repair in response to chronic inflammation.

Airway remodeling can be defined as an airflow obstruction despite aggressive antiinflammatory therapies, including regimens of inhaled corticosteroids and systemic corticosteroids. It was first appreciated over 75 years ago by Huber and Koessler in their classic description of fatal asthma. The natural history of airway remodeling is poorly understood, and it does not appear to be a universal finding or a modifiable factor with early treatment.

The effect of bronchoconstriction on airway remodeling has been studied by exposing subjects to a dust mite allergen or repeated methacholine inhalation challenge. Both agents cause bronchoconstriction, although dust mite allergen induces an eosinophilic inflammation. The repetition of the exposure leading to bronchoconstriction after 4 days, observed in bronchial biopsy specimens, established that both the allergen and methacholine groups developed airway remodeling that was independent of inflammation for the second group.

On histopathologic examination, the airway remodeling is associated with a variety of features including airway wall thickening, mucous gland hyperplasia, persistence of inflammatory cellular infiltrates, release of fibrogenic growth factors along with collagen deposition, and elastolysis. Increase in the number and size of vessels in the airway wall is one of the most consistent features of asthma remodeling occurring in the lungs of patients with mild, moderate, and severe asthma. Airway wall thickening is the result of a dense fibrotic response that occurs in the lamina reticularis. The pathologic significance of subepithelial fibrosis is not clear, but this process has been associated with disease severity and correlated with a decline in forced expiratory volume in 1 second (FEV_1).

All components of the airway wall have been reported to be thickened in asthma (Figure 38-7). Elements involved in this response are increase in airway smooth muscle, increased myocyte muscle mass, edema, inflammatory cell infiltration, glandular hypertrophy and hyperplasia, and connective tissue deposition. The recently popularized “perturbed equilibrium hypothesis” also suggests that wall thickening can destabilize the dynamic forces that control airway caliber, leading to airway collapse.

Mucus Metaplasia Mucus hypersecretion, epithelial hypertrophy, mucus metaplasia, and airway obstruction due to bronchial mucus plugging are well-documented features of chronic asthma and status asthmaticus. Epithelial hypertrophy and increased airway mucus can contribute to the airway obstruction seen in asthma.

Airway Hyperresponsiveness Airway hyperresponsiveness is the characteristic functional abnormality of asthma, resulting in airway narrowing in response to a known or unknown stimulus. In turn, this airway narrowing leads to variable airflow limitation and intermittent symptoms. Airway hyperresponsiveness is linked to both inflammation and repair of the airways and is partially reversible with therapy. Its mechanisms are incompletely understood, although it has been related to increased volume or contractility of airway smooth muscle cells, excessive airway contraction due to inflammatory changes, and exaggerated bronchoconstriction occurring in response to sensory stimuli in sensory nerves sensitized by excessive inflammation.

Special Circumstances

Acute Exacerbations

Transient worsening of asthma symptoms and underlying inflammation may result from exposure to risk factors for asthma, such as exercise, emotional stress, air pollutants, or occupational exposure. More prolonged worsening usually is due to viral infections of the upper respiratory tract (particularly from rhinovirus and respiratory syncytial virus [RSV]) or allergen exposure leading to increased inflammation in the lower airways (acute or chronic inflammation), which may persist for several days or weeks.

Asthma exacerbations constitute a primary reason for attendance at hospital emergency departments worldwide. Asthma exacerbations have been shown to significantly reduce health-related quality of life in patients classified as having moderate to severe asthma. A multivariable analysis of data from a prospective and multicenter study conducted in Canada that included 695 patients presenting to emergency departments demonstrated that older asthmatic patients with a history of previous hospital admission for asthma in the past 2 years and patients receiving either oral or inhaled corticoids, with an increased need for β_2-agonist puffs among others, are more likely to require hospital admission.

Nocturnal Asthma

Asthma usually worsens at night. The mechanisms accounting for this nocturnal worsening of symptoms are not completely understood but may be driven by circadian rhythms of circulating hormones such as epinephrine, cortisol, and melatonin and neural mechanisms such as cholinergic tone. An increase in airway inflammation at night has been reported. This finding may reflect a reduction in endogenous antiinflammatory mechanisms.

Difficult-to-Treat Asthma

In a minority of patients, asthma may prove difficult to manage and relatively insensitive to the effects of glucocorticosteroids. The reasons are not well understood. Common associations are poor compliance with treatment and psychological and psychiatric disorders. However, genetic factors may contribute in some instances. Many of these patients have difficult-to-treat asthma from disease onset, rather than progressing from milder asthma. In such patients, airway closure leads to air trapping and hyperinflation. Although the histopathologic pattern appears broadly similar to that in other forms of asthma, additional features include an increase in neutrophils, more small airway involvement, and further structural changes. Research over the past 2 decades has identified allergic pathways as being fundamental to asthma pathogenesis with a prominent role played by a subset of T cells (designated T_H2-like) that produce cytokines and chemokines implicated in the regulation of IgE and the maturation, recruitment, priming, and activation of mast cells, basophils, and eosinophils. Allergic pathways that contribute to airway dysfunction in mild-moderate asthma are largely sensitive to corticosteroids. In more severe asthma, however, the inflammatory profile commonly changes, with greater involvement of neutrophils and evidence of tissue destruction and airway remodeling.

Smoking and Asthma

The prevalence of smoking among persons with asthma reflects that in the general population; thus, smokers with asthma comprise a large group of patients with poorly controlled disease. Smoking cessation is an effective intervention for smokers with asthma, but because sustained quitting rates are low, additional or alternative therapies are needed for patients with asthma who smoke.

As seen in patients with chronic obstructive pulmonary disease (COPD), asthmatic patients who smoke may have a neutrophil-predominant inflammation in their airways and exhibit a poor response to glucocorticosteroids. Tobacco smoking makes asthma more difficult to control, results in more frequent exacerbations and hospital admissions, and produces a more rapid decline in lung function with an increased risk of death.

The antiinflammatory actions of corticosteroids are mediated in part by the recruitment of histone deacetylase (HDAC), a nuclear enzyme involved in the switching off of activated inflammatory genes. Cigarette smoke reduces HDAC activity in vitro, which may potentially explain corticosteroid insensitivity in smokers with asthma, as has been observed in COPD.

RISK FACTORS

Asthma is a condition characterized by lung airway inflammation initiated and perpetuated by an inappropriate immune response, increased airway responsiveness, and variable airflow obstruction. These results come from complex interactions between multiple genetics and environmental influences. Although a clear cause-and-effect association is not always possible to demonstrate, numerous risk factors have been identified (Box 38-1).

The asthma risk factors can be divided into genetic and environment factors, including in the latter allergens, nutritional factors, perinatal factors, and tobacco smoke (active and secondhand smoking). In addition, a series of trigger factors, either direct or indirect, also can worsen asthma symptoms.

Box 38-1 Asthma Risk and Trigger Factors

Risk Factors

Genetics
Atopy
Airway hyperresponsiveness
Obesity
Sex

Environmental Factors
Allergens
Diet
Perinatal factors
Tobacco smoke
Infections
Occupational exposure

Trigger Factors

Direct
Respiratory infections
Nonspecific irritants
Weather changes

Indirect
Exercise
Emotional extremes
Food allergens
Medications
Gastroesophageal reflux disease
Menstruation
Pregnancy

Among the direct factors are infections, nonspecific irritants such as tobacco smoke, outdoor air pollution, industrial spills, bonfire smoke, and meteorologic changes (low temperatures, high humidity). Indirect factors are exercise, extremes of emotion, food allergens, medications, menstruation, gastroesophageal reflux disease (GERD), and pregnancy.

GENETICS

Certain components of the asthma phenotype appear to be strongly heritable, such as atopy, airway hyperresponsiveness, obesity, and gender. In fact, a family history of asthma is a clear risk factor for developing asthma. Current data show that multiple genes may be involved in the pathogenesis of asthma, although the specific genes responsible for these inherited components have not yet been identified.

The relative risk for asthma in a first-degree relative of the patient is between 2.5% and 6%; in monozygotic twins, the risk is 60% and in dizygotic twins, 25%. In contrast with other pathologic conditions caused by a unique genetic abnormality (e.g., cystic fibrosis) in which a hereditary pattern can be explained with a simple mendelian pattern, asthma is a heterogeneous disease in which multiple genes interact. The final phenotype depends on the smaller additive actions of these particular genes, combined with and modulated by environmental factors.

One of the most commonly studied genetic factors is atopy. *Atopy* can be defined as the genetic predisposition to develop IgE antibodies against specific allergens. Atopy is considered the main factor contributing to development of asthma. The atopic pattern is characterized by atopic dermatitis, allergic rhinitis, and asthma. Not all atopic patients, however, develop all three conditions. The incidence of atopy in the general population is approximately 30%, whereas that of asthma is much lower—the implication being that not all atopic persons develop asthma, but that almost all asthmatic patients have atopy.

Other areas of the asthmatic phenotype in which a search for genetic factors has been focused are airway hyperresponsiveness, inflammatory responses, and T_H1-T_H2 immune responses. In some cases, a number of chromosomal regions associated with asthma susceptibility have been identified, such as the major locus near the long arm of chromosome 5 (5q), although with inconsistent results.

Obesity is another factor that has been associated with asthma. Asthma is more frequently observed in obese people (body mass index greater than 30) and is more difficult to control in obese asthmatics. The influence of obesity on lung mechanics and the generation of a proinflammatory state in addition to hormonal or neurogenic influences are likely to play a role. This risk may be greater with nonallergic asthma than with allergic asthma.

A clear-cut genetic factor also has been established—asthma is twice as frequent in male children as in females. This predilection reverses by adulthood, when the prevalence of asthma is greater in women than in men, and it reaches its maximal differences when related to severe asthma.

Approximately 20 genome-wide linkage screening studies have been reported in different populations for investigating chromosomal regions that are linked to asthma and atopy, or related phenotypical features such as elevated IgE levels, wheezing, and bronchial hyperresponsiveness. A number of chromosomal regions have been repeatedly identified, across multiple studies, that contain genes of biologic relevance to asthma and allergic disease, including the cytokine cluster on 5q (containing interleukin-3 [IL-3], IL-5, and GM-CSF), *FCER1B* on 11q, *IFNG* (interferon-γ) and *STAT6* on 12q, and *IL4R* (the IL-4Rα chain, also part of the IL-13 receptor) on 16p. Linkage studies followed by positional cloning approaches have resulted in the identification of a handful of novel asthma susceptibility genes, including *CYFIP2*, *DPP10*, *HLAG*, *PHF11*, *GPRA*, and *ADAM33*. *GPRA* (G protein—coupled receptor for asthma) and *ADAM33* (a disintegrin and metalloproteinase domain–containing protein 33) have generated considerable interest, because their expression in bronchial smooth muscle cells suggests roles in the pathobiology of asthma and pulmonary allergic disease.

ENVIRONMENTAL FACTORS

The environment plays a pivotal role in the development of asthma because it interacts with the genetic susceptibility of the subject to develop an asthmatic phenotype. Environmental factors, however, frequently overlap with trigger factors that can precipitate asthma symptoms, and their influence can be additive.

Risk Factors in Childhood

Phenotypes of Asthma

Although some 50% of preschool children have wheezing, only 10% to 15% have a diagnosis of "true" asthma by the time they reach school age. Commonly described phenotypes in early infancy and childhood are transient wheezing, nonatopic wheezing, late-onset wheezing, and persistent wheezing. Only transient wheezing in early infancy has been well characterized, with decreased airflow rates on pulmonary function testing at birth, onset of wheezing within the first year, and resolution by mid-childhood, with no lasting effects on pulmonary function. The other three phenotypes have been described primarily by age at onset in cohort studies, and their genesis in early infancy is largely unknown. A majority of children with persistent wheezing (in whom asthma will subsequently be diagnosed) experience their first symptoms before the age of 3. By 3 years, they have abnormal lung function that persists to adulthood, and by adolescence, most have atopy. Of children with nonatopic and late-onset wheezing, some experience remission, whereas others experience persistent symptoms and exhibit atopy. Distinguishing among these different phenotypes in early childhood is critical to an understanding of the role of risk factors and their timing in early infancy.

Breast-feeding

The influence of breast-feeding on the risk of childhood atopy and asthma remains controversial. Presented next is a review of observational data accumulated to date: Some studies have shown protection, whereas others have reported higher rates of allergy and asthma among breast-fed children. A metaanalysis and several individual studies showed that exclusive breast-feeding for at least 3 months was associated with lower rates of asthma between 2 and 5 years of age, with the greatest effect occurring among those with a parental history of atopy. One of the difficulties in interpreting these data lies in differentiating viral infection–associated wheeze in childhood from the wheeze of atopic asthma. In a longitudinal birth cohort study, breast-feeding was associated with a higher risk of atopic asthma in later childhood, with the greatest influence among children with a maternal history of atopy. The benefit of avoiding nutritional allergens during breast-feeding also is controversial. In some studies, exclusion of milk, eggs, and fish from the maternal diet was associated with decreased atopic dermatitis in infancy, but other studies found no association. Studies in children from birth to the age of 4 years have demonstrated no effect of maternal dietary restriction during lactation on the subsequent development of atopic diseases, including asthma.

Nutritional Factors

The increase in incidence of asthma and atopy in developed countries has been associated with changes in the nutritional habits (processed foods, low antioxidant intake, high *n*-6 polyunsaturated fatty acids). Breast-fed infants are less likely to develop wheezing illness during early childhood than are intact cow's milk– or soy protein–fed infants.

Lung Function

Decreased airway caliber in infancy has been reported as a risk factor for transient wheezing, perhaps related to prenatal and postnatal exposure to environmental tobacco smoke. Furthermore, the presence of airways with decreased caliber has been associated with increased bronchial responsiveness and increased symptoms of wheeze. Several studies have suggested an association between reduced airway function in the first few weeks of life and asthma in later life. The magnitude of the effect of this risk factor in isolation (i.e., without concomitant allergy) is unclear; perhaps persons with smaller airways require less stimulus (i.e., airway inflammation) before symptoms become apparent. Children with wheezing (and diagnosed asthma) persisting to adulthood have a fixed decrement in lung function as early as the age of 7 or 9 years. Recent studies of preschool children have documented abnormal lung function in those with persistent wheezing as early as the age of 3 years. However, some infants in whom persistent wheezing develops have normal lung function shortly after birth, which suggests a critical period of exposures within the first few years of life, before the development of these persistent abnormalities in expiratory flow. By contrast, infants who exhibit early transient wheezing exhibit decreased airflow shortly after birth. Maternal smoking with in utero nicotine exposure has been correlated with this type of lung dysfunction, but the effects of other exposures have been less well studied.

Family Structure

Family size and the number and order of siblings may affect the risk of development of asthma. The hygiene hypothesis posits that exposure of an infant to a substantial number of infections and many types of bacteria stimulates the developing immune system toward nonasthmatic phenotypes. This hypothetical scenario may be exemplified in the real world by large family size, whereby later-born children in large families would be expected to be at lower risk for asthma than first-born children because of exposure to their older siblings' infections. Although this theory has been supported by some studies of allergy prevalence, it has been partially refuted by recent studies of this topic suggesting that although large family size (more than 4 children) is associated with a decreased risk of asthma, birth order is not involved. Furthermore, doubt has been cast on simplistic renditions of this hypothesis, in that infections per se cannot explain some epidemiologic patterns (e.g., prevalence rates for allergy and asthma are high in some South American countries, where exposures to infection are higher than in some countries with lower rates of asthma). In addition, not only allergic but also autoimmune and other chronic inflammatory diseases are increasing, a trend that is difficult to explain using the hygiene hypothesis alone, because allergic and autoimmune diseases are associated with competing immunologic phenotypes.

Socioeconomic Status

Children of parents with lower socioeconomic status have greater morbidity from asthma, but findings with respect to the prevalence of asthma are mixed. Such results may depend both on how socioeconomic status is measured and on the specific outcome examined. Some studies have reported associations of lower socioeconomic status with higher rates of airway obstruction and symptoms but not with a diagnosis of asthma. Whether socioeconomic status is as relevant to the incidence of allergy and asthma as it is to the expression, severity, and management of these diseases remains unclear. Parental stress also has been prospectively associated with wheezing in infancy, and family difficulties have been linked to asthma. Children whose caregivers report high levels of stress and who have difficulties parenting are at greatest risk for development of asthma.

Antibiotics and Infections

The use of antibiotics has been associated with early wheezing and asthma in several studies. One suggested mechanism for this association is immunologic stimulation through changes in the bowel flora, but other studies found no coincident increase in eczema or atopy, despite increased wheezing rates—an observation that argues against this mechanism. Greater antibiotic use also may potentially represent a surrogate marker for a higher numbers of infections (perhaps viral) in early life.

Viral infections of the lower respiratory tract contribute to early childhood wheezing. Whether lower respiratory tract infection promotes sensitization to aeroallergens causing persistent asthma is controversial: Childhood viral infections may be pathogenic in some children but protective in others. Infants of mothers with allergy or asthma have a relatively persistent maturational defect in T_H1 cytokine synthesis in the first year of life, which may play a role in the development of persistent or severe viral infections. Severe viral infection of the lower respiratory tract in genetically susceptible infants who are already sensitized to inhalant allergens may lead to deviation toward T_H2 responses promoting asthma. It is unclear whether these effects of lower respiratory tract infection are virus-specific (e.g., RSV, rhinovirus) or whether synergistic exposures to allergens can induce asthma even in children (or adults) who are not genetically susceptible. Interactions of genes with environmental exposures (including allergens, air pollution, environmental tobacco smoke, and diet) modulate the host response to infections. It remains controversial whether the occurrence or timing of childhood infection is pathogenic or protective for the development and long-term outcome of asthma and allergy and of nonallergic wheeze phenotypes. This controversy relates in part to small sample size, cross-sectional analysis, lack of precise case definition, and incomplete microbial assessment in studies of this phenomenon. Respiratory infections in early childhood are associated with early wheezing, but it is unclear whether infection alone has a role in the development of persistent asthma. Repeated lower respiratory tract infection may affect infants who are already at risk for asthma because of family history or atopy. Severe infection with certain viruses such as RSV and rhinovirus may play a role in persistent wheezing, although other studies have suggested no effect. Considered as a proxy for viral infections, day care attendance is associated with higher incidence of early wheeze but lower incidence of persistent wheeze.

Allergens

Allergens are well known to trigger asthma symptoms and also are considered to be the main environmental risk factors. The exposure to allergens can be outdoor (pollens, fungi, molds, yeasts) or indoor (house dust mite, animal proteins [particularly dog and cat dander], cockroaches, and fungi). Most of the allergens associated with asthma are in the air and to induce a condition of hypersensitivity must be present in abundance over considerable periods of time. As soon as the sensitization occurs, the patient can show extreme reactivity, to the point that minimum quantities of the antigen produce significant exacerbations of the disease.

Total serum IgE level, a surrogate for allergen sensitivity, has been associated with the incidence of asthma. High levels of IgE at birth were associated with greater incidence of both atopy and aeroallergen sensitivity but not necessarily asthma. However, sensitization to aeroallergens, particularly house dust mite, cat, and cockroach allergens, is well documented as being associated with asthma. Immune responses in the developing infant and young child may affect the development of asthma. For example, impairment in interferon-γ production at 3 months was associated with a greater risk for development of wheeze. Immaturity in neonatal immune responses may promote the persistence of the T_H2 immune phenotype and development of atopy, but an association with persistent asthma is as yet unproved. More recent work has focused on the role of the innate immune system in handling and presentation of antigens and suggests that polymorphisms in Toll-like receptors (TLRs) may play a greater role than has been previously recognized in the development of the skewed immune responses associated with persistent asthma.

Exposure to Animals

Although several studies have demonstrated a lower risk of development of atopy and asthma with exposure to farm animals in early life, the findings of studies on the influence of exposure to domestic cats and dogs have been inconsistent. In some studies, exposure to cats was associated with a greater risk of allergic sensitization, whereas other studies showed a lower risk. Exposure to dogs may be protective not only against the development of specific sensitization to dog allergen but also against other sensitization (e.g., to house dust mites) and asthma. Other studies of exposure to dogs have suggested that protection against wheezing may be mediated by high levels of endotoxin.

Perinatal Factors

Several prenatal and perinatal factors are proposed to be associated with the development of asthma. Risk factors in the prenatal period are multifactorial. Assessment is complicated by the variety of wheezing conditions that may occur in infancy and childhood, only some of which evolve to classic asthma. The principal prenatal factor is exposure to maternal smoking. The exposure to smoking during pregnancy increases the risk of acquiring asthma up to 37% at the age of 6 and up to 13% after that age. The exposure is clearly associated with fetus growth retardation with disproportionately small airways relative to the size of the lung parenchyma, which in turn is associated with increased airway hyperreactivity, low pulmonary function, asthma, and increased frequency of emergency department visits for treatment of acute exacerbations.

The perinatal factors studied have been maternal age, diet during pregnancy, prematurity, mode of delivery, and in utero exposure to antibiotics. The incidence of wheezing illnesses during childhood is inversely related to maternal age. In one study evaluating young maternal age as a risk factor for childhood asthma, children born to mothers younger than 20 years of age had the highest risk for development of asthma.

Diet and Nutrition Observational studies examining prenatal nutrient levels or dietary interventions and the subsequent development of atopic disease have focused on foods with antiinflammatory properties (e.g., omega-3 fatty acids) and antioxidants such as vitamin E and zinc. Several studies have demonstrated that higher intake of fish or fish oil during pregnancy is associated with lower risk of atopic disease (specifically eczema and atopic wheeze) up to the age of 6 years. Similarly, higher prenatal vitamin E and zinc levels have been associated with lower risk of development of wheeze up to the age of 5 years. However, no protective effect against the development of atopic disease in infants has been shown for maternal diets that excluded certain foods (e.g., cow's milk, eggs) during pregnancy. Two recent studies reported an inverse relation of maternal vitamin D levels with onset of wheeze in early life, but no relation with atopy or symptoms in later life. The Mediterranean diet during pregnancy is associated with reduced risk of atopy and asthma.

Prematurity and mode of delivery also have been proposed to be associated with asthma. Delivery by cesarean section has been reported to increase the risk of childhood asthma over that associated with vaginal delivery. The possible explanation—an extension of the hygiene hypothesis—is that microbial exposure and infections during early childhood protect against allergic disease; however, data in support of this extended hypothesis are conflicting. Development of atopy was two to three times more likely among infants delivered by emergency cesarean section, although no such association occurred with elective cesarean section. Potential reasons for these findings include maternal stress and differences in the infant's gut microflora associated with specific modes of delivery.

Prenatal Stress A number of animal models have suggested that prenatal maternal stress acts through regulation of the offspring's hypothalamic-pituitary-adrenal axis to decrease cortisol levels, which may affect the development of an allergic phenotype. Although a correlation has been found between caregiver stress early in the infant's life and higher levels of IgE in the infant and early wheezing, no studies to date have shown an association with asthma.

Antibiotic Use The association between prenatal antibiotic treatment and subsequent development of atopic disease has been examined in two ways: (1) with treatment as a dichotomous predictor (i.e., any antibiotic use) and (2) by number of courses of antibiotics during pregnancy. Longitudinal cohort studies examining any antibiotic use showed a greater risk for persistent wheeze and asthma in early childhood and a dose-response relation between number of antibiotic courses and risk of wheeze or asthma.

Adult-Onset Asthma

Asthma in adults may have persisted from childhood, may have occurred as a relapse of earlier childhood asthma (whether or not recalled by the affected patient) or may be true adult-onset asthma, with history of no symptoms earlier in life. New-onset asthma in adulthood may have environmental (especially occupational) causes with or without allergen sensitization. Although adult asthma may develop in relation to treatment with specific drugs (e.g., beta blockers, nonsteroidal antiinflammatory drugs) or, in women, the use of hormone replacement therapy, occupational exposure to sensitizing agents or irritants is more common.

Tobacco Smoke and Environmental Tobacco Smoke Exposure

Active smoking and environmental tobacco exposure are associated with increased bronchial responsiveness, frequent bronchial irritation symptoms, increased sensitization to occupational agents, exaggerated decline in lung function, aggravation of acute symptoms, and decreased response to the treatment.

Secondhand smoke is a combination of the smoke given off by the burning end of a cigarette, pipe, or cigar and the smoke exhaled by the smoker. Maternal smoking is the most important cause of secondhand exposure and is associated with the development of asthma in early life. In adults, secondhand smoke exposure increases the risk of asthma, wheezing, bronchitis, and dyspnea; this risk is significantly higher with a daily exposure of longer than 8 hours.

Occupational Exposure

Occupational asthma is found predominantly in adults, and workplace sensitization is responsible for 1 in 10 cases of asthma among adults of working age (see Chapter 40). High-risk occupations for the development of asthma include farming and agricultural work, painting, plastic manufacturing, and cleaning. IgE- and cell-mediated allergic reactions are involved in its pathobiology.

Infections

Early infections with RSV or parainfluenza virus have clinical features similar to symptoms of asthma. Prospective studies in infants infected with RSV early in life have shown that 40% continue with wheezing or develop asthma in later childhood.

Hygiene Hypothesis

The hygiene hypothesis, proposed by Strachan in 1989, suggested that infection and unhygienic contact with older siblings or through other exposures may confer protection against the development of atopy. The lower exposure to these infections among the youngest family members secondary to the improvement in standard of living, programs of immunization, and the indiscriminate use of antibiotics is suggested to be the origin of the problem.

TRIGGER FACTORS

As mentioned earlier, a number of factors are associated with worsening of symptoms and the development of asthma exacerbations.

DIRECT TRIGGERS

Respiratory Infections

Viral respiratory infections are the main trigger factors associated with exacerbations. In small children, RSV and parainfluenza virus are the most common agents; in older children and adults, rhinovirus and influenza virus are predominant.

Nonspecific Irritants

Smoke and bonfire exposure, industrial spills, and pollution (e.g., nitrogen dioxide, sulfur dioxide, carbon monoxide) are sources of nonspecific irritants. Outbreaks of asthma exacerbations have been shown to occur in relationship to increased levels of air pollution, although the role of pollutants in the development of asthma is less well defined.

Meteorologic Changes

Low temperatures, high humidity, cold, and dry air are common asthma triggers and can cause severe symptoms. Hot, humid air also can trigger asthma symptoms. In certain areas, heat and sunlight combine with pollutants to create ground-level ozone, which can be a strong asthma trigger. Wet weather (which encourages the growth of mold) and windy weather (which blows pollen and mold in the air) also are associated with worsening of symptoms.

INDIRECT TRIGGERS

Exercise

Exercise can induce an asthma attack in people who have no other triggers and do not experience asthma under any other circumstances. People with exercise-induced asthma are believed to be more sensitive to changes in the temperature and humidity of the air. The contrast between the warm air in the lungs and the cold inhaled air or the dry inhaled air and moist air in the lungs, evidently can trigger an attack.

Emotional Extremes

Laughing, weeping, anger, and fear all can provoke hyperventilation and unleash airway hyperreactivity, with consequent development of a bronchoconstrictive crisis.

Food Allergens

Food allergy is frequently associated with asthma. Eggs, peanuts, milk, soybean, shellfish, fish, wheat, chocolate, nuts, or orange, among others, might induce asthma in sensitized patients with an incidence between 3% and 10% of children with asthma.

Medications

Aspirin and other nonsteroidal antiinflammatory agents can exacerbate asthma and can cause severe exacerbations. Beta blocker drugs can induce bronchospasm in patients with asthma, either administered orally or intraocularly. Newer cardioselective beta blockers could be safer in asthmatics with ischemic heart disease although further studies are needed. Also, a number of studies have found an association between regular acetaminophen ingestion in early childhood and asthma. This association comes from the depletion induced by acetaminophen in the antioxidant glutathione in lung tissue. As a result, oxidative damage may occur, prostaglandin E_2 (PGE_2) production increases, and T_H2 processing may be promoted.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) can be silent in about 75% of cases and is a frequent cause of chronic cough and asthma exacerbations. In two series, between 50% and 80% of asthmatic patients reported classic GERD symptoms such as heartburn. The mechanism by which GERD can worsen asthma is mainly the tracheobronchial aspiration of gastric acid contents, resulting in airway inflammation. Different studies have determined that treating GERD in asthmatic patients reduces asthma treatment needs and decreases asthma symptoms, although no improvement in lung function test variables has been demonstrated. In fact, a systematic review that analyzed different treatment options for GERD symptoms in asthmatic patients concluded that none of the therapeutic interventions resulted in clinical improvement as reflected in reduced bronchial hyperreactivity or asthma-like symptoms.

Pregnancy

Asthma in pregnant women can remain unchanged, improve, or worsen, and it is estimated to be present in 4% to 8% of gestational women, as the predominant chronic respiratory disease during the gestational period. Asthma control and management should be established to ensure adequate fetal growth. The main complications are observed more frequently in patients with poorly controlled asthma, in women with severe asthma, and as a consequence of exacerbations predominantly secondary to viral infections. Although the principal physiopathologic mechanisms leading to changes in asthmatic pregnant women remain unclear, the elevation of different types of hormones (progesterone, cortisol) and the lack of treatment compliance during pregnancy seems to play an important role.

Section 7
AIRWAY DISEASES

Chapter 39
Diagnosis and Management of Asthma in Adults

Ian D. Pavord • Ruth H. Green • Pranabashis Haldar

Asthma is a disorder of the airways that is characterized by typical symptoms arising from a complex interplay between chronic inflammation and disordered airway function. Worldwide disease prevalence has, until recently, risen steadily, and the condition contributes to a significant amount of morbidity and is responsible for many preventable deaths, particularly in developed countries, where 1 in 10 children and 1 in 20 adults have a diagnosis of asthma. The goals of management of asthma are to make an accurate diagnosis; to quantify current morbidity and assess risk of future morbidity; and to use pharmaceutical and nonpharmaceutical interventions to eliminate or minimize current symptoms and future risk of asthma attacks and accelerated decline in lung function. Because asthma usually is a lifelong disease, good patient education and a collaborative approach to management can be expected to increase the chances of success. Pharmacologic management involves the stepwise use of β-agonist bronchodilators, inhaled corticosteroids, and other agents in dosages usually titrated according to symptom management. Important nonpharmacologic measures include patient education, avoidance of triggers, and smoking cessation. Satisfactory control of asthma is achieved in a majority of patients. However, between 5% and 10% of cases of so-called refractory asthma remain poorly controlled and contribute disproportionately to asthma-related morbidity, health care costs, and mortality. The reasons for this are complex and multifactorial, and many patients with refractory asthma require referral to specialist centers.

DEFINITION AND KEY FEATURES OF ASTHMA

Asthma is derived from the Greek word *aazein*, meaning "to labor in breathing" and was first used by Hippocrates, in 450 BCE, to describe a condition characterized by spasms of breathlessness. The present Global Initiative for Asthma (GINA) definition of the disease (**Box 39-1**) is a lengthy description of histopathologic, pathophysiologic, and clinical features that encompass the major disease characteristics. Fundamental features are airway hyperresponsiveness, chronic airway inflammation, disordered airway mucosal immunity, and structural changes to the airways (airway remodeling).

AIRWAY HYPERRESPONSIVENESS

Airway hyperresponsiveness is considered to be the cardinal pathophysiologic abnormality in asthma. It represents an exaggerated bronchoconstrictor response to a variety of largely exogenous inhaled stimuli causing bronchoconstriction, either by a direct effect on airway smooth muscle or indirectly by interacting with neural pathways or mast cells. Airway hyperresponsiveness is likely to be the basis for the variable airflow obstruction that is responsible for many of the day-to-day symptoms of asthma, including those associated with exercise-induced asthma, nocturnal asthma, and asthma induced by fumes or cold air.

Airway hyperresponsiveness can be objectively demonstrated as a 20% fall in the forced expiratory volume in 1 second (FEV$_1$) after inhalation of histamine or methacholine) at a concentration below 8 mg/mL. This represents an abnormal effector response of airway smooth muscle, characterized by heightened pharmacologic sensitivity and reactivity to the bronchoconstrictor stimulus (**Figure 39-1**). Naturally occurring airway hyperresponsiveness reflects an abnormally amplified response of airway nerves and mast cells to exogenous stimuli, as well as an intrinsic abnormality of the airway smooth muscle response. The basis for this generalized hyperresponsiveness is not entirely clear, but sensitization of airway nerves, mast cells, and smooth muscle by inflammatory mediators, along with loss of epithelial barrier function, reduced production of bronchoprotective factors, an intrinsic abnormality of airway smooth muscle, and structural changes to the airway, all are likely to play a part (**Figure 39-2**). One key pathologic feature associated with airway hyperresponsiveness in asthma not seen in nonasthmatic eosinophilic bronchitis is infiltration of the bronchial smooth muscle layer by mast cells, implying that the interaction between these cells is fundamentally important in the pathogenesis of airway hyperresponsiveness.

CHRONIC AIRWAY INFLAMMATION

Histopathologic examination of postmortem specimens from patients with fatal asthma show an inflammatory response characterized in many cases by the presence of airway eosinophilia. Typically, eosinophilic infiltration can be found throughout the airway wall, within thick viscid plugs that occlude the airway lumen and often extend into the lung parenchyma and alveolar spaces and even into adjacent blood vessels (see Figure 39-2). In addition, extensive eosinophilic degranulation with deposition of major basic proteins occurs. Associated findings include widespread shedding of the airway surface epithelium, thickening of the reticular basement membrane, and enlargement of airway smooth muscle and submucosal glands. A minority of patients dying from asthma, particularly those with sudden-onset fatal

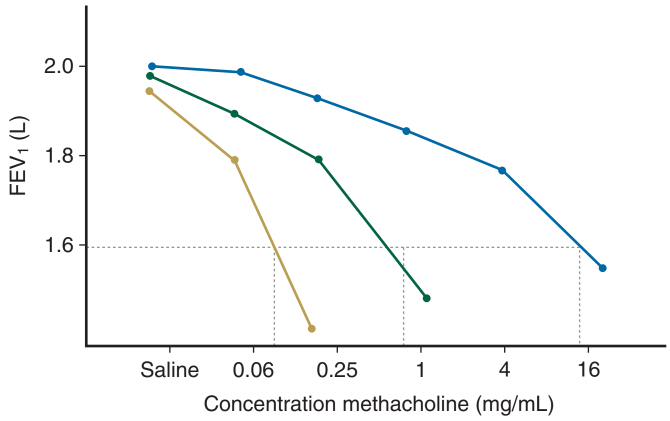

Figure 39-1 Airway responsiveness measured as the fall in forced expiratory volume in 1 second (FEV_1) after increasing inhaled concentrations of methacholine. Severe (*yellow*), moderate (*green*), and mild (*blue*) airway hyperresponsiveness are shown. Note increased airway responsiveness is associated with a lower provocative concentration required to cause a 20% fall in FEV_1 (PC_{20}) (see *green line*), a steeper gradient, and a higher maximum % fall in FEV_1.

Box 39-1 Global Initiative for Asthma (GINA) Description of Asthma

Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, in particular, mast cells, eosinophils, T lymphocytes, neutrophils, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning. These episodes are usually associated with widespread airflow obstruction that is typically reversible either spontaneously or with treatment.

From Global Strategy for Asthma Management and Prevention (Update 2009). Available at www.ginaaasthma.org.

asthma, exhibit evidence of eosinophilic inflammation. In these cases it is believed that widespread mast cell degranulation is the primary event with evidence for a relative excess of neutrophils in the distal airways and parenchyma.

Bronchoscopy and bronchial biopsy studies in patients with mild asthma show similar although less dramatic changes. Eosinophil numbers are increased in bronchial biopsy specimens and bronchoalveolar lavage (BAL) fluid, and the eosinophils are activated, with increased concentrations of major basic proteins and leukotrienes found in BAL fluid. Endobronchial biopsy specimens also show increased numbers of $CD4^+$ T cells of T_H2 type, producing the interleukins IL-4, IL-5, and IL-13. These cytokines increase production of IgE and play an important role in the maintenance of eosinophilic airway inflammation.

The limited number of patients studied by bronchoscopy makes it difficult to investigate heterogeneity of the lower airway inflammatory response, but less invasive assessment of airway inflammation using induced sputum analysis has shown that a significant proportion of patients with asthma studied when stable and during an attack have normal eosinophil numbers in induced sputum samples. This sputum cell profile has been reported in patients with severe asthma and in patients who are not treated with inhaled corticosteroids, and the absence of eosinophilic airway inflammation has been confirmed by bronchoscopy studies. Thus, the presence of a distinct noneosinophilic corticosteroid-resistant asthma phenotype across the range of asthma severity seems secure. Noneosinophilic asthma is discussed in more detail later in the chapter.

DISORDERED AIRWAY MUCOSAL IMMUNITY

The airway mucosa in persons with asthma mounts an abnormally amplified immunologic response to a variety of exogenous stimuli, including inhaled allergens, cigarette smoke, infectious agents, and air pollutants. Some or all of these abnormal responses may be the consequence of failure of maturation of the immune response in early life as a result of reduced exposure to pathogens at a critical point in development.

Particular interest has focused in the response to allergen, because atopy is twice as common in patients with asthma as in control subjects without asthma, and inhalation of allergen in a patient with atopic asthma who is sensitized to the allergen results in a marked eosinophilic airway inflammatory response, developing 4 to 6 hours after inhalation associated with airflow obstruction (the late response) and increased airway responsiveness lasting for days and weeks. Common aeroallergens in many Westernized countries include house dust mite, cat fur, grass pollen, ragweed, and *Aspergillus fumigatus* spores. Most patients with childhood-onset asthma are sensitized to one of more of these allergens, and many have extrapulmonary manifestations of allergy, including eczema and allergic rhinitis. Opinions regarding the significance of the response to allergen vary, ranging from a fundamentally important role in the pathogenesis of airway inflammation and dysfunction in asthma to a position in which it is seen as a more peripheral mechanism. The occurrence of histopathologically similar forms of asthma in nonatopic patients and the disappointing therapeutic effect of allergen avoidance and anti-IgE treatment suggest that the latter position is correct, although uncertainty remains.

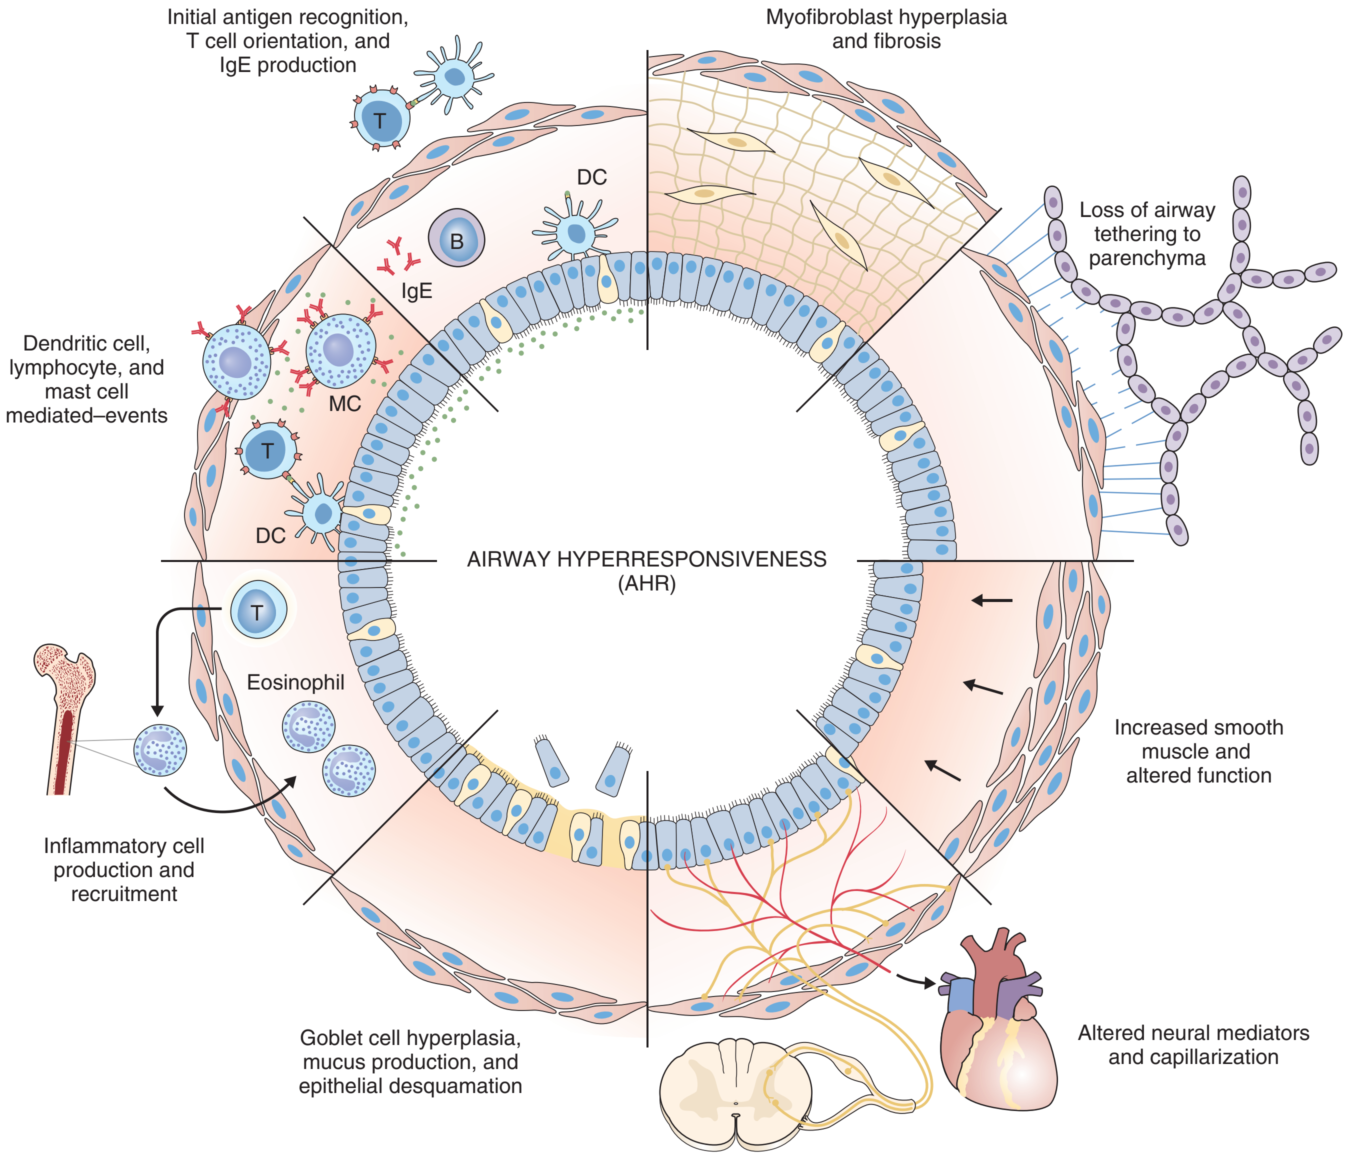
Growing evidence points to an abnormal airway response to infecting respiratory viruses, resulting in an amplified airway inflammatory response and more pronounced clinical consequences. The molecular mechanisms of this remain uncertain but constitute an active area of current study. There is little doubt that viral infection is an important trigger for acute severe asthma. Smoking and perhaps exposure to other environmental pollutants have been linked to worsening of symptoms, an increased risk of asthma attacks, and the development of fixed airflow obstruction. This association may reflect an abnormality of the innate immune response; patients with asthma who smoke or are exposed to environmental pollutants tend to have noneosinophilic, neutrophilic airway inflammation.

STRUCTURAL CHANGES TO THE AIRWAY

Structural changes in airway morphology (airway remodeling) probably occur as a result of chronic airway inflammation and dysfunction. These changes are likely to be the basis for the accelerated lung function decline and fixed airflow obstruction seen in some patients with asthma. Key features of airway remodeling include thickening of the subepithelial basement membrane caused by abnormal deposition of collagen, increased airway smooth muscle bulk, increased mucus-secreting cells, and increased airway vascularity (see Figure 39-2). In severe asthma, bronchiectasis, small airway fibrosis, and emphysema may be features. The bronchiectasis is associated with sensitization to *Aspergillus*.

PATHOPHYSIOLOGIC BASIS OF ASTHMA

Asthma is a complex condition in which it is not always obvious which of the various pathophysiologic abnormalities is



Initial antigen recognition, T cell orientation, and IgE production
T
Myofibroblast hyperplasia and fibrosis
DC
B
IgE
Loss of airway tethering to parenchyma
Dendritic cell, lymphocyte, and mast cell mediated–events
MC
T
DC
AIRWAY HYPERRESPONSIVENESS (AHR)
T
Eosinophil
Increased smooth muscle and altered function
Inflammatory cell production and recruitment
Goblet cell hyperplasia, mucus production, and epithelial desquamation
Altered neural mediators and capillarization

Figure 39-2 Schematic diagram of the inflammatory and remodeling processes in the airway that may potentially contribute to airway hyperresponsiveness and airflow obstruction. *(Courtesy Professor Mark Inman.)*

responsible for morbidity at any one time. In order to make some sense of this complexity, it can be helpful to consider five potentially important pathophysiologic factors, presented in alphabetical array for convenience:

- Airway hyperresponsiveness
- Bronchitis
- Cough reflex hypersensitivity
- Damage to the airways and surrounding lung
- Extrapulmonary factors.

These abnormalities are likely to be linked, but the mechanism is complex, and cross-sectional and longitudinal correspondence among them is not close. Accordingly, each is best considered as a relatively independent factor.

It is likely that these factors contribute to airflow obstruction and morbidity in different ways (Figure 39-3). Airway hyperresponsiveness is responsible for short-term, bronchodilator-responsive variable airflow obstruction which is the basis for many of the day-to-day symptoms experienced by patients and is suppressed by bronchodilator therapy, and to a lesser extent corticosteroids. Bronchitis, which may be eosinophilic and corticosteroid-responsive or neutrophilic and corticosteroid-unresponsive, manifests with cough and sputum and a relatively bronchodilator-resistant but potentially corticosteroid-responsive airflow obstruction of more gradual onset. Inflammation-mediated airflow obstruction is particularly important in the pathogenesis of asthma attacks. Cough and a small amount of sputum production is common in asthma. It probably reflects airway inflammation but also may be due to cough reflex hypersensitivity, a common but poorly understood and difficult-to-treat aspect of asthma and other airway diseases. Airway damage may manifest with disability caused by bronchodilator and corticosteroid-resistant airflow obstruction or mucus retention and infection as a result of airway and lung parenchymal damage. Extrapulmonary conditions linked to the inflammatory airway disease or independent of it also may contribute to symptoms (Box 39-2).

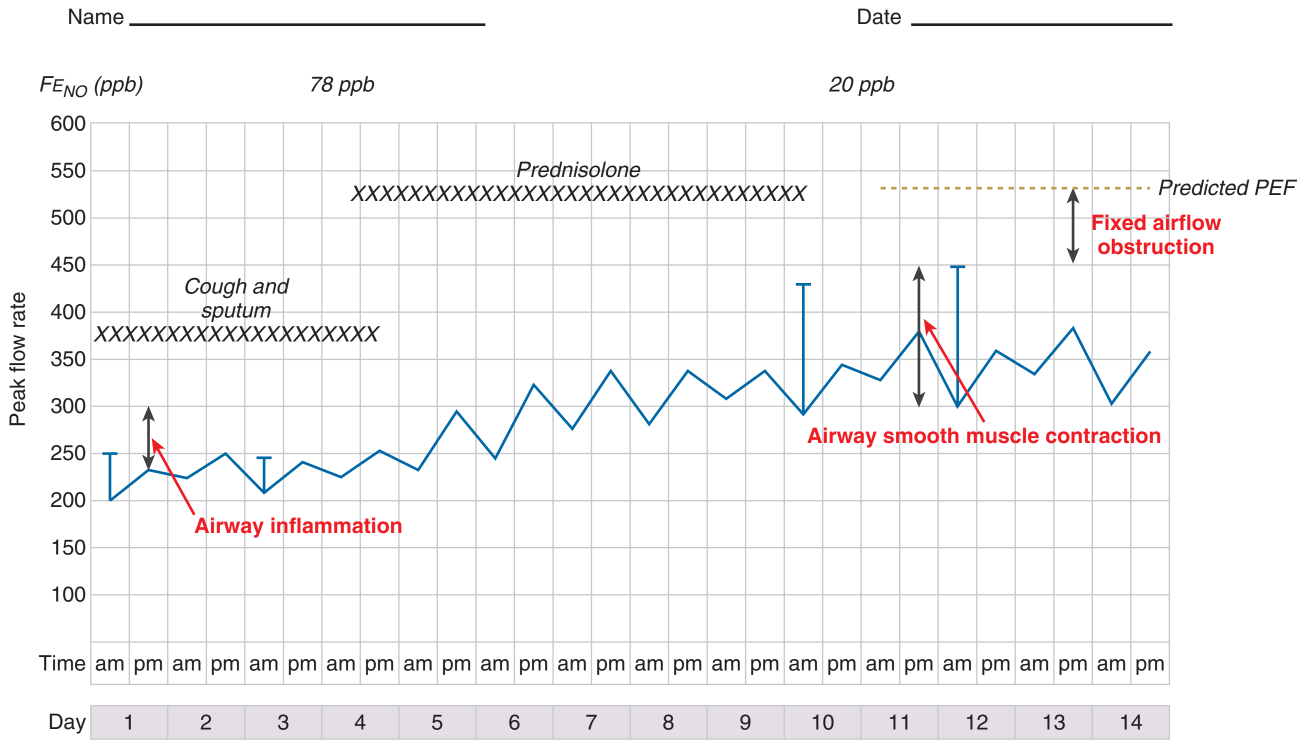


Figure 39-3 Peak expiratory flow (PEF) chart illustrating airflow obstruction due to at least three discrete mechanisms: airway smooth muscle contraction (note good acute response to inhaled salbutamol); airway inflammation (note loss of acute bronchodilator response but gradual increase in PEF with oral prednisolone); and airway damage (bronchodilator and steroid-unresponsive airflow obstruction).

Box 39-2 Differential Diagnosis of Asthma in Adults With and Without Airflow Obstruction*

Without Airflow Obstruction
Chronic cough syndromes
Hyperventilation syndrome
Vocal cord dysfunction
Rhinitis
Gastroesophageal reflux
Cardiac failure
Pulmonary fibrosis

With Airflow Obstruction
COPD
Bronchiectasis†
Inhaled foreign body†
Obliterative bronchiolitis
Large airway stenosis
Lung cancer†
Sarcoidosis†

*FEV_1 <70% predicted, FEV_1/FVC <0.7.
†May also be associated with nonobstructive spirometry values.
COPD, chronic obstructive pulmonary disease; *FEV_1*, forced expiratory volume in 1 second; *FVC*, forced vital capacity.

ASTHMA HETEROGENEITY AND CLINICAL SUBGROUPS OF PATIENTS WITH ASTHMA

Asthma has long been recognized as a heterogeneous disease. As early as 1918, Francis Rackemann identified clear clinical subgroups on the basis of history, skin tests, and response to "a clinical experiment such as a change in residence, a restriction in diet or an elimination of some supposedly offending substance." He made a distinction between "extrinsic asthma" due to "hypersensitivity to some foreign substance outside of the body and "intrinsic asthma . . . implying the essential cause of the trouble is inside of the body." The subdivision of extrinsic (atopic) and intrinsic (nonatopic) asthma remains popular. The most obvious difference is that the peak age at onset of atopic asthma is in childhood, whereas nonatopic asthma often manifests first in adults. It has not been possible to identify consistent histopathologic differences. In general, patients with atopic asthma exhibit more airway hyperresponsiveness and better responses to inhaled corticosteroids than those with nonatopic asthma. Nonatopic asthma is associated with greater heterogeneity of the lower airway inflammatory response, because a majority of patients with noneosinophilic asthma are nonatopic.

Asthma also has been classified according to the dominant clinical characteristic. Exercise-induced asthma, premenstrual asthma, and seasonal asthma are examples. These subdivisions help to remind the clinician of the dominant trigger but do not identify patients with a distinct pathologic process or treatment response. Important exceptions are aspirin-induced asthma, asthma in endurance athletes, and occupational asthma. These conditions are considered later.

Current interest is in categorization of asthma by the pattern of lower airway inflammation. The development of induced sputum as a means to non-invasively assess airway inflammation has made it possible to do this. Cross-sectional studies show that 20% to 40% of patients with symptomatic asthma do not have sputum evidence of eosinophilic airway inflammation. Many have a sputum neutrophilia and evidence of airway release of cytokines linked to the innate immune response. This sputum profile is evident in corticosteroid-naive as well as corticosteroid-treated persons and is consistently seen in patients with asthma, suggesting it is not always an artifact related to infection or treatment. Noneosinophilic asthma is clinically important, because response to corticosteroids is less pronounced in patients with this inflammatory profile than in persons with more typical sputum features. Noneosinophilic asthma has been associated with smoking, obesity, high-level endurance training in athletes, menopause, occupational endotoxin exposure, and recurrent bacterial bronchitis. Treatment and management approaches have not been investigated extensively, but aggressive corticosteroid therapy is unlikely to be helpful. Preliminary evidence indicates that long-term macrolide antibiotics may be of benefit.

Cross-sectional sputum studies also have shown that some patients with cough have eosinophilic airway inflammation but normal airway function (eosinophilic bronchitis). Eosinophilic bronchitis is closely related to "atopic cough," a condition described in Japan and characterized by cough, atopy, and evidence of large airway eosinophilic inflammation. Cough variant asthma initially was described as asthma manifesting with a bronchodilator-responsive chronic cough. More recently, this entity has been extended to encompass patients presenting with cough and objective evidence of asthma (i.e., variable airflow obstruction and/or airway hyperresponsiveness). All of these conditions are characterized clinically by a corticosteroid-responsive chronic cough.

GENETICS OF ASTHMA

Asthma has long been known to run in families. Studies of monozygotic and dizygotic twins, which control for environmental exposure, have estimated heritability of 30% to 70%. Considerable effort and resources have been put into identifying the genetic basis of asthma. This work is inevitably compromised by the rather general and imprecise definition of the disease, and results have been mixed and often are inconsistent. A better understanding of different phenotypes of asthma and a stronger focus on aspects of the disease (i.e., fixed airflow obstruction, airway hyperresponsiveness, atopy, eosinophilic airway inflammation), rather than on the syndrome, may be the way forward. Despite these limitations, some consistent genetic associations have been identified.

Functionally important polymorphisms of the prostaglandin D_2 (PGD_2) receptor gene have been associated with asthma in case control studies in racially diverse populations. PGD_2 is an important product of mast cells, and the receptor is involved in T cell recruitment. Mice deficient in this gene do not develop airway inflammation in response to allergen. Interest in this receptor has increased recently, because preliminary evidence indicates that PGD_2 receptor antagonists have useful therapeutic effects in asthma. Positional cloning studies have identified a consistent association between asthma and multiple single nucleotide polymorphisms of the *ADAM33* gene, particularly when asthma is associated with airway hyperresponsiveness or fixed airflow obstruction. This gene may be involved in control of airway structure and myogenesis. The minor allele (G) of the functional variant of the promoter region of the matrix metalloproteinase 12 gene (*MMP12*) has been associated with better lung function in patients with asthma and in smokers, suggesting a role for *MMP12* in maintaining lung function and raising the possibility of a common mechanism for the development of fixed airflow obstruction in smokers and in patients with asthma. Polymorphisms of the genes for IL-13 and FcεR1B, which modifies the activity of the high-affinity IgE receptor, may have a closer link with atopy, IgE, eosinophilic airway inflammation, and mucus production. Other genetic associations with asthma such as polymorphisms of the gene for the microbial pattern recognition receptors CD14, Toll-like receptor-1 (TLR-1), and this should be T cell immunoglobulin mucin-like domain-1 (TIM-1) may operate primarily by modifying innate immunity and the maturation of the immune system.

Genetic polymorphisms also may potentially influence the response to treatment. Variation in the gene for the β_2-adrenergic receptor (*ADRB2*) has been the subject of much interest, because persons who are Gly16 homozygotes or heterozygotes have a diminished acute bronchodilator response compared with Arg16 homozygotes. On the other hand, Arg16 homozygotes are more susceptible to β_2-receptor downregulation and may potentially be at risk for an adverse response to regular use of β_2-agonists. Evidence for such an effect, however, has not been seen consistently, particularly with long-acting β_2-agonists. Important genetic diversity in the response to corticosteroids has been more difficult to establish, in part because the response to this treatment is more difficult to quantify. The response to leukotriene antagonists has been associated with the C allele of the LTC4 synthase gene promoter (A-444C) polymorphism. This polymorphism is also associated with aspirin-induced asthma, an asthma variant associated with increased airway production of cysteinyl leukotrienes.

DIAGNOSIS

One of the problems facing clinicians and epidemiologists is the absence of a "gold standard" modality for defining or diagnosing asthma. Characteristic clinical features (Box 39-3) coupled with objective demonstration of variable airflow obstruction and/or airway hyperresponsiveness usually will provide sufficient evidence to make the diagnosis.

HISTORY

Asthma symptoms typically are variable reflecting variability in airflow obstruction and other aspects of the disease.

Box 39-3 Factors Affecting Likelihood of Asthma as Cause of Respiratory Symptoms*

Factors Associated With Increased Probability of Asthma
- More than one of the following symptoms: cough, breathlessness, wheeze, chest tightness
- Symptoms worse at night and in the early morning
- Symptoms occurring in response to exercise, allergen exposure, and cold air
- Symptoms developing after taking aspirin or beta blockers
- History of atopic disorder
- Family history of asthma and/or atopic disorder
- Variable wheeze heard on auscultation of the chest
- Variable PEF (see Clinical Examination Section)
- Otherwise unexplained low PEF

Factors Associated With Lower Probability of Asthma
- Prominent dizziness, light-headedness, peripheral tingling
- Isolated cough
- Repeatedly normal physical examination of chest when symptomatic
- Normal PEF when symptomatic
- Voice disturbance
- Symptoms with colds only
- Chronic productive cough
- Significant smoking history (i.e., more than 20 pack-years)
- Cardiac disease

*Presence of any one factor is sufficient evidence for or against a diagnosis of asthma.

PEF, peak expiratory flow [rate].

Exaggerated diurnal variation in physiologic bronchomotor tone causes airflow obstruction and symptoms at night, maximally at 4 AM. Other symptoms reflect airway hyperresponsiveness to a multitude of possible trigger factors. Symptoms occurring after exercise, after exposure to allergens, and in response to inhaled noxious fumes such as cigarette smoke are most commonly reported. Box 39-3 lists some of the symptoms that increase and decrease the probability of asthma. An assessment of disease severity can be made from the frequency of daily symptoms, exercise limitation, nocturnal wakening, and exacerbation frequency (**Table 39-1**).

The pattern of daytime symptoms and seasonal variations can help identify common triggers. In patients with adult-onset symptoms, the possibility of occupational asthma or an alternative diagnosis should be carefully explored. Symptoms that worsen at work but remit outside of the workplace should alert the clinician to the possibility of occupational asthma.

CLINICAL EXAMINATION

Findings on the clinical examination frequently are normal in persons with well-controlled symptoms. Patients with persistent symptoms may display features of obstructive airway disease, notably a hyperinflated and hyperresonant chest and diffuse polyphonic expiratory wheeze. These signs are indistinguishable from those found in chronic obstructive pulmonary disease (COPD). Physical examination is helpful for identifying features of an alternative diagnosis.

Measuring Airflow Obstruction

The demonstration of obstructive spirometry in patients with a history suggestive of asthma strongly supports the diagnosis and is a strong basis to commence therapy. Spirometry is the preferred method for demonstrating airflow obstruction, because it is less effort-dependent than peak expiratory flow. Airflow obstruction is defined as an FEV_1/FVC ratio of less than 0.7.

Measuring Variability in Airflow Obstruction

The spirogram frequently is normal in patients with asthma who are asymptomatic at the time of testing. In this clinical scenario, measurement of *variability* in airflow obstruction will provide useful additional information. A number of different methods exist to measure variability:

Diurnal variation in peak expiratory flow (PEF): Calculated from serial PEF measurements (see Figure 39-3); typically expressed as the difference between the highest and lowest daily readings as a percentage of the mean (see Table 39-1)

Assessment of the bronchodilator response: Measured as the change (improvement) in FEV_1 or PEF from baseline with either a short-acting bronchodilator (bronchodilator responsiveness) or after a therapeutic trial of corticosteroid (steroid responsiveness)

Assessment of airway responsiveness: Measuring the fall in FEV_1 in response to bronchoconstrictor stimuli, including pharmacologic agents (methacholine or histamine challenge tests), exercise, and allergen challenge (see Figure 39-1)

The measurement characteristics of the various tests to assess variable airflow obstruction and asthma in general are outlined in Table 39-1. An algorithm for the assessment of patients with suspected asthma is presented in **Figure 39-4**.

DIAGNOSTIC PATHWAY

The diagnostic pathway followed will depend on the pretest probability for the diagnosis, response to therapy, and level of clinical suspicion for an alternative diagnosis. The scope of the differential diagnosis is quite different in patients with and without airflow obstruction (see Box 39-2), and the main diagnostic question also is different. In the former, the clinician often is seeking support for a clinical diagnosis of asthma and the initiation of antiasthma therapy; in the latter, the evidence for an airway problem is more clear-cut, and the question is not whether inhalers should be used but how intensive the corticosteroid component of that therapy should be.

The key point in the history is to establish that symptoms are variable and linked to airflow obstruction and/or variable eosinophilic airway inflammation. Problems arise when symptoms are clearly associated with infections. A prolonged postviral cough is common in otherwise healthy persons but also can be the presenting manifestation of asthma. Recurrent bouts of bronchitis in a patient with a long-standing chronic productive cough and focal coarse crackles should raise the possibility of bronchiectasis. Prominent dizziness, panic, peripheral tingling, light-headedness, and chest tightness are very suggestive of dysfunctional breathing.

Vocal cord or glottic dysfunction is an important condition that can cause serious diagnostic difficulty in both adolescents and adults and, if not recognized, unnecessary overtreatment. Wheezing that arises from the glottis is heard throughout the lung fields but also is easy to hear without the stethoscope, with prominent noises arising from the neck. Direct visualization of the glottis by laryngoscopy may reveal the characteristic inspiratory apposition of the cords. Sometimes persons who have asthma make this noise, because they subconsciously feel the need to impress on the examiner the severity of their condition. In other patients, the noise occurs for purely psychological reasons, and no evidence of asthma is found. Patients may be of either gender but are often women in the age range of 16 to 50 years, who may have a paramedical background. Their “asthma” seems “resistant” to standard treatments, and often they have been hospitalized on many occasions and been treated unsuccessfully with large doses of corticosteroids and other treatments. Home peak flow readings and attempts at spirometry may be variable but show little correlation with attacks or treatment. Flow-volume curves may show a characteristic “fluttering” of the inspiratory curve. Measurement of total airway resistance in a body plethysmograph may be diagnostic, because the panting maneuver necessary for such measurement abolishes the vocal cord adduction, and airway resistance can be shown to be normal. Occasionally patients end up being mechanically ventilated because of “severe” asthma, but once pharmacologic paralysis is achieved, it can be seen that airway resistance is normal and that there is no necessity for high inflation pressures.

Vocal cord dysfunction probably is much more common than has been appreciated and if the condition is underdiagnosed or the relevant symptoms are mistaken for asthma, overtreatment is likely. Correct diagnosis is essential, and if vocal cord dysfunction is the sole or major part of the wheezing disorder, speech therapy can be helpful.

Diagnostic Strategy in Patients With Normal Spirometry Findings

In patients with normal spirometry findings, the primary considerations in the differential diagnosis are non–bronchodilator-,

Table 39-1 Summary of Tests Used to Assess Asthma

Measurement	Methodology	Measurement Characteristics	Comments
Spirometry	Enables clear demonstration of airflow obstruction FEV_1 largely independent of effort and highly repeatable Less applicable in acute severe asthma Assesses only one aspect of the disease state	Normal ranges widely available and robust Short-term (20-minute) 95% range for repeat measure of FEV_1 <160 mL; FVC <330 mL, independent of baseline value	Good for short- and longer-term reversibility testing in subjects with preexisting airflow obstruction >400-mL increase in FEV_1 highly suggestive of asthma Less helpful in subjects with normal pretreatment values because of ceiling effect
Peak expiratory flow (PEF)	Widely available and simple Applicable in a wide variety of circumstances including acute severe asthma PEF variability can be determined from home readings in most subjects PEF effort dependent and not as repeatable as FEV_1 Assesses only one aspect of the disease state	Normal ranges of PEF are wide, and currently available normative tables are outdated and do not encompass ethnic diversity Change in PEF more meaningful than absolute value >60 L/min increase in PEF suggested as best criteria for defining reversibility Normal range of PEF variability defined as amplitude % highest <8% or <20% depending on number of readings and degree of patient coaching	Useful for short- and longer-term reversibility testing in subjects with preexisting airflow obstruction Less helpful in subjects with normal pretreatment values because of ceiling effect Little information on the use of PEF variability as an index of treatment response PEF monitoring may improve asthma control in patients with more severe disease and in those with poor perception of bronchoconstriction
Asthma Control Questionnaire	Response to 7 questions, 5 relating to symptoms, 1 rescue treatment use and 1 FEV_1 Response usually assessed over the preceding week Shortened, five-question symptom only questionnaire is just as valid	Well-controlled: ≤0.75; inadequately controlled: ≥1.5 95% range for repeat measure ± 0.36 Minimal important difference 0.5	
Mini Asthma Quality of Life Questionnaire (AQLQ)	Response to 15 questions in 4 domains (symptoms, activity limitations, emotional function, environmental stimuli) Response usually assessed over the preceding week Closely related to larger 32-item Asthma Quality of Life Questionnaire	95% range for repeat measure ± 0.36 Minimal important difference 0.5	Well-validated quality of life questionnaire Could be used to assess response to longer term treatment trials
Airway responsiveness	Responsive to change (particularly indirect challenges such as inhaled mannitol) Less of a ceiling effect Not applicable in patients with impaired lung function (i.e., FEV_1/FVC <0.7 and <70% predicted)	Normal methacholine PC_{20} >8 mg/mL 95% range for repeat measure ± 1.5-2 doubling doses	Has not been widely used to monitor disease and assess treatment responses
Exhaled nitric oxide (FENO)	Measurements can be obtained in almost all adults Results immediately available Reasonably close relationship between FENO and eosinophilic airway inflammation, which is independent of gender, age, atopy, and inhaled corticosteroid use Not closely related to other measures of asthma morbidity	Normal range <25 ppb at exhaled flow of 50 mL/sec. 95% range for repeat measure 4 ppb >50 ppb highly predictive of a positive response to corticosteroid therapy <25 ppb highly predictive of a poor response to corticosteroids or successful step down in corticosteroid therapy	Evidence that FENO can be used to guide corticosteroid treatment is mixed. Protocols for diagnosis and monitoring have not been well defined, and more work is needed Low FENO (<25 ppb) may be of particular value in identifying patients who can step down corticosteroid treatment safely
Sputum eosinophil differential count	Information available in 80-90% of patients, although immediate results not available Sputum eosinophil count not closely related to other measures of asthma morbidity	Normal range <2%; 95% range for repeat measure ± 2-3 fold	Close relationship between raised sputum eosinophil count and corticosteroid responsiveness Use of sputum eosinophil count to guide corticosteroid therapy associated with reduced exacerbations in patients with more severe disease

non–corticosteroid-responsive conditions. All tests of variable airflow obstruction lack sensitivity in this setting, meaning that negative findings are not particularly helpful. Positive findings are obtained more frequently with repeated testing or if care is taken to perform the assessment when the patient is symptomatic. Assessment of airway hyperresponsiveness is a more sensitive test, so the absence of airway hyperresponsiveness should prompt careful consideration of an alternative diagnosis.

Diagnostic Strategy in Patients With Obstructive Spirometry

In patients with obstructive spirometry, tests of airway responsiveness and reactivity are less specific for a diagnosis of asthma. The measurement of airway hyperresponsiveness is therefore not helpful. Bronchodilator challenge tests and therapeutic trials of corticosteroid treatment may aid diagnosis, because larger changes in FEV_1 (i.e., more than 400 mL) are very suggestive of asthma. In many cases it may not be possible to assign a precise diagnostic label, although bronchodilator and steroid reversibility studies do help guide the intensity of therapy with these agents.

Other Investigations

Further investigations are helpful if an alternative diagnosis or presence of an additional disorder that may aggravate asthma symptoms is suspected. Further imaging of the upper airway, esophageal pH monitoring, a computed tomography (CT) chest scan, and sputum culture may help in selected cases. Objective assessment of atopy with skin prick testing or measurement of IgE and allergen-specific IgE may help support a diagnosis of atopic asthma and will provide an important guide to allergen avoidance strategies, anti-IgE treatment, and antifungal therapy (see further on). A raised blood eosinophil count commonly is seen in asthma; in the absence of an obvious systemic explanation (e.g., eczema), it is a specific but not sensitive marker of eosinophilic airway inflammation.

One of the most important recent advances in the field of assessment of airway disease has been the development of techniques to assess airway inflammation that are safe and feasible in most patients (i.e., inflammometry, as described later on). Two techniques are in widespread use: induced sputum analysis, in which differential and total cell counts are used to determine the characteristics and intensity of the lower airway inflammatory response, and measurement of exhaled nitric oxide (FENO), whereby the concentration of nitric oxide in exhaled air is used to provide information about the presence of potentially corticosteroid responsive airway inflammation. Measurement of FENO is particularly relevant to primary care practice, because the instruments needed for this assessment have become affordable, the technique is simple, and it provides an immediate result, making it ideal for monitoring purposes. A raised sputum eosinophil count or FENO concentration is sufficiently common in untreated asthma to be of diagnostic value, but abnormal results are nonspecific, occurring in up to a third of patients classified as having cough and COPD. The real value of these techniques is that raised values are strongly associated with a positive response to corticosteroid treatment irrespective of the context in which the abnormal test result occurs.

MANAGEMENT OF STABLE ASTHMA

AIMS

Three major consequences of clinical importance in asthma are recognized, as reflected in the following management goals:

1. Control of asthma symptoms
2. Prevention of asthma attacks
3. Preservation of normal lung function

Both pharmacologic and nonpharmacologic measures play an important role in achieving these aims (Box 39-4; Figures 39-5 and 39-6).

Control of Symptoms

Asthma symptoms are a cause of both physical and psychological morbidity that exert considerable impact on quality of life. Any of several well-validated questionnaires can be used to assess the control of asthma symptoms (see Table 39-1).

Prevention of Asthma Attacks

Asthma attacks are defined as periods of poor asthma control manifested by an increase in symptoms and deterioration in lung function that are not adequately managed by the individual patient's usual therapeutic regime. They frequently are precipitated by allergen exposure or viral infections. Severe attacks lead to hospitalization and constitute the primary cause of asthma-related death. The management of asthma attacks is considered later in this chapter.

Box 39-4 Goals of Asthma Management

- Minimal (ideally no) chronic symptoms, including nocturnal symptoms
- Minimal (infrequent) exacerbations
- No emergency visits
- Minimal (ideally no) use of β_2-agonist on an as-needed basis
- No limitations on activities, including exercise
- PEF circadian variation of less than 20%
- (Near-) normal PEF
- Minimal (or no) adverse effects

PEF, peak expiratory flow.

Addressing Lung Function Decline

Chronic asthma is associated with accelerated decline in lung function that is considered to be a function of persistent airway inflammation. Clinically important decrease in lung function may occur early in the disease, presenting a challenge to efforts at prevention. The rate of decline in adults is more marked in those with severe adult-onset disease, in smokers, and in patients with frequent exacerbations. Although interventions preventing decline are poorly understood, smoking cessation, early removal from occupational sensitizers, and possibly optimal corticosteroid therapy are likely to be effective.

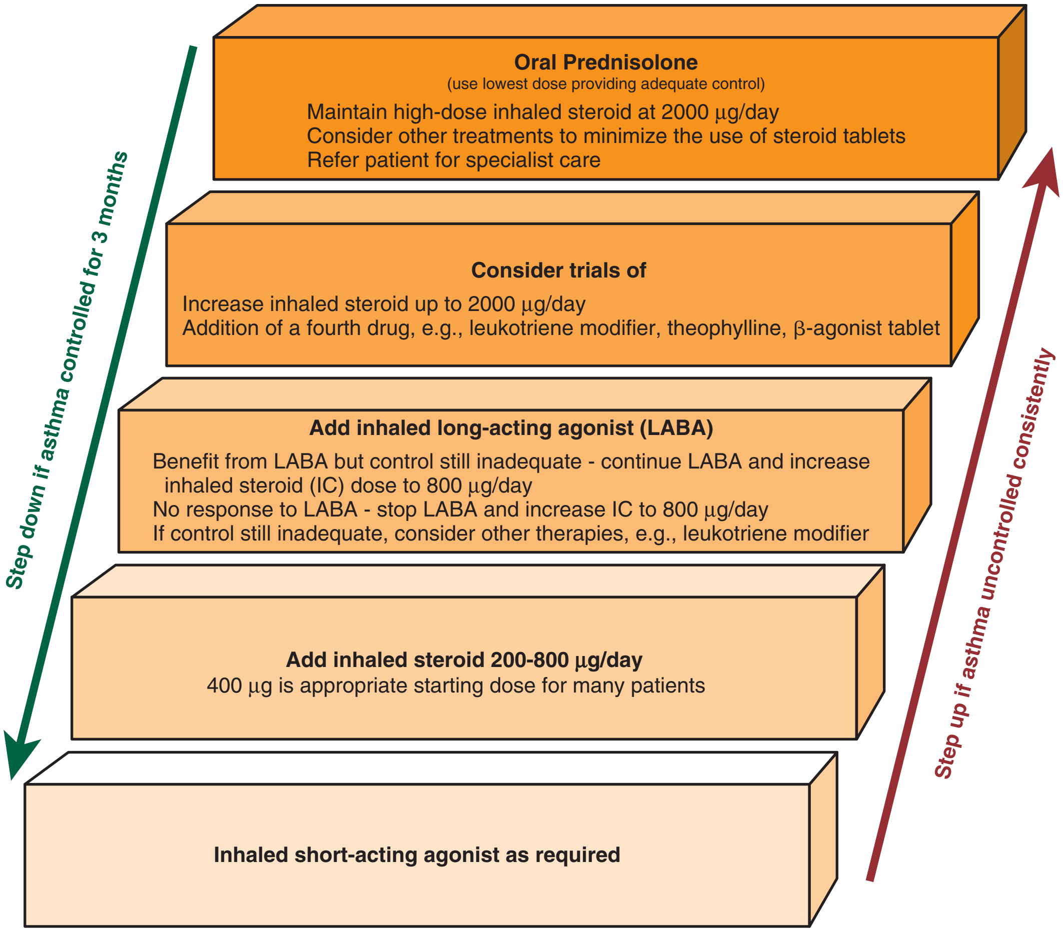
PHARMACOTHERAPY IN ASTHMA

Inhaled pharmacologic therapies are central to asthma management. The range of available drugs may be categorized mechanistically into bronchodilators and antiinflammatory agents.

Bronchodilators

β_2-*Agonists*

β_2-Agonists act by a common final pathway of increased intracellular cyclic adenosine monophosphate (cAMP) in smooth muscle cells that inhibits contractility, leading to improvements in lung function and decrease in airway hyperresponsiveness. The primary role of bronchodilators is in the relief and prevention of symptoms, by means of short- and long-acting agents, respectively. Additionally, the regular use of long acting bronchodilators can lead to sustained improvements in lung



Oral Prednisolone
(use lowest dose providing adequate control)
Maintain high-dose inhaled steroid at 2000 µg/day
Consider other treatments to minimize the use of steroid tablets
Refer patient for specialist care
Consider trials of
Increase inhaled steroid up to 2000 µg/day
Addition of a fourth drug, e.g., leukotriene modifier, theophylline, β-agonist tablet
Add inhaled long-acting agonist (LABA)
Benefit from LABA but control still inadequate - continue LABA and increase inhaled steroid (IC) dose to 800 µg/day
No response to LABA - stop LABA and increase IC to 800 µg/day
If control still inadequate, consider other therapies, e.g., leukotriene modifier
Add inhaled steroid 200-800 µg/day
400 µg is appropriate starting dose for many patients
Inhaled short-acting agonist as required
Step down if asthma controlled for 3 months
Step up if asthma uncontrolled consistently

Figure 39-5 Stepwise approach to asthma management in adults. *(Modified from British Thoracic Society/Scottish Intercollegiate Guidelines Network.)*

		Control of asthma symptoms	Prevention of exacerbations	Preservation of lung function

function and may reduce exacerbations, particularly less severe events.

Short-acting β_2-agonists are widely used for rescue symptomatic therapy. At present, long-acting β_2-agonists, such as salmeterol and formoterol, generally are recommended as agents of first choice for patients who have symptoms that persist despite regular inhaled corticosteroids. Salmeterol is a partial agonist of the β_2 receptor, whereas formoterol is a full agonist. These agents appear to have similar clinical effects, but formoterol has a more rapid onset of action. Side effects of tachycardia, tremor, and muscle cramps are rarely a problem unless these drugs are given in high doses. Tolerance to the effects of long-acting β_2-agonists with loss of bronchodilator activity after the subsequent administration of both short- and long-acting β_2-agonists has been reported but is of uncertain clinical relevance.

As with short-acting β_2-agonists, these agents work primarily through the relaxation of airway smooth muscle, with additional inhibitory effects on mast cells and vascular permeability. Long-acting β_2-agonists have no measurable effects on eosinophilic airway inflammation, and their use as first-line agents in patients with asthma is not recommended. When added to inhaled steroids, long-acting β_2-agonists control daytime and nighttime symptoms and reduce the need for rescue β_2-agonists more than other treatment options. The generalizability of the clinical trials showing this has been questioned, however, because most recruited only patients who demonstrated large acute improvements in FEV_1 after use of inhaled bronchodilators.

Theophylline

Theophylline has been used for many years in relatively high doses as a bronchodilator, but owing to its narrow therapeutic window and recognized adverse effects, it often has been reserved for use in patients with more severe asthma. Gastrointestinal upset is particularly common, but tachycardia and arrhythmia also can occur, and measurements of serum concentration generally are advised with high-dose treatment. Recent interest has focused on the use of lower-dose theophylline, because side effects are less of an issue, and the combination of low-dose inhaled corticosteroids and theophylline has been shown to result in asthma control comparable with that achieved with higher doses of inhaled corticosteroids and may provide slightly greater improvements in lung function. A metaanalysis has suggested that long-acting β_2-agonists are more effective than theophylline in patients taking low doses of inhaled corticosteroids and result in fewer side effects. Unlike long-acting β_2-agonists, however, theophylline has been shown to have possible antiinflammatory activity and may therefore have a role in the management of some patients with corticosteroid-resistant disease.

Antiinflammatory Therapies

Inhaled Corticosteroids

Inhaled corticosteroids are the mainstay of asthma pharmacotherapy. They act topically in the large- and medium-sized airways, binding to glucocorticoid receptors that are expressed ubiquitously by cells. The antiinflammatory effects of corticosteroids are mediated by the direct repression of transcription factors such as nuclear factor κB. The poor systemic bioavailability of inhaled corticosteroids minimizes systemic side effects, although chronic treatment with higher doses of potent steroid may be associated with mild adrenal suppression and stunted growth in children. Corticosteroids effectively suppress eosinophilic inflammation, which is associated with a decrease in symptoms, lower rate of exacerbations, and reduced asthma mortality.

Inhaled corticosteroids are less effective for managing severe asthma and may not be useful to treat severe asthma exacerbations, perhaps because of the intensity and site of airway inflammation. Oral therapy is believed to be more effective in these circumstances.

Patients often are concerned about the possibility of adverse effects of inhaled corticosteroids, and in some parts of the world, notably North America, this concern has led to their relative underuse. At low doses, up to 800 μg daily of beclomethasone dipropionate (BDP) or budesonide or 500 μg daily of fluticasone, side effects are not usually significant, but they do become an issue at doses above this. Furthermore, there is little additional therapeutic benefit beyond the point at which local and systemic side effects become common, and it is becoming clear that use of an alternative drug is a better strategy than increasing the dose of inhaled steroid in most patients.

Dysphonia commonly occurs as a consequence of deposition of inhaled corticosteroid particles locally in the oropharynx and local side effects such as oral candidiasis and hoarseness of voice may also develop. Use of a large-volume spacer device and careful rinsing of the mouth after the use of inhaled corticosteroids will reduce the risk of these local effects. Systemic side effects include bruising and atrophy of the skin, cataract formation, glaucoma, and reduced bone mineral density. Suppression of the adrenocortical axis can occur with high-dose inhaled corticosteroids, and specific advice on use of corticosteroid replacement therapy during intercurrent illness should be considered in patients who genuinely require long-term high-dose therapy. Systemic effects occur partly as a result of gastrointestinal absorption of swallowed particles and partly due to systemic absorption via the airways. The use of spacer devices, dry powder mechanisms, and mouth rinsing after inhaler use will minimize adverse effects. Another approach to minimize local side effects is to use ciclesonide, a prodrug that is activated by contact with the lower airway epithelium. Drugs with high first pass metabolism in the liver such as budesonide and fluticasone have less systemic side effects than beclomethasone, but at high doses (more than 800 to 1000 μg daily of BDP/budesonide or more than 500 μg daily of fluticasone), systemic absorption through the buccal and airway mucosa becomes increasingly important.

Antileukotrienes

Antileukotrienes act by inhibiting different levels of the lipoxygenase pathway, which is involved in the formation of leukotrienes from arachidonic acid. Leukotrienes are important proinflammatory mediators in asthma that also promote bronchoconstriction. Leukotriene receptor antagonists (e.g., montelukast) reduce exercise-induced asthma and have a modest suppressive effect on asthma symptoms. They appear to work best in patients not taking inhaled corticosteroids and, because of their excellent safety profile, often are considered for use in children. Inhibitors of leukotriene biosynthesis may offer an advantage over receptor antagonists in that they inhibit production of the noncysteinyl leukotriene LTB_4. Whether this results in important clinical advantages has not been clearly defined, and concerns have been raised about liver toxicity with the only available inhibitor, zileuton.

Oral Corticosteroids and Corticosteroid-Sparing Agents

A further group of patients have severe persistent asthma that remains difficult to control despite the aforementioned measures as outlined. In these circumstances, treatment with oral corticosteroids, usually in the form of daily prednisolone, may be required to minimize symptoms and prevent severe asthma exacerbations. Although courses of oral corticosteroids are unquestionably a vital part of the management of acute exacerbations, careful consideration should be made before they are administered on a long-term basis because of the high associated risk of significant adverse effects. When they are required, the lowest dose that maintains asthma control should be given. Preventive therapy for osteoporosis should be considered, and patients should be monitored for the development of hypertension, diabetes, cataracts, glaucoma, and adrenal suppression. Obesity, thinning and bruising of the skin, and myopathy also are important concerns. Inhaled corticosteroids should always be continued, because these agents are likely to allow a reduction in the oral corticosteroid dose; this may be one situation in which higher-dose inhaled steroids are justified.

Corticosteroid-sparing agents include methotrexate, gold, and cyclosporine. Some evidence suggests that these agents have steroid-sparing effects in asthma, but each comes with its own safety concerns, and use of these agents should be confined to specialist units. The risk of adverse effects from the use of long-term oral corticosteroids and the lack of safe alternatives necessitate careful monitoring of the response to treatment. A small minority of patients with severe asthma demonstrate resistance to corticosteroid treatment despite apparently good compliance. The mechanisms for this resistance are not fully understood but may relate to transcriptional regulation of genes associated with steroid-responsive inflammation.

Anti-IgE Monoclonal Antibody

IgE has an important role in the development of allergic diseases in atopic persons, and suppression of IgE is therefore a potential target in the management of atopic asthma. The monoclonal antibody omalizumab blocks the interaction of IgE with mast cells and basophils. It is given as a subcutaneous injection at doses titrated to serum IgE levels and patient weight. Clinical trials have shown improved symptom control, fewer exacerbations, and greater reductions in inhaled corticosteroid dose with no apparent adverse effects. The therapy is expensive, however, and the efficacy and cost-effectiveness of treatment in unselected patients remain uncertain. Omalizumab therefore appears to be a potentially useful antiinflammatory agent in patients with atopic asthma.

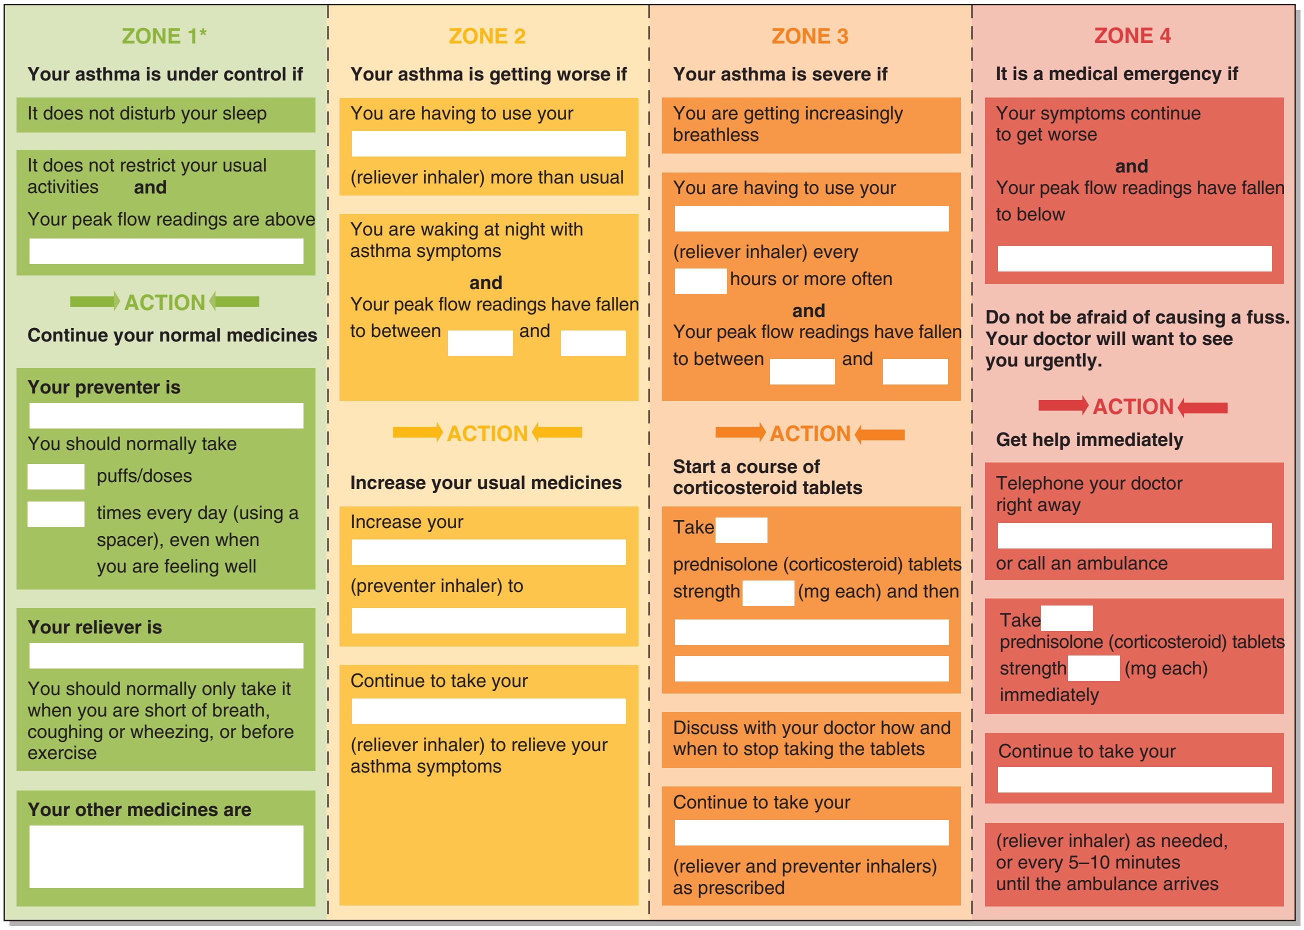
STEPWISE ALGORITHM FOR ASTHMA TREATMENT

Guidelines recommend the titration of therapy for asthma in a stepwise manner, with the primary aim of satisfactorily controlling symptoms at the lowest dose of corticosteroid (see Figure 39-5). Changes in therapy should be reviewed every 3 months until stability is achieved. This algorithm assumes clinical control is concomitantly associated with control of underlying airway inflammation and therefore fulfillment of all three targets of care.

Of note, step 3 of the British Thoracic Society (BTS) treatment pathway recommends the addition of a long-acting β-agonist to low-dose corticosteroid therapy over an increase in corticosteroid dose. There is molecular evidence for a synergistic effect between the two drug classes. In clinical practice, the strategy achieves clinical improvement, as indicated by reduction of symptoms, optimization of lung function, and a fall in exacerbation frequency, comparable with that provided by a dose escalation in corticosteroid alone. Combination inhalers of long-acting β-agonists and inhaled corticosteroids have been developed and are now commonly prescribed. They have the advantage of patient convenience but do not allow independent dose alterations of the component drugs.

Monitoring Asthma Control and Guided Self-Management Plans

A number of potential tools are available to assess asthma (see Table 39-1). All such tools assess different aspects of the disease, and it is likely that they provide complementary information. Objective symptom scores are particularly useful, because



ZONE 1*

Your asthma is under control if

It does not disturb your sleep

It does not restrict your usual activities **and**

Your peak flow readings are above

ACTION

Continue your normal medicines

Your preventer is

You should normally take

puffs/doses

times every day (using a spacer), even when you are feeling well

Your reliever is

You should normally only take it when you are short of breath, coughing or wheezing, or before exercise

Your other medicines are

ZONE 2

Your asthma is getting worse if

You are having to use your

(reliever inhaler) more than usual

You are waking at night with asthma symptoms

and

Your peak flow readings have fallen to between and

ACTION

Increase your usual medicines

Increase your

(preventer inhaler) to

Continue to take your

(reliever inhaler) to relieve your asthma symptoms

ZONE 3

Your asthma is severe if

You are getting increasingly breathless

You are having to use your

(reliever inhaler) every

hours or more often

and

Your peak flow readings have fallen to between and

ACTION

Start a course of corticosteroid tablets

Take

prednisolone (corticosteroid) tablets strength (mg each) and then

Discuss with your doctor how and when to stop taking the tablets

Continue to take your

(reliever and preventer inhalers) as prescribed

ZONE 4

It is a medical emergency if

Your symptoms continue to get worse

and

Your peak flow readings have fallen to below

Do not be afraid of causing a fuss. Your doctor will want to see you urgently.

ACTION

Get help immediately

Telephone your doctor right away

or call an ambulance

Take

prednisolone (corticosteroid) tablets strength (mg each) immediately

Continue to take your

(reliever inhaler) as needed, or every 5–10 minutes until the ambulance arrives

*If you are persistently in this zone, your doctor may reduce your usual medication.

Figure 39-7 Page from a typical preprinted self-treatment plan. *(From Partridge MR: Asthma: clinical features, diagnosis, and treatment. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, Mosby, 2008.)*

patients may adjust to their impairment and not question symptoms that are potentially reversible. The extent to which these assessments allow risk stratification is unclear; this is an important area for further study. Table 39-1 outlines the characteristics of some of the most common methods used to assess asthma.

Regular review appointments also provide an opportunity to review patient education, inhaler technique, and self management skills. Self-management plans are individualized written protocols instructing patients in recommended courses of action on the basis of their asthma control that is graded and risk-stratified according to symptoms or peak flow (Figure 39-7). They are attractive for being patient-centered. Both symptom- and peak flow–guided plans lessen asthma morbidity and reduce the frequency of hospitalizations and unscheduled doctor visits. Although little evidence has been found for the superiority of one strategy over another, a peak flow–based plan may be more appropriate in patients with impaired perception of airflow obstruction.

Referral to a Specialist

Asthma often is managed very successfully in primary care. Patients for whom referral for specialist care typically will be required fall into three broad groups:

- Patients with suspected occupational asthma
- Patients with treatment-refractory asthma, defined as those failing to achieve control despite appropriate high-dose therapy (BTS step 4 or 5). Although constituting 5% to 10% of the asthma population, this group accounts for over 60% of health care resource utilization for asthma in the United Kingdom. The reasons for a poor therapeutic response are multifactorial (Box 39-5).
- Patients at higher risk for asthma-related death (Box 39-6). Relative risk is additive; accordingly, patients with several minor risk factors, as well as those with a single major risk factor, require referral.

NONPHARMACOLOGIC ASPECTS OF ASTHMA CARE

Patient Education

Appropriate patient education is essential for the provision of care based on self-management. Several aspects of this component of the management program have been identified:

- Identifying and avoiding asthma triggers, the most important of which is smoking.
- Understanding the role of different prescribed therapies—that is, distinguishing between therapy for immediate relief from symptoms ("relievers") and therapy to prevent or reduce the frequency of symptoms ("preventers"), to support compliance with therapy, which is a considerable problem in asthma care
- Encouraging compliance with medication
- Ensuring correct inhaler technique
- Recording and monitoring peak flow
- Following a self-management plan

Box 39-5 Factors Contributing to Refractory or Severe Asthma

Patient Factors

- Poor inhaler technique and incorrect use of inhalers
- Poor compliance with therapy
  - Particularly in younger patients and those with psychological disorders
- Persistent exposure to sensitized allergen
  - Occupation
  - Pets
- Smoking
  - Associated with increased symptoms, accelerated decline in lung function, and impaired steroid responsiveness
- Obesity
  - Associated with increased symptoms and impaired steroid responsiveness
- Concomitant psychological morbidity
  - Both anxiety and depression can heighten perception of breathlessness, leading to increased symptoms

Disease Factors

- Coexistent aggravating disorders
  - Dysfunctional breathing disorders
  - Rhinosinusitis
  - GERD
  - Cardiac failure
- *Aspergillus*-associated asthma
  - Associated with more intense eosinophilic airway inflammation and bronchiectasis
- Churg-Strauss syndrome
- True steroid-resistant asthma
  - This subgroup constitutes a minority of patients with refractory asthma
  - High doses of oral or parenteral steroid usually overcome the impaired response to conventional therapy
- Absence of demonstrable eosinophilic airway inflammation (noneosinophilic asthma)
  - Patients with this condition have corticosteroid resistance, so escalation of steroids unlikely to be helpful
  - Best management uncertain

GERD, gastroesophageal reflux disease.

Box 39-6 Risk Factors for Severe Asthma

Major Risk Factors

- Previous mechanical ventilation for asthma
- Previous admission to intensive care unit
- Recent hospital admission for asthma

Minor Risk Factors

- Asthma requiring oral steroids or theophylline for control
- High β-agonist consumption
- Factors associated with poor compliance
  - Lower socioeconomic class
  - Coexistent psychopathology
  - History of drug abuse or alcohol dependence
  - Adolescence

Specialist asthma nurses are central providers of information and education for patients. Regular follow-up with an asthma nurse reinforces key messages and leads to superior asthma control.

Smoking Cessation and Allergen Avoidance

Approximately 25% of patients with asthma smoke. Smoking in this population is associated with increased symptoms and accelerated lung function decline. Smoking cessation studies have shown a significant improvement in the control of symptoms and lung function within weeks of stopping.

Allergen sensitization and exposure are common and often contribute to increased asthma symptoms. Simple measures such as limiting contact with household pets, notably cats, should be advised. Evidence is lacking for a proven benefit of more intensive and often expensive measures to lower the burden of ubiquitous allergens (e.g., house dust mite). Regular use of antihistamines may be helpful when there is a clear association between allergen exposure and deteriorating asthma control (e.g., loss of control with concomitant hay fever).

Breathing Retraining Techniques

Disordered breathing patterns such as hyperventilation frequently coexist with asthma and may contribute significantly to the clinical expression of asthma-like symptoms. The diagnosis should be suspected in patients with prominent symptoms that do not follow a predictable or episodic pattern and are out of proportion to objective evidence of airway dysfunction. Physiotherapy-based breathing retraining programs can be effective and may avoid the inappropriate escalation of pharmacotherapy.

RECENT DEVELOPMENTS IN ASTHMA MANAGEMENT

The failure to optimize asthma control in some patients highlights deficiencies in current therapeutic modalities and strategies. Four key areas of ongoing research are likely to influence future asthma care, particularly in subgroups of patients with refractory disease:

- Inflammation-guided management (inflammometry)
- The use of a single inhaled combination treatment for relief and maintenance therapy
- The development of monoclonal antibody therapies as targeted antiinflammatory agents
- Novel techniques for treating airway dysfunction

Inflammometry

Several important observations have increased interest in the use of inflammometry in the clinical assessment of asthma and other airway diseases. First, the presence of eosinophilic, corticosteroid-responsive airway inflammation is not closely related to either the pattern or the severity of the airway dysfunction or symptoms. A raised sputum eosinophil count is seen in 70% to 80% of corticosteroid-naive patients with asthma, 50% of corticosteroid-treated patients with symptomatic asthma, 30% to 40% of patients with cough, and up to 40% of patients with COPD. Within diagnostic groups, a weak correlation has been noted between the presence of eosinophilic airway inflammation and the severity of symptoms or disordered airway function. Thus, little can be deduced about the presence and severity of eosinophilic airway inflammation from a standard clinical assessment, and if this information is required, then measurement of the sputum eosinophil count is informative.

Second, the presence of eosinophilic airway inflammation is more closely associated with a positive response to corticosteroids than any other clinical measure. Moreover, a positive response to corticosteroids is seen irrespective of the pattern of airway disease in which eosinophilic airway inflammation occurs. Thus, if the clinical question were whether a patient with chronic respiratory symptoms should receive corticosteroid treatment, then the identification of a raised sputum eosinophil count or FeNO would be a better basis for making this decision than the findings of other tests.

Third, the sputum eosinophil count is a better marker for titrating corticosteroid therapy than are standard clinical measures. Studies in asthma and COPD have shown that use of management strategies in which decisions about corticosteroid use and dose are guided by the sputum eosinophil count results in a lower frequency of exacerbations and more economical use of corticosteroids in comparison with management guided by traditional clinical measures. FENO measurements also have been used to guide corticosteroid treatment, but with more mixed results. Studies thus far have suggested that FENO-based management may allow more economical use of corticosteroids by more accurately identifying patients in whom reduced doses will suffice.

The link between eosinophilic airway inflammation and corticosteroid responsiveness, together with the development of inexpensive nitric oxide monitors, has opened the way for a new approach to the management of airway disease in clinical practice, with the emphasis more on assessing airway inflammation than on diagnostic labeling. Figure 39-8 outlines an approach to assessment of patients presenting with new-onset airway disease whereby decisions about the use of corticosteroids are based on assessment of eosinophilic airway inflammation or FENO, rather than on recognition of patterns of symptoms and airway dysfunction.

Single-Inhaler Therapy

The combination of budesonide and formoterol is licensed for use in a single combination inhaler for relief of symptoms and maintenance of asthma control. This dual role is made possible because formoterol is a long-acting β-agonist with a rapid onset of action, comparable with that of salbutamol. Thus, the frequency of inhaler use will be governed by the severity and frequency of symptoms, ensuring higher doses of corticosteroid during periods of poor control. This is appropriate if deteriorating symptoms are associated with worsening underlying airway inflammation. Studies have shown improvements in lung function, reduction in exacerbation frequency, and better symptom control with this approach. It may be particularly applicable in patients with variable treatment adherence.

Monoclonal Antibody Therapies

A growing number of monoclonal antibodies are being developed to target key proinflammatory mediators of the T_H2 pathway that are considered important for perpetuating inflammation in asthma. Of these, mepolizumab, a monoclonal antibody blocking IL-5 (a key cytokine responsible for eosinophil maturation and recruitment) has been shown to reduce the frequency of severe exacerbations in patients with severe asthma and eosinophilic airway inflammation. Trials exploring blocking antibodies to IL-4 and IL-13 and oral antagonists of the PGD_2 receptor $CRTH_2$ also are under way. It is likely that all of these agents will work best in the subgroup of patients with an eosinophilic T_H2-type pattern of airway inflammation and that the main benefits of treatment will be a reduction in frequency of asthma attacks. Identification of these patients by means of inflammometry will become increasingly important.

Bronchial Thermoplasty

Bronchial thermoplasty offers a nonpharmacologic approach to asthma treatment. The technique is targeted at the airway smooth muscle, which is considered central to airway dysfunction in asthma. Thermal energy is applied bronchoscopically to the bronchial wall using a wire basket. (A video of the procedure is available on Expert Consult.) Bronchial thermoplasty is thought to prevent bronchoconstriction by disrupting airway smooth muscle bundles. A sham-controlled study has shown improvement in asthma-related quality of life and reduced exacerbation numbers for at least a year after the procedure.

MANAGEMENT OF IMPORTANT PATIENT SUBGROUPS

SEVERE ASTHMA

A proportion of patients will have persistent symptoms despite appropriate treatment for moderate persistent asthma as just outlined. Although representing a relatively small minority, these patients experience much morbidity, consume significant health care resources, and probably are best managed in specialist settings. Severe asthma can be defined simply as asthma that continues to cause significant morbidity despite high-level anti-asthma therapy (i.e., step 4 of the BTS asthma management guidelines) (see Figure 39-5).

Increase dose Consider referral

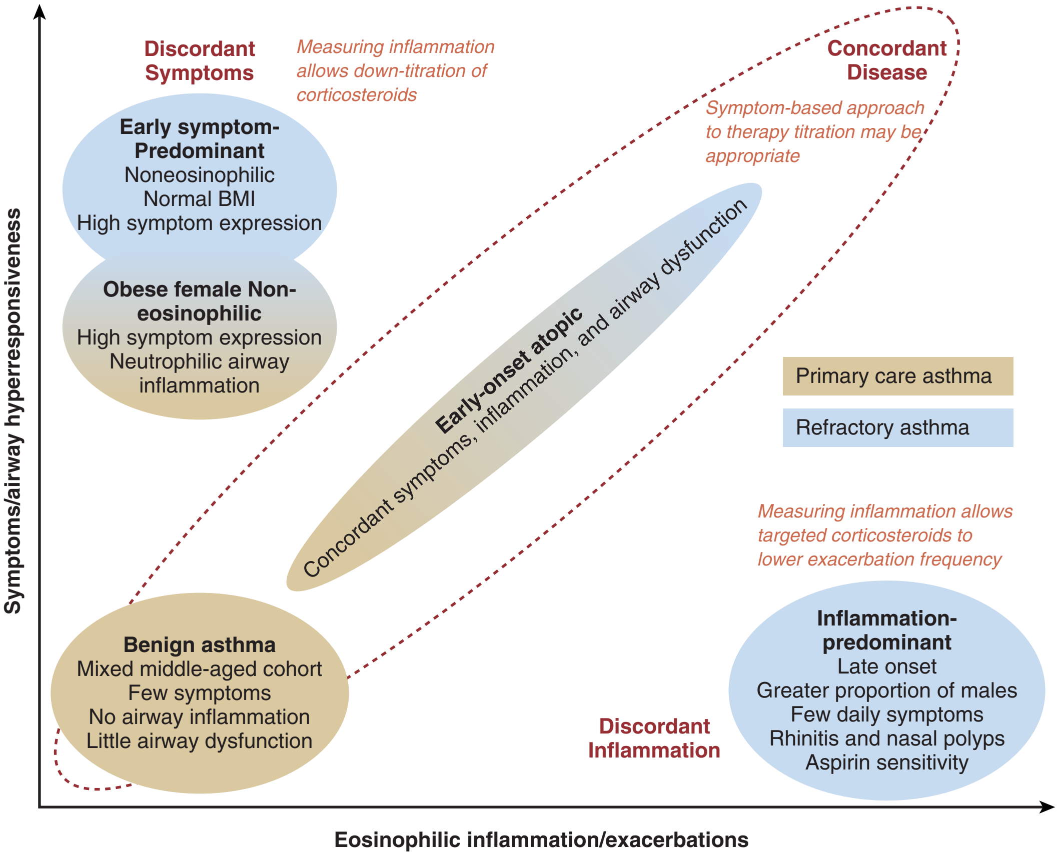
Figure 39-8 Suggested algorithm for assessment of airways disease. Eosinophilic airway inflammation can be assessed using induced sputum eosinophils or FENO. *Potentially treatable aggravating factors include rhinitis, anxiety-hyperventilation syndrome, vocal cord dysfunction, bronchiectasis, and gastroesophageal reflux disease. †Symptomatic therapy includes short- and long-acting bronchodilator therapy, oral theophylline, and mucolytics, as well as specific treatments for the aggravating factors. ‡As supported by limited evidence, some patients with symptoms suggesting airways disease have raised FENO that is not reflective of eosinophilic airway inflammation and is not corticosteroid-responsive. Therefore, a persistently raised FENO after corticosteroid treatment should prompt a more thorough assessment of airway inflammation using induced sputum specimens when available. The suggested cutoff points for "high" and "low" FENO in adults are 25 ppb and 50 ppb, respectively, but this is a very loose guideline. The interpretation of FENO in the range of 25 to 50 ppb varies between individual patients, and in some instances, different cutoff points may apply.

Before additional therapeutic measures are considered, it is important to accurately confirm the diagnosis, to ensure that persistent symptoms are due to asthma, rather than to other aggravating or coexisting factors such as dysfunctional breathing, vocal cord dysfunction, obesity, bronchiectasis, COPD, rhinitis, or gastroesophageal reflux (see Box 39-5). Box 39-3 lists some features that increase the probability that non–asthma-related factors are responsible for persistent morbidity. Next, it is important to assess compliance with existing therapy, ideally using relatively objective measures such as prescription refill rates and blood theophylline and/or prednisolone levels. Poor adherence is very common in patients with severe asthma and has been linked with poor outcomes, notably an increased risk of fatal and near-fatal attacks. The best means to detect poor treatment adherence and to tackle it have yet to be established. This is an important area for further study.

Once these issues have been addressed, current guidelines advocate a step up in treatment, usually to regular oral steroids. The response to oral steroids, however, is known to be mixed, and side effects are an important issue; moreover, the efficacy of alternative drugs in patients with severe asthma often has not been well established. Much of the current research effort in severe asthma focuses on patients with severe asthma, and there is increasing realization that new treatments are unlikely to be helpful in all patients. The future is likely to be individualization of treatment based on a more complete understanding of the mechanism of persistent morbidity and the ways in which this can be modulated.

Recently there have been attempts to identify clinically important groups of patients using mathematical techniques such as factor analysis and cluster analysis. **Figure 39-9** shows the results of one of the first attempts to phenotype patients with asthma recruited from primary care practices and from a severe asthma cohort being seen in a specialist hospital clinic. The main finding was that patients with severe asthma had more marked discordance in expression of symptoms and airway inflammation. The presence of these discordant phenotypes in patients with refractory asthma in particular suggests that a management approach which relies on symptoms to guide antiinflammatory treatment would result in suboptimal outcomes in a significant number of patients and that management guided by an objective measure of corticosteroid-responsive inflammation (i.e., eosinophilic airway inflammation) may be better. This is exactly what has been found in trials that have compared inflammation-guided use of steroids with symptom-guided use. The main outcome of these trials has been a reduction in the frequency of asthma attacks, suggesting that the main clinical benefit of controlling eosinophilic airway inflammation is to reduce the risk of attacks.

The recognition of these various groups of patients not only helps to guide corticosteroid treatment but also may identify patients for whom alternative noncorticosteroid treatments may be helpful. Long-term low-dose macrolide antibiotics may be particularly effective in patients with refractory noneosinophilic asthma. Bronchial thermoplasty, a treatment that specifically targets airway smooth muscle but has no known effect on



Symptoms/airway hyperresponsiveness
Discordant Symptoms
Measuring inflammation allows down-titration of corticosteroids
Concordant Disease
Symptom-based approach to therapy titration may be appropriate
Early symptom-Predominant
Noneosinophilic
Normal BMI
High symptom expression
Obese female Non-eosinophilic
High symptom expression
Neutrophilic airway inflammation
Early-onset atopic
Concordant symptoms, inflammation, and airway dysfunction
Primary care asthma
Refractory asthma
Measuring inflammation allows targeted corticosteroids to lower exacerbation frequency
Benign asthma
Mixed middle-aged cohort
Few symptoms
No airway inflammation
Little airway dysfunction
Discordant Inflammation
Inflammation-predominant
Late onset
Greater proportion of males
Few daily symptoms
Rhinitis and nasal polyps
Aspirin sensitivity
Eosinophilic inflammation/exacerbations

Figure 39-9 Clinical phenotypes of asthma: A summary of phenotypes identified using cluster analysis in primary and secondary care asthma populations. The clusters are plotted according to their relative expression of symptoms and inflammation, because these are the two clinically pertinent and modifiable dimensions of the disease. The plot highlights greater discordance to be a feature of secondary care asthma. Although reasons for this dissociation are unclear, the use of measures of airway inflammation in these subgroups is clinically informative. *BMI*, body mass index. *(Reproduced with permission from Haldar P, Pavord ID, Shaw DE, et al: Cluster analysis and clinical asthma phenotypes*, Am J Respir Crit Care Med *178:218–224, 2008.)*

airway inflammation, may also be a helpful treatment in patients with predominant airway dysfunction. Patients with inflammation-predominant disease, without much in the way of day-to-day symptoms or disordered airway function, may benefit from specific antiinflammatory treatments such as anti-IL-5, omalizumab, and, if they are sensitized to *Aspergillus*, antifungal treatment. Mepolizumab, the monoclonal antibody against IL-5, is a particularly attractive treatment option, because it is a very specific and effective inhibitor of the eosinophilic airway inflammation.

ASPIRIN-INDUCED ASTHMA

Around 5% of adults with asthma develop significant bronchoconstriction, often with rhinorrhea and urticaria, after ingesting aspirin and other cyclooxygenase inhibitors. Bronchoconstriction occurs as a consequence of inhibition of production of bronchoprotective prostaglandin E_2 and unchecked production of cysteinyl leukotrienes. Aspirin-induced asthma usually is seen in patients with nonatopic, adult-onset disease, many of whom have, in addition, rhinitis and nasal polyps (i.e., Samter's triad). Patients tend to have severe eosinophilic airway inflammation that often is difficult to control with inhaled corticosteroids alone, and a high proportion of patients require, and do well with, oral corticosteroids taken either intermittently or continuously. Drugs blocking the production and action of leukotrienes may be particularly helpful in patients with aspirin-induced asthma.

CHURG-STRAUSS SYNDROME

Churg-Strauss syndrome is characterized by vasculitis and histologic evidence of extravascular granulomas in a patient with asthma and allergic rhinitis. The criteria for diagnosis of Churg-Strauss syndrome are summarized as follows:

- Presence of asthma
- Peripheral blood eosinophilia (presence of more than 1.5×10^9 cells/L)
- Systemic vasculitis involving two or more extrapulmonary organs

Biopsy of easily accessible affected tissue can be helpful to confirm the presence of vasculitis and extravascular granuloma (Figure 39-10) but should not delay institution of treatment. Antineutrophilic cytoplasmic antibodies (ANCA) are present in two thirds of cases, but this finding is not specific. The key to prompt diagnosis is maintaining clinical awareness of the condition, especially in an adult patient who presents with allergic rhinitis, sinusitis, asthma, or an eosinophilia (which can be marked), together with systemic features such as fever, rash (especially lower limb purpura), weight loss, or arthralgia. Other features include pulmonary infiltrates, peripheral neuropathy, cranial and other isolated nerve palsies, cerebrovascular accidents, abdominal pain, bloody diarrhea, and, occasionally, intestinal perforation. Renal disease is uncommon, but cardiac involvement can occur and is a serious complication potentially leading to heart failure and sudden death. These manifestations of disease may develop over a short period, emphasizing the importance of a prompt diagnosis. The differential diagnosis clearly depends on the specific manifestation of Churg-Strauss syndrome occurring in the individual patient, but pulmonary manifestations may need differentiating from allergic bronchopulmonary aspergillosis, other pulmonary eosinophilias, pulmonary sarcoidosis, Wegener granulomatosis, microscopic polyangiitis, and polyarteritis nodosa.

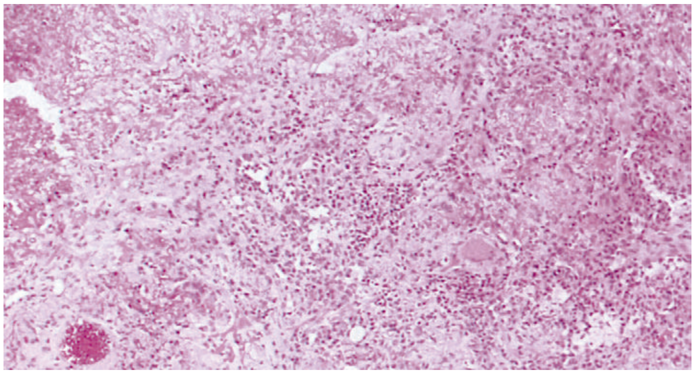


Figure 39-10 Histopathologic features of Churg-Strauss syndrome (CSS). This photomicrograph shows a combination of parenchymal necrosis and focally marked tissue eosinophilia in CSS. The inflammatory infiltrate includes a combination of eosinophils and variable numbers of epithelioid histocytes in a vaguely granulomatous appearance. *(From Partridge MR: Asthma: clinical features, diagnosis, and treatment. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, Mosby, 2008.)*

In many cases, the response to steroids alone may be very good, and it is possible to achieve long-term control with low-dose prednisolone. With more aggressive disease, additional treatment with cyclophosphamide is necessary. Prognosis reflects the degree of severity of the disease and its manifestations, with the worst outcomes in patients with cardiac decompensation or cerebrovascular manifestations. The association of Churg-Strauss syndrome with the use of leukotriene antagonists has recently attracted attention. Although theoretically any drug may potentially induce a hypersensitivity vasculitis, the most likely reason for development of relevant problems after initiation of leukotriene antagonist is that improved control of the patient's asthma has led to a reduction in oral steroid dose with subsequent unmasking of a previously silent systemic condition.

ASPERGILLUS-*ASSOCIATED ASTHMA*

The fungus *Aspergillus* is globally distributed and found in soil and decaying leaf mold and vegetable matter. Fungal spores are dispersed by the wind, and peak levels are found during the autumn and winter. Some patients with asthma develop an IgE- and IgG-mediated response to *Aspergillus* and other molds on repeated exposure. Patients who are highly atopic, have long-standing disease, and exhibit evidence of airway damage are at particular risk. Some develop the arbitrarily defined condition *allergic bronchopulmonary aspergillosis* (ABPA), which features, in addition to asthma and *Aspergillus* sensitivity, pulmonary eosinophilia and infiltration with an intense allergic reaction in the proximal airways. This reactivity can result in bronchial occlusion, which may give rise to segmental or lobar collapse and, especially if untreated, significant bronchial wall damage and development of bronchiectasis of the proximal airways (Figure 39-11). It is becoming clear that less well-developed forms of this condition are common, and the term *Aspergillus*-associated asthma is preferred. Up to 40% of patients with severe asthma have *Aspergillus* sensitization, and many grow *Aspergillus* in their sputum when this organism is looked for specifically.

The following features should alert the clinician to the possibility of *Aspergillus*-associated asthma:

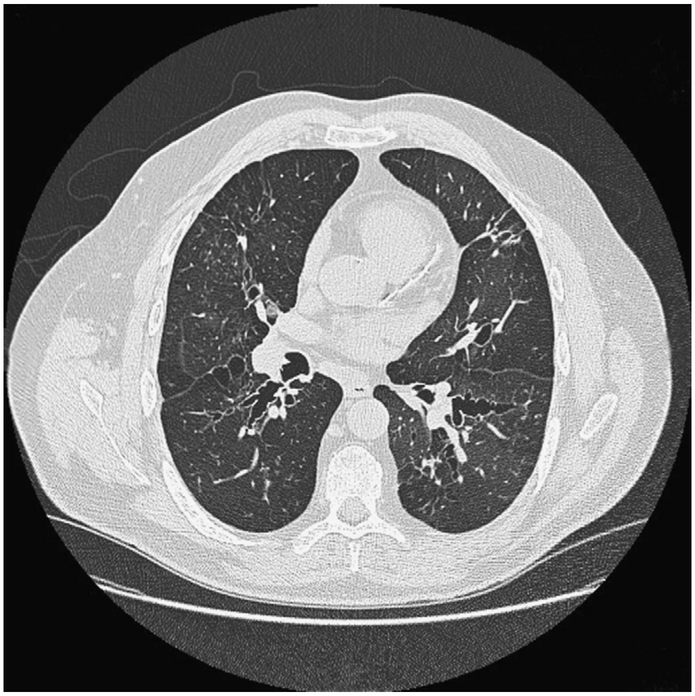

Figure 39-11 Computed tomography scan of the thorax of a patient with bronchopulmonary aspergillosis. Significant proximal airway bronchiectasis is evident. *(From Partridge MR: Asthma: clinical features, diagnosis, and treatment. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, Mosby, 2008.)*

- A marked peripheral blood and sputum eosinophilia
- Demonstration of a positive result on immediate skin prick testing or RAST for *A. fumigatus*
- Positive precipitins (i.e., IgG antibodies) to *A. fumigatus*
- *A. fumigatus* grown on sputum culture
- A raised total immunoglobulin E level
- Lung imaging showing lobar collapse, infiltrates, and bronchiectasis, which is classically worst in the proximal airways in this condition (see Figure 39-11)

The combination of *Aspergillus* sensitization and colonization may be an important and potentially modifiable factor responsible for airway damage and the development of fixed airflow obstruction, and there is increasing interest in screening for this condition in patients with more severe disease. The acute syndrome associated with pulmonary infiltration is undoubtedly helped by oral corticosteroid therapy, and a maintenance regimen of inhaled steroids between attacks probably prevents recurrent attacks and preserves lung function. Long-term maintenance oral corticosteroid therapy may be necessary. Increasing evidence suggests that antifungal drugs (e.g., itraconazole 200 mg twice daily for 4 months) are effective in patients with aspergillus-associated asthma.

OCCUPATIONAL ASTHMA

Approximately 15% of patients with adult-onset asthma are thought to have occupational asthma. The causes, diagnosis, investigation, and management of occupational asthma are discussed in more detail in Chapter 40. The key point in the history is that symptoms are worse at work and better away from work, particularly with prolonged work absence during holidays. It should be possible to document this work effect objectively with PEF measurements done at work and away from work. A computerized analysis system is available online (see under "Web Resources"); this has been shown to be a valid means of diagnosing occupational asthma provided accurate and frequent (i.e., every 2 hours during waking hours) PEF readings are available. Occupational asthma results in considerable expense to the patient as a result of lost productivity, estimated to be in the order of £13 million in the United Kingdom over the course of his or her lifetime. Society contributes a similar amount, so reducing the incidence of occupational asthma is an important priority.

Work can aggravate preexisting asthma because of exposure to irritant stimuli (e.g., cold air) or can cause new-onset disease because the worker becomes sensitized to an occupational high- or low-molecular-weight sensitizer. Occupational asthma due to exposure to a sensitizer often occurs after the worker has been exposed for some time and is classically preceded by work-related rhinitis. This latent period is not seen with work-aggravated asthma. If the condition is recognized early, then removal of the worker from the occupational sensitizer can lead to complete remission; cessation of exposure is an important priority even if complete remission is not achieved. Environmental control with appropriate management of underlying asthma often is all that is needed in work-aggravated asthma. Asthma also can develop after sudden accidental exposure to a high concentration of toxic fumes, resulting in the so-called reactive airway dysfunction syndrome (RADS).

ASTHMA IN ATHLETES

A high proportion of endurance athletes report symptoms suggesting asthma and have abnormalities of airway function consistent with this condition. Up to 50% of Olympics-standard swimmers and winter sport athletes report use of asthma treatment. The prevalence may be highest in athletes participating in these sports, because endurance exercise occurs in challenging environments. The pathophysiologic basis of airway dysfunction is incompletely understood but the injurious effect of pollution and cold air on the airway mucosa is likely to be important. Athletes with asthma tend to have noneosinophilic airway inflammation and respond poorly to inhaled corticosteroid treatment.

ASTHMA IN PREGNANCY

Asthma may worsen, stay the same, or improve during pregnancy. The pattern may be repetitive in subsequent pregnancies. For women who experience a worsening of asthma, this is likeliest in the second and third trimesters; problems during labor are extremely unusual. Treatment for asthma should be the same during pregnancy as in the nonpregnant state, except that leukotriene antagonists should not be initiated during pregnancy. In the absence of appropriate advice, those with asthma may stop their medication on discovering they are pregnant, and it is important that pregnant women are reassured as to the safety of usual asthma treatment. After delivery, breast-feeding should be encouraged; none of the commonly used asthma medications are secreted in breast milk to the degree that any alteration in treatment is necessary.

ASTHMA ATTACKS

Asthma attacks are the third leading cause of preventable admissions to the hospital, and are responsible for more than 5000 deaths per year in the United States and 1500 deaths per year in the United Kingdom. Attacks are often not acute. In around half of patients the asthma attack has often been developing for days or weeks and there have been many opportunities to alter their treatment to prevent deterioration to crisis levels. Thus, undertreatment or inappropriate therapy is an important contributor to asthma morbidity and mortality.

People who have asthma die because they, their loved ones, or their doctors underestimate the severity, because of delays in seeking medical treatment, and because of underuse of oxygen and corticosteroid tablets. The severity of an exacerbation must therefore be carefully assessed, and the outcome determines the therapy given and the optimal treatment setting. Box 39-7 and Table 39-2 show features associated with exacerbations of asthma of mild, moderate, severe, or critical nature. All but the mildest attacks require treatment with bronchodilators, corticosteroids, and oxygen, with careful follow-up and assessment of responses to each intervention (Figure 39-12). Non–life-threatening asthma can be treated initially with four to six puffs of salbutamol from a pressurized metered dose inhaler (pMDI) with a large-volume spacer plus ipratropium, four puffs from a pMDI with large-volume spacer, both repeated as necessary every 10 to 15 minutes. A good response with symptom relief and an improvement in PEF to greater than 80% of the patient's best is followed by continuing regular β-agonists every 4 hours for 24 to 48 hours, a four-fold increased dose of inhaled corticosteroids for at least 7 days, and careful review of the patient's disease control status within days.

In life-threatening asthma, bronchodilators (albuterol [salbutamol] 5 to 10 mg and ipratropium bromide 0.5 mg) are administered by a nebulizer. All patients with life-threatening asthma and patients with non–life-threatening asthma who have an incomplete response (PEF 50% to 80% of predicted or

Box 39-7 Recognition and Assessment of Acute Severe Asthma in the Hospital Setting

Features of Acute Severe Asthma

Peak expiratory flow rate (PEFR) 50% of predicted (or patient's best) or less
Cannot complete sentences in one breath
Respiratory rate 25 breaths/minute or greater
Pulse greater than 110

Life-Threatening Features

PEFR less than 33% of predicted or best
Silent chest, cyanosis, or feeble respiratory effort
Bradycardia or hypotension
Exhaustion, confusion, or coma
If arterial saturation of oxygen is less than 92% or a patient has any life-threatening features, measure arterial blood gases

Blood Gas Markers of a Very Severe, Life-Threatening Attack

Normal (36-45 mm Hg) or high arterial partial pressure of carbon dioxide (PaCO_2)
Severe hypoxia, with PaO_2 less than 60 mm Hg irrespective of treatment with oxygen
A low pH (or high H^+)

No other investigations are needed for immediate management.

Caution: Patients experiencing severe or life-threatening attacks may not appear distressed and may not demonstrate all or even most of these abnormalities. The presence of any listed factor, however, should strongly signal this possibility to the clinician.

best) with persistent symptoms require continuation of β-agonists every 2 to 4 hours and prompt addition of oral corticosteroids (prednisolone 30 to 40 mg once daily for 7 to 14 days). Either hospitalization is arranged or the patient is seen again urgently (the same day or the next morning).

A chest radiograph is indicated and should be performed if there is suspicion of additional intrathoracic pathology such as a pneumothorax or infective consolidation that will require additional therapeutic measures, if the patient fails to respond or deteriorates after initial therapy, or if the asthma attack is life-threatening or mechanical ventilation is being considered. If the blood oxygen saturation (Sa_{O_2}) does not reach 92% with the patient breathing room air or if the PEF is less than 100 L/min, arterial blood gas analysis is indicated. Patients with features of severe disease (see Table 39-2) should be referred urgently for intensive care monitoring. The first warning of this level of acuteness may be a normal or raised arterial partial pressure of carbon dioxide (Pa_{CO_2}) on blood gas sampling. Repeat blood gas sampling should be done in patients who are not clearly improving or appear to be deteriorating.

A single dose of magnesium sulfate (1.2 to 2 g intravenous infusion over 20 minutes) has also been shown to be safe and effective in severe asthma attacks and there is preliminary evidence that inhaled magnesium can be helpful when added to nebulized salbutamol. Intravenous aminophylline, 250 mg given slowly over 20 minutes followed by an infusion of 0.5 mg/kg/hour, is widely used if the patient is not taking regular oral theophyllines, although this practice is not strongly evidence-based.

Once clinical recovery has been achieved, the following criteria for successful management should be ascertained at discharge of the patient from the hospital:

- The patient has been on discharge medication for 24 hours.
- Inhaler technique has been checked.
- PEF should be greater than 75% of predicted or better and PEF rate diurnal variability should be less than 25%, unless the patient's respiratory physician confirms otherwise.
- Treatment with oral and inhaled corticosteroids in addition to bronchodilators has been prescribed.
- The patient has a PEF meter for home use, along with a written asthma action plan.
- Local follow-up evaluation has been arranged for within a week.
- A follow-up appointment in the chest clinic within 4 weeks has been scheduled.

The reason(s) for the exacerbation and admission must be determined and details sent to the primary care physician, together with a discharge plan and potential best PEF. Patients need to be given clear advice on how long to continue corticosteroid tablets, which should be continued in full dose until clinical stability is achieved and then either stopped suddenly (if the patient was not previously on corticosteroids and has taken them for less than 2 weeks) or tapered off.

Every attack of severe asthma and every hospital admission or emergency department visit must be regarded as a sign of failure of that patient's previous asthma management. Patients presenting with acute severe asthma are at high risk for recurrent attacks and have a poor prognosis, often reflecting poor self-management skills. After successful medical management of the attack, a full review of the lessons that can be learned from the attack is warranted, and a self-management plan for the future should be formulated and communicated to the primary care physician. The most important elements of the management plan are illustrated in Figure 39-7.

CONTROVERSIES AND PITFALLS

A growing view is that the current "one size fits all" guidelines approach to diagnosis and management is not appropriate with such a poorly defined entity as asthma. Much of the evidence on which guideline management suggestions are based is derived from clinical trials conducted in relatively homogeneous populations bearing little resemblance to the population receiving treatment for asthma in the community. The future is likely to see increasing individualization of therapy, with management decisions based on a rigorous analysis of the mechanism of the patient's morbidity and an accurate assessment of the risk of attacks, rather than a desperate and largely futile attempt to shoehorn different cases into a diagnostic category and then follow the relevant guideline. This individualized therapy approach requires more thorough evaluation of patients with suspected asthma, which includes an assessment of airway inflammation.

The development of new drugs has been a slow and frustrating process, with few therapeutic advances in the past 15 to 20 years. In part, this limitation reflects the problems with asthma as a diagnostic entity, as outlined previously. There needs to be a wider appreciation that new and existing treatments may be efficacious only in certain subgroups of patients and are likely to modulate only particular aspects of the syndrome. These subgroups and the aspects of the syndrome that are modified often are entirely predictable from the mode of action of the treatment. The archetypal example of drug development being adversely affected by unhelpful disease labels is the story of the clinical development of blocking antibodies against IL-5, in particular mepolizumab, which very specifically ablates eosinophils. Eosinophilic airway inflammation is associated with exacerbations of asthma, but not with airway hyperresponsiveness, which causes most asthma symptoms. Yet for 10 years, mepolizumab was tested exclusively against outcomes related to airway hyperresponsiveness in patients identified by the presence of variable airflow obstruction and/or airway hyperresponsiveness. It is therefore not surprising that the results were negative. When the drug was tested in patients with eosinophilic airway inflammation against outcomes associated with an airway eosinophilia (asthma attacks), it worked. Clinical researchers and regulatory authorities need to embrace this new understanding and ensure that future trials assess sensible outcomes in the right populations of patients. Clinicians using these agents need to develop the expertise to identify these potentially treatment-responsive subgroups of patients.

Some patients continue to do badly as a result of poor treatment adherence. Many patients struggle to appreciate that current treatments suppress the disease but do not cure. There is also a failure to understand that asthma is an episodic condition that very rarely remits completely. New and imaginative ways to educate hard-to-reach and nonadherent patients are needed. Clinicians often adopt a safety-first approach to treatment, and a growing view is that a significant number of patients with mild, low-risk disease are overtreated. Confidential enquiries into asthma deaths also continue to highlight undertreatment of high-risk patients. Better risk stratification is needed, and more precise definition and quantification of modifiable risk factors for poor asthma outcomes are urgently needed. Better risk stratification will allow clinicians to target treatment more effectively and also will facilitate discussion with patients. One aspect of asthma that is very poorly understood is the development of irreversible airflow obstruction. Decline is difficult to measure, and how much of a problem it represents has not been established; only a very basic understanding of risk factors has been achieved thus far. More research in this area is urgently required.

Perhaps the most important pitfall is the failure to recognize “pseudoasthma” in a patient whose symptoms are not responding to escalating antiasthma therapy. Clinicians should repeatedly question the validity of the diagnosis in patients who are doing well and should actively seek objective confirmation of the presence of abnormal airway function or airway inflammation. This assessment should be capable of identifying corticosteroid-unresponsive phenotypes of asthma such as noneosinophilic asthma. Box 39-2 lists some features that should alert the clinician to an alternative explanation for asthma-like symptoms.

SUMMARY

- Asthma is a clinical diagnosis that is made on the basis of the history and a demonstration of variable airflow obstruction.
- It is a syndrome, rather than a discrete entity; a growing interest in defining clinically important subgroups of asthma is influencing today’s research.
- Bronchial provocation testing with methacholine or histamine should be performed if diagnostic uncertainty remains in patients with normal spirometry findings.
- In patients with fixed airflow obstruction, it may not be possible to make a clear distinction between asthma and other related conditions, notably COPD. Assessment should focus more on defining mechanisms of airflow limitation, best achievable lung function, and optimal symptom control.
- Treatment goals for asthma are targeted at controlling symptoms, preventing asthma attacks, and preserving normal lung function.
- Asthma pharmacotherapy is broadly categorized into bronchodilator and antiinflammatory agents. These are currently prescribed in a stepwise manner with the primary aim of controlling symptoms.
- From 5% to 10% of patients have treatment-refractory asthma. Alternative or additional diagnoses should be sought in such cases. Newer therapies and different management strategies are being developed, but these agents have a limited spectrum of effects and are likely to work well only in certain subgroups. Assessment of airway inflammation is helpful in patients with severe asthma and may help identify patients who respond to these treatments.

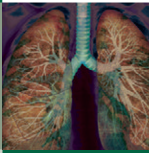
Section 7
AIRWAY DISEASES



Chapter 40
Occupational Asthma

Olivier Vandenplas • Jean-Luc Malo

The workplace environment can lead to the development of different types of work-related asthma (Figure 40-1), including occupational asthma (OA) (i.e., asthma *caused* by work) and work-exacerbated asthma (i.e., preexisting or coincident asthma *exacerbated* by nonspecific stimuli at work). OA is defined as a disease characterized by variable airflow limitation and/or bronchial hyperresponsiveness and/or airway inflammation secondary to factors and conditions attributable to a particular working environment and not to stimuli encountered outside the workplace. OA may result either from immunologically mediated sensitization to occupational agents (i.e., "allergic" OA, or "OA with a latency period") or from exposure(s) to high concentrations of irritant compounds (i.e., irritant-induced asthma [IrIA], best typified by the *reactive airways dysfunction syndrome* [RADS]).

In recent years, a growing interest in occupational asthma (OA) has emerged, for several reasons:

- The frequency of asthma has increased progressively during the past 2 decades, with a recent plateau, and occupational exposure may be a contributing factor.
- Epidemiologic data indicate that approximately 18% of cases of asthma in adults are attributable to workplace exposures.
- The number of agents that can cause OA is steadily increasing (www.asthme.csst.qc.ca).
- OA, together with diseases related to exposure to asbestos dust, has become the most prevalent occupational lung disease in many developed countries, resulting in an increased burden to society.
- OA is an excellent model to study the epidemiology, pathophysiology, genetics, and other aspects of asthma in humans.

EPIDEMIOLOGY

CAUSAL AGENTS

The workplace agents causing immunologically mediated OA usually are categorized as either high-molecular-weight (HMW) or low-molecular-weight (LMW) substances (i.e., with molecular weights above or below 5000, respectively). HMW agents are (glyco)proteins of vegetable and animal origin, whereas LMW agents include chemicals, metals, and wood dusts. The intrinsic characteristics of occupational agents that determine their sensitizing potential remain largely uncertain. Of note, however, LMW agents causing OA typically are highly reactive electrophilic compounds that are capable of combining with hydroxyl, amino, and thiol functionalities on airway proteins. Quantitative structure-activity relationship models have identified a number of reactive groups that are associated with a high risk of respiratory sensitization, such as isocyanate ($N{=}C{=}O$), carbonyl ($C{=}O$), and amine (NH_2), particularly when two or more groups are present within the same molecule.

A very large number of substances (more than 400) used at work can cause the development of immunologically mediated OA. The most common causal agents and occupations are listed in Table 40-1. A few agents—specifically, flour, diisocyanates, latex, persulfate salts, aldehydes, animals, wood dusts, metals, and enzymes—account for 50% to 90% of OA cases. Nevertheless, the distribution of causal agents may vary widely across geographic areas, depending on the pattern of industrial activities. The highest rates of OA occur in bakers and pastry makers, other food processors, spray painters, hairdressers, wood workers, health care workers, cleaners, farmers, laboratory technicians, and welders.

All agents in exceedingly high concentrations can theoretically cause OA through nonimmunologic mechanisms, especially with agents occurring in vapor or gaseous form, by apposition to dry particles, such as chlorine and ammonia, but fire smoke and alkaline dusts, such as those released during the World Trade Center disaster, also have been incriminated in the development of persistent asthma.

PREVALENCE AND INCIDENCE

Cross-sectional surveys of workforces exposed to sensitizing agents found highly variable prevalence rates of OA. In general, the prevalence of OA caused by HMW agents is less than 5%, and that for LMW agents ranges from 5% to 10%. Cohort studies reported incidence rates of 2.7 to 3.5 cases of OA per 100 person-years among workers exposed to laboratory animals, 4.1 per 100 person-years among those exposed to wheat flour, and 1.8 per 100 person-years among dental health apprentices exposed to natural rubber latex. Estimates of the incidence of OA in the general population provided by voluntary notification schemes, medicolegal statistics, and population-based surveys are summarized in Table 40-2. Acute IrIA accounts for about 10% of all reported cases of OA.

RISK FACTORS

OA results from complex interactions between environmental factors and individual susceptibility. The environmental and individual risk factors are summarized in Table 40-3, together with the level of evidence supporting their role. The intensity of exposure to sensitizing agents currently is the best-identified and the most important environmental risk factor for the

Table 40-1 Principal Agents Causing Immunologic Occupational Asthma

	Agent	Occupation/Industry
High-Molecular-Weight Agents		
Cereals, flour	Wheat, rye, barley, buckwheat	Flour milling, bakers, pastry makers
Latex		Health care workers, laboratory technicians
Animals (food animals, other)	Mice, rats, cows, seafood	Laboratory workers, farmers, seafood processors
Enzymes	α-Amylase, maxatase, alcalase, papain, bromelain, pancreatin	Baking products manufacture, bakers, detergent production, pharmaceutical industry, food industry
Low-Molecular-Weight Agents		
Diisocyanates	Toluene diisocyanate (TDI), methylene diphenyl-diisocyanate (MDI), hexamethylene diisocyanate (HDI)	Polyurethane production, plastic industry, molding, spray painters
Metals	Chromium, nickel, cobalt, platinum	Metal refinery, metal alloy production, electroplating, welding
Biocides	Aldehydes, quaternary ammonium compounds	Health care workers, cleaners
Persulfate salts		Hairdressers
Acid anhydrides	Phthalic, trimellitic, maleic, tetrachlorophthalic acids	Epoxy resin workers
Reactive dyes	Reactive black 5, pyrazolone derivatives, vinyl sulfones, carmine	Textile workers, printers, food industry workers
Woods	Red cedar, iroko, obeche, oak, others	Sawmill workers, carpenters, cabinet and furniture makers

development of OA. Characterization of the relationship between the level of exposure to occupational agents and the development of IgE sensitization and OA has been greatly enhanced by the use of personal sampling techniques, direct analytic methods for chemicals, and immunoassay techniques for the quantification of airborne protein allergens. Exposure-response relationships may be affected by the nature of the sensitizing agent, individual susceptibility, and timing of exposure. Some agents seem to be more potent than others in inducing sensitization; the dose-response relationship for IgE sensitization is steeper for the bakery enzyme alpha-amylase than for wheat allergens. Some evidence indicates that the exposure-response relationships are not linear for certain occupational agents (e.g., laboratory animals, wheat flour), thereby suggesting an unexplained protective effect of high-level exposures. The role of genetic susceptibility markers, such as certain human leukocyte antigen (HLA) class II alleles, may become more apparent at low levels of exposure to occupational agents. The timing of exposure also may play a role, because the frequency of onset of work-related asthma symptoms is consistently higher within the first 1 to 4 years of exposure to HMW agents, and exposure-response gradients are more clearly documented in this early period of exposure.

A number of studies indicate that exposure to cigarette smoke can increase the risk for IgE-mediated sensitization to some HMW and LMW agents, but the evidence supporting an association between smoking and the development of clinical OA is still very weak. The role of other environmental cofactors, such as non-respiratory routes of exposure and concomitant exposure to endotoxin and pollutants at work, remains largely uncertain.

Atopy has been consistently demonstrated as an important host risk factor for the development of IgE sensitization and OA, but only for HMW agents. Prospective cohort studies of workers entering exposure to occupational sensitizing agents have shown that the presence of rhinitis and nonspecific

bronchial hyperresponsiveness at baseline is associated with an increased risk for subsequent IgE sensitization and development of OA.

With the advances in human genetics, research has been directed toward investigating the genetic basis of individual susceptibility to develop OA. Certain HLA class II molecules (i.e., HLA-DR, HLA-DQ, and HLA-DP alleles), which are involved in the presentation of processed antigens to T lymphocytes, were found to confer either susceptibility to or protection against OA due to various LMW and HMW occupational allergens (i.e., isocyanates, red cedar, acid anhydrides, platinum salts, natural rubber latex, and laboratory animals). Other evidence suggests that genes associated with T_H2 cell differentiation (i.e., polymorphism of the IL-4 receptor α chain, IL-13, and CD14 (C159T) genes) may play a role in the development of OA. Genes involved in the protection against oxidative stress, such as glutathione *S*-transferase (GST) and *N*-acetyltransferase (NAT), have been associated with an increased risk of isocyanate-induced OA (e.g., *GSTM1*-null genotype and slow *N*-acetylator phenotypes) or a protective effect (e.g., GSTP1*Val/Val allele). Overall, the currently available information indicates that the utility of genetic testing is limited for both diagnostic and preventive purposes. In addition, there is convincing evidence that a wide variety of environmental factors can interact with genetic determinants to affect disease susceptibility. For instance, a gene-environment interaction has been demonstrated in platinum refinery workers, in whom the relative risk of sensitization associated with the HLA-DR3 phenotype was more apparent at lower levels of exposure.

PATHOPHYSIOLOGY

OA can be classified according to pathogenic mechanisms as either immunologically or nonimmunologically mediated. Immunologically mediated OA is characterized by a latency period that is necessary for acquiring sensitization, whereas nonimmunologically mediated OA has no latency period.

IMMUNOLOGIC, IMMUNOGLOBULIN E-MEDIATED OCCUPATIONAL ASTHMA

HMW occupational agents act as complete antigens and induce specific IgE antibody production. The best examples are laboratory animals and flour. Some LMW occupational agents, including platinum salts, trimellitic anhydride, and other acid anhydrides, also induce specific IgE antibodies, and some others, specific IgG antibodies. They probably act as haptens and bind with proteins to form complete antigens, which are then recognized by antigen-presenting cells, and mount a $CD4^+$ response, with production of specific IgE antibodies by B cells stimulated by several interleukins.

Reactions between specific IgE and antigens lead to a cascade of events that result in the release of inflammatory mediators and influx of cells in the airway, with consequent airway inflammation and development of airway hyperresponsiveness, as in asthma involving common allergens. Although other classes of antibodies have been postulated to have a role in asthma, evidence for their participation is not available. In the case of diisocyanates, mechanisms of allergic sensitization that are independent of IgE antibody have been postulated. There are no apparent differences in the pathogenetic mechanisms between OA induced by HMW occupational agents and those of allergic nonoccupational asthma.

Table 40-3 Summary of Potential Risk Factors for Development of Occupational Asthma (OA)

Risk Factor	Strength of Evidence	Agents/Settings
Environmental Risk Factors		
High level of exposure	+++	*HMW agents*: Wheat flour, α-amylase, laboratory animals, detergent enzymes, snow crab allergens *LMW agents*: Platinum salts, acid anhydrides
	++	Diisocyanates
Skin exposure	+	Diisocyanates
Cigarette smoking	++	*IgE sensitization*: Laboratory animals, snow crab, shrimp, salmon, psyllium, green coffee, enzymes, acid anhydrides, platinum, reactive dyes
	+	*Clinical OA*: Laboratory animals, enzymes
Individual Risk Factors		
Atopy	+++	*HMW agents*: Flour, laboratory animals, snow crab, psyllium, detergent enzymes, α-amylase
	+	*LMW agents*: Platinum, acid anhydrides
Genetic Markers		
HLA class II alleles	++	*LMW agents*: Diisocyanates, red cedar, acid anhydrides, platinum salts *HMW agents*: Laboratory animals, latex
Antioxidant enzyme* variants	++	Diisocyanates
TLR-4/8551 G variant	+	Laboratory animals
IL-4RA (I50V) II variant	+	Diisocyanates
Preexisting nonspecific bronchial hyperresponsiveness	+	Apprentices exposed to HMW agents (laboratory animals, flour, latex)
Preexisting rhinitis	+	IgE sensitization to HMW agents (laboratory animals, flour, latex)
Work-related rhinitis	+++	Nonoccupational asthma in the general population and OA in cohorts of workers exposed to laboratory animals
Gender—female	+	Snow crab processors

*Glutathione *S*-transferase (GSTM) and *N*-acetyltransferase (NAT).

IMMUNOLOGIC, NON-IMMUNOGLOBULIN E-MEDIATED OCCUPATIONAL ASTHMA

Many LMW agents, including diisocyanates and plicatic acid (responsible for red cedar asthma), have been shown to cause OA, yet specific IgE antibodies cannot be detected or are found in only a small percentage of affected persons. Specific IgG antibodies also are found and have been discovered to be significantly associated with the development of OA.

The significance of IgE and IgG antibodies in the pathogenesis of asthma is not clear. Bronchial biopsy specimens from patients with OA obtained at the time of diagnosis have shown activation of T lymphocytes, suggesting that T lymphocytes may play a direct role in mediating airway inflammation. This hypothesis has been substantiated by the finding of proliferation of peripheral blood lymphocytes when stimulated with the appropriate antigen in a proportion of affected persons with nickel-induced asthma and Western red cedar asthma. In isocyanate-induced asthma, an increase in CD8$^+$ cells and in percentage of eosinophils was found in the peripheral blood of patients during a late asthmatic reaction induced by exposure testing. Cloning of T cells from bronchial biopsy specimens of these subjects showed that most of the clones exhibited CD8$^+$ phenotype that produced IL-5, with very few clones producing IL-4. This finding provides supportive evidence that CD8$^+$ cells may play a direct role in OA without the necessity of producing IgE antibodies.

Early asthmatic reactions induced by occupational allergens probably are associated with smooth muscle contraction and edema induced by inflammatory mediators such as histamine and leukotrienes but not cellular infiltration. Late asthmatic reactions are associated with influx of inflammatory cells. Although both asthma and OA have been identified as diseases in which eosinophilic inflammation plays a key role, the role of neutrophils has recently been examined. Induced sputum examination is a noninvasive means to assess cell profiles and currently is more often used as an interesting investigative tool. Eosinophilic and neutrophilic variants of OA have been found in the case of OA due to LMW agents, especially diisocyanates. Some LMW agents have pharmacologic properties that cause bronchoconstriction. For example, diisocyanates may block the β_2-adrenergic receptor. Diisocyanates and other occupational agents also may stimulate sensory nerves to release substance P and other peptides that have been shown to inhibit neutral endopeptidases necessary for the inactivation of neuropeptides. Neuropeptides affect many cells in the airways and may participate in airway inflammation by causing smooth muscle

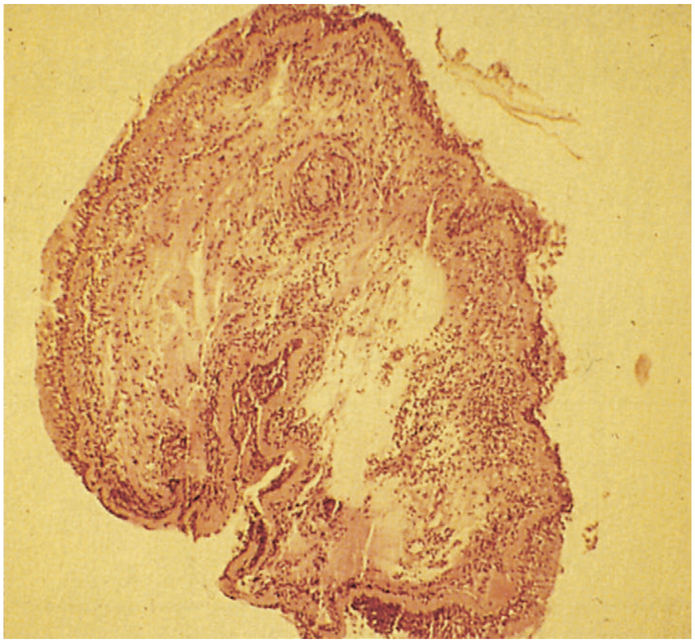

Figure 40-2 Bronchial biopsy specimen from a patient who had occupational asthma caused by exposure to toluene diisocyanates. Even after removal from exposure, partial desquamation of the epithelium, thickened basement membrane, and some cellular infiltration are evident.

contraction, mucus production, and recruitment and activation of inflammatory cells. Thus, LMW occupational agents such as diisocyanates may have a variety of proinflammatory effects and induce asthma through more than one mechanism. An autopsy study of the lung of a person with isocyanate-induced asthma who died after reexposure showed denudation of airway epithelium, subepithelial fibrosis, infiltration of the lamina propria by leukocytes (mainly eosinophils), and diffuse mucous plugging of the bronchioles, similar to findings in persons who died from non-OA. Bronchial biopsy specimens of 18 patients with proven OA also have shown extensive epithelial desquamation, ciliary abnormalities of the epithelial cells, smooth muscle hyperplasia, and subepithelial fibrosis (Figure 40-2). The total cell count, eosinophils, and lymphocytes were increased compared with those in healthy control subjects.

NONIMMUNOLOGIC OCCUPATIONAL ASTHMA

OA resulting from nonimmunologic mechanisms is characterized by the absence of latency. The underlying mechanism of IrIA is not known. It has been postulated that the extensive denudation of the epithelium in these conditions leads to airway inflammation and airway hyperresponsiveness by several mechanisms, including loss of the epithelial cell–derived relaxing factors, exposure of the nerve endings leading to neurogenic inflammation, and nonspecific activation of mast cells with release of inflammatory mediators and cytokines (Figure 40-3). Secretion of growth factors for epithelial cells, smooth muscle, and fibroblasts may lead to airway remodeling. Sequential changes in the airways of a patient with IrIA have been described. In the acute phase of IrIA, rapid denudation of the mucosa with fibrinohemorrhagic exudate in the submucosa is followed by regeneration of the epithelium with proliferation of basal and parabasal cells and subepithelial edema (Figure 40-4). In the chronic phase of IrIA, marked thickening of the airway wall is seen (Figure 40-5). In a study of IrIA caused by multiple exposures to an irritant, inflammatory infiltrate with eosinophils and lymphocytes and diffuse deposition with collagen fibers were found. Similar sequential changes have been reproduced in animal models of IrIA.

CLINICAL FEATURES

OA induced by immunologic mechanisms is a form of asthma that is characterized by the clinical features of hypersensitivity: (1) work-related asthma symptoms develop only after an initial symptom-free period of exposure (i.e., the latency period),

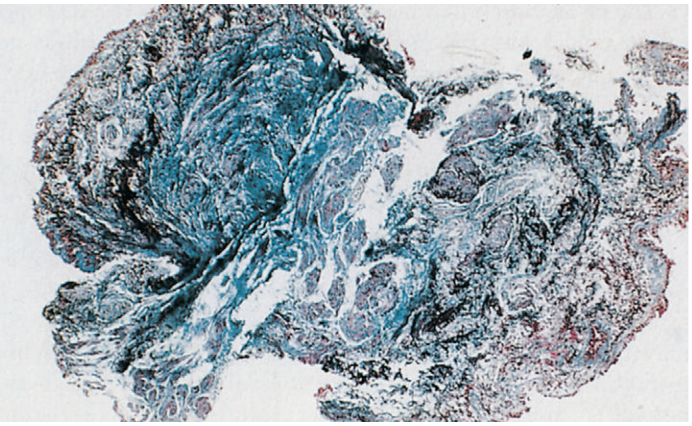

Figure 40-5 Bronchial biopsy specimen taken 2 years after an acute accidental inhalation of chlorine, showing severe desquamation of epithelial cells. Smooth muscle cells are surrounded by reticulocollagenic fibrous tissue. (Weigert-Masson stain.)

which is required to acquire the immunologic sensitization; (2) once OA is initiated, the asthmatic reactions tend to recur on reexposure to the causal agent at concentrations not affecting others who are similarly exposed; and (3) asthma affects only a proportion (usually a minority) of those exposed to the agent.

A typical history of OA includes the appearance or worsening of asthma symptoms at work and their disappearance or improvement away from work. This pattern frequently is obscured, however, because late asthmatic reactions can develop after the workshift, and asthma symptoms can be triggered by nonspecific stimuli outside the workplace. In addition, when affected workers continue to be exposed to the sensitizing agent, remission of symptoms in the evenings or during weekends tends to disappear, and much longer periods off work are necessary for improvement to take place. Thus, OA often remains unrecognized by affected workers and their physicians for long periods, the diagnosis usually being made 2 to 4 years after the onset of symptoms. The latency period typically is within 2 years of starting exposure to sensitizing agents, but OA may develop after much longer periods of exposure.

Some differences in the clinical presentation of subjects with OA caused by HMW and that implicating LMW agents have been noted, with isolated late or atypical asthmatic reactions more frequently observed after specific inhalation challenges with LMW agents. A majority of workers with OA also suffer from occupational rhinitis. Work-related rhinitis symptoms are more frequent and severe when HMW agents are involved. In those patients with associated rhinitis, work-related nasal symptoms frequently precede the onset of OA, especially with exposures to HMW agents.

The acute IrIA originally described by Brooks and colleagues in 1985 under the term *reactive airways dysfunction syndrome* is due to acute airway injury from accidental exposure to a high dose of irritants. In the typical clinical presentation, symptoms of asthma and airway obstruction or nonspecific bronchial hyperresponsiveness develop within a few hours after the acute exposure in a person without a history of respiratory disease, although sometimes the interval to symptom onset is longer. Certain features distinguish IrIA from allergic OA: At the time of the acute event, coughing generally is a predominant symptom. Thereafter, bronchial obstruction, if present, does not respond as well to bronchodilators, which may potentially be explained by the marked airway remodeling that has been documented in bronchial biopsy specimens from patients with IrIA.

DIAGNOSIS

Confirmation of the diagnosis of OA by objective means is necessary for several reasons. The diagnosis of OA has considerable socioeconomic implications for the worker and his or her family; it typically means a change of job in most instances, with its financial and other consequences. Asthma is a common disease, and it has been estimated that up to 50% of workers are exposed at one time or another to agents with sensitizing or irritating properties. The combination of having asthma and working in an environment with an agent known to give rise to OA does not make the diagnosis of OA. An occupational cause should be suspected for all new cases of adult-onset asthma, especially in persons who report worsening of their asthma symptoms at work. A detailed occupational history including past and current exposure to possible causal agents in the workplace, possible episodes of accidental exposures to irritant material, work processes, and specific job duties should be obtained. In addition, the intensity, frequency, and peak concentrations of exposure in the workplace should be assessed qualitatively. Worksite-specific information, including material safety data sheets, also can be requested, although in some instances, the information is incomplete on all constituents of the product, especially those constituents with concentrations less than 1%. Computerized databases and published lists of agents and workplaces are useful. Walk-through visits of the workplace may be necessary. Industrial hygiene data and employee health records can be obtained as well. Open medical questionnaires should be regarded as fairly sensitive but not specific tools for diagnostic purposes. Temporal associations are not sufficient to diagnose work-related asthma.

A person with suspected OA is best evaluated by a specialist in this area of practice. The role of this specialist is to confirm the diagnosis of OA by objective means if possible and to assess for impairment or disability. A delay in referral may jeopardize the chance of confirming the diagnosis with objective measurements, because the subject may have left the workplace and have recovered, or the working conditions may have changed. In cases of OA, however, inhalation challenges with a specific agent generally remain positive even 2 years or more after cessation of exposure.

An algorithm for the clinical investigation of OA is shown in Figure 40-6. The advantages and pitfalls of the various tools in confirming the diagnosis of OA are listed in Table 40-4. The presence of sensitization to occupational agents can be detected either by skin testing or by radioallergosorbent test (RAST) or enzyme immunosorbent assay (ELISA) techniques. In patients with a compatible clinical history of OA and bronchial hyperresponsiveness, a positive result on a skin test or RAST probably has a diagnostic accuracy close to 80% in the case of HMW agents. Unfortunately, very few standardized testing materials are commercially available for skin tests or for RASTs in OA, and for most LMW agents, an IgE-mediated mechanism has not been confirmed

For HMW agents, skin tests to detect immediate reactivity and measurements of specific IgE antibodies are important tools. The absence of nonspecific bronchial hyperresponsiveness in a subject at the end of 2 weeks of working under the usual conditions virtually excludes the diagnosis of asthma and OA. If nonspecific bronchial hyperresponsiveness is present, further testing is required. Spirometric measurements obtained

Table 40-4 Advantages and Disadvantages of Diagnostic Methods in Occupational Asthma

Method	Advantages	Disadvantages
Questionnaire	Simple, sensitive	Low specificity
Immunologic testing	Simple, sensitive	Only for agents of high molecular weight and for some of low molecular weight; identifies sensitization, not disease; no "standardized" or commercially available agents
Bronchial responsiveness to methacholine/ histamine	Simple, sensitive	Not specific for asthma or occupational asthma; occupational asthma not ruled out by a negative test result if subject is no longer exposed
Measurement of forced expiratory volume in 1 second (FEV_1) before and after a work shift	Simple, inexpensive	Low sensitivity and specificity
Assessment of airway inflammation (induced sputum, exhaled nitric oxide [NO])	Addresses physiopathology of asthma; identifies eosinophilic bronchitis	Not specific for occupational asthma; limited to specialized centers
Peak expiratory flow monitoring	Relatively simple, inexpensive	Requires patient's cooperation and honesty; not as sensitive as FEV_1 or a computerized method to assess airway caliber to interpret changes
Specific inhalation challenges in a hospital laboratory	Positive result is confirmatory	Diagnosis not ruled out by a negative result on confirmatory testing (e.g., with use of wrong agent or with cessation of work exposure); expensive; few referral centers
Serial FEV_1 measurement at work under supervision	Negative result rules out diagnosis when patient tested under usual work conditions	A positive result may be obtained in conditions of irritation; requires collaboration of employer

From Chan-Yeung M, Malo JL: Occupational asthma, *N Engl J Med* 333:107–112, 1995.

before and after a work shift have not been found to be sensitive or specific. Two options (controlled exposure and PEF) can be considered for objective confirmation, depending on availability (see Figure 40-6). Exposure to the suspected agent under control conditions in a hospital laboratory can be done as originally described by Pepys and Hutchcroft in 1975. Attempts have been made to improve specific challenge tests by exposing subjects in the laboratory to low and stable levels of dry or wet aerosols and vapors to avoid nonspecific reactions. However, these tests can give false-negative results if an incorrect agent is used for testing or if the subject has been away from work for too long, although such occurrences are rare. In the latter instance, the subject should be instructed to return to the workplace, if feasible, and specific laboratory or worksite challenges should be repeated at a later time.

Burge and co-workers were the first to propose the use of serial measurement of peak expiratory flow (PEF) by use of portable devices in the diagnosis of OA. An example of serial PEF recording is shown in **Figure 40-7**. Although relatively good correlation has been found between the results of serial PEF monitoring and OA as confirmed by specific inhalation challenges in the laboratory, several limitations and pitfalls in PEF monitoring are recognized (see Table 40-4). When PEF monitoring is suggestive of OA and specific inhalation challenges in the laboratory are not possible or yield negative results, it is advisable to confirm OA by sending a technician to the workplace to record serial spirometric variables throughout a work shift. The use of computerized peak flowmeters is very helpful in overcoming some of the problems of PEF monitoring. Computerized programs to assess changes in PEF are currently available (e.g., OASYS [Occupational Asthma Expert System]). Combining PEF monitoring with serial assessments

HLA,* human leukocyte antigen. *(From Malo JL, Ghezzo H, D'Aguino C, et al: Natural history of occupational asthma: relevance of type of agent and other factors in the rate of development of symptoms in affected subjects,* J Allergy Clin Immunol *90:937–943, 1992.)*

of nonallergic bronchial responsiveness can provide further objective evidence, although this approach does not add to the sensitivity and specificity of PEF monitoring alone. Finally, assessment of airway inflammation (percent eosinophils) in induced sputum has recently been found to be sensitive and specific in the diagnosis of OA. Such measurements improve the sensitivity and specificity of PEF monitoring. Assessing airway inflammation at work and away from work also can be done by assessing exhaled NO, but the reliability of this technique has not been demonstrated in the investigation of OA.

The main diagnostic criteria for IrIA are (1) the report of at least one inhalational accident (dates, times); (2) the onset of symptoms generally within 24 hours; and (3) the presence of airway obstruction or hyperresponsiveness.

CLINICAL COURSE

Subjects with OA will deteriorate if they continue in the same job without protection. Fatalities in workers who continue to be exposed have been reported. A scheme of the progressive natural history of OA is shown in Figure 40-8. Most patients with OA improve but do not recover completely even several years after removal from exposure. Even those subjects apparently cured as indicated by clinical and functional assessments continue to show airway inflammation and remodeling on subsequently obtained bronchial biopsy specimens. Follow-up studies of various types of OA have shown that persons who became asymptomatic after leaving exposure had better lung function and a lower degree of nonallergic bronchial hyperresponsiveness at the time of diagnosis and a shorter duration of exposure after the onset of symptoms. These findings suggest that they were diagnosed at an earlier stage of the disease. Early diagnosis and removal from exposure are essential in ensuring recovery. Although symptoms subside and lung function improves within 1 year of leaving the job involving exposure, decrease in nonallergic bronchial hyperresponsiveness depends on the length of the interval from cessation of exposure. Specific IgE antibodies decrease even more slowly, with no plateau after 5 years as shown in persons with snow crab–induced asthma. It has been recommended that assessment of permanent respiratory impairment or disability take place after at least 2 years of cessation of exposure. The rate of decline in lung function of patients with OA with continuous exposure is higher than in patients without asthma. Moreover, specific bronchial reactivity to the offending occupational agents often persists after the person has left exposure for 2 or more years. Thus, it is not advisable for these patients to return to the same job after they became asymptomatic. Finally, although fewer follow-up studies are available, the outcome with IrIA seems similar to that with immunologic OA.

A histologic basis for the persistence of symptoms and nonallergic bronchial hyperresponsiveness in patients with OA has been confirmed. Higher total cell count and eosinophils in bronchoalveolar lavage fluid were found in persons with Western red cedar asthma who did not recover than in those who recovered completely after removal from exposure. Saetta and co-workers in 1992 documented some reversal of airway wall remodeling (thickness of subepithelial fibrosis and number of subepithelial fibroblasts) in patients with toluene diisocyanate (TDI)-induced asthma 6 months after cessation of exposure, but no decrease in bronchial inflammation and in the degree of nonallergic bronchial hyperresponsiveness was seen. Signs of airway inflammation and remodeling may persist for intervals of 10 years or more after the cessation of exposure, even in apparently cured workers. The reasons for the persistence of symptoms and nonallergic bronchial hyperresponsiveness, as well as of airway inflammation and remodeling, after removal from exposure are not known.

Some researchers have explored the possibility of further improving clinical outcomes by combining the use of inhaled steroids to reduce the degree of airway inflammation with removal from exposure. Although more improvement in various clinical and functional parameters was shown by comparison with removal from exposure only, no case of cure from asthma was documented. Because most cases of IrIA occur in isolation, it is difficult to study the natural history in a series of such patients. However, the time course of improvement seems to follow the same pattern as for OA caused by sensitization. Cure in the first 2 to 3 years after the inhalational accident has been described in approximately 25% of persons who incurred the exposure, with the remainder still showing airway inflammation and remodeling many years after the inhalational accident.

PREVENTION

Primary prevention aims at reducing the risk of the development of immunologic sensitization to workplace agents and subsequent OA. In view of the strong evidence for an exposure-response relationship, primary preventive efforts should focus on the control of workplace exposures. Various interventions can be implemented to reduce exposure at the workplace, including the elimination of hazardous agents whenever feasible; the modification of sensitizing materials (e.g., encapsulation of detergent enzymes); the substitution of highly sensitizing agents by materials with lower asthmagenic potential (e.g., nonvolatile oligomers of diisocyanates, latex gloves with a lower content of powder and protein allergens); engineering changes to the workplace (e.g., improved ventilation, enclosure of industrial process); implementation of safer work practices; and the use of personal protective equipment. Such primary preventive strategies have been shown to be effective in reducing the incidence of OA resulting from enzymes in the detergent industry and from latex gloves in health care facilities.

Another approach is to identify susceptible persons at the time of preemployment examination and exclude them from employment or from high-risk jobs. Unfortunately, the currently identified markers of individual susceptibility (see Table 40-3) have a low positive predictive value for the development of OA. The high prevalence of these markers among the general population, compared with the relatively low risk of occupational sensitization, precludes such screening from being an effective strategy and would unduly exclude many workers in whom OA would never develop. Accordingly, primary prevention should be directed toward reducing exposure to low-enough levels to prevent the onset of asthma in all workers, irrespective of their individual susceptibility. Nevertheless, physicians caring for adolescents with asthma and allergic diseases may offer useful advice regarding careers in which their underlying atopic status increases the risks for work-related sensitization to HMW agents.

Secondary prevention involves the detection of the disease process at an early (preferably preclinical) stage to prevent the development of overt OA and to minimize long-term respiratory impairment by appropriate interventions, which usually involve removal of the worker from exposure. The rationale underlying secondary prevention is the consistent finding that the outcome of OA is better with early diagnosis and milder asthma at the time of removal from exposure. Reduction in the delay between the onset of respiratory and appropriate assessment and intervention could be achieved by increasing awareness of the disease among workers and health professionals. All workers with new-onset asthma or worsening of existing asthma should be interviewed to discover any temporal relationship between work exposure and their symptoms. In the field of occupational medicine, early identification of OA requires the implementation of periodic health surveillance programs in high-risk industries that may be based on questionnaires, spirometry, and identification of allergen-specific IgE when such tests are available and reliable. Surveillance programs should focus on the very first years of exposure, when the incidence of sensitization is highest. Growing evidence indicates that appropriately designed surveillance programs are effective in identifying OA in subjects with less severe asthma and a more favorable outcome.

TREATMENT

Workers with immunologic OA who remain exposed to the causal agent are likely to experience a worsening of asthma symptoms and nonspecific bronchial hyperresponsiveness, with an accelerated decline in FEV_1 over time. This adverse long-term outcome is not prevented by treatment with inhaled corticosteroids and long-acting β_2-agonists. Thus, the ideal treatment for patients with OA is complete removal from the causal exposure. Nevertheless, OA is associated with substantial long-term morbidity. Complete avoidance of exposure results in an overall improvement in asthma, but asthma symptoms and nonspecific bronchial hyperresponsiveness persist in approximately 70% of the patients with OA several years after removal from the offending environment.

Avoidance of exposure is associated with a substantial adverse socioeconomic impact, because maintaining the affected worker at the same job after elimination of the causal agent from the workplace or accommodation of the worker to an unexposed job often is not feasible.

Reduction in rather than complete avoidance of exposure to causal agents may lead to clinical improvement in terms of asthma symptoms and exacerbations and could be considered as an alternative to complete avoidance, in order to minimize the socioeconomic impact of OA when elimination of exposure is not feasible or when jobs that do not entail exposure are not available. Reducing a worker's exposure can be implemented by various engineering measures (see earlier section, "Prevention") or by relocation of the affected worker to a less exposed area or job in the same company. Nevertheless, the limited available evidence indicates that the option of exposure reduction is less beneficial than cessation of exposure, and that this approach requires careful medical monitoring of the subject to ensure early identification of asthma worsening.

Besides environmental interventions, the pharmacologic treatment of OA should follow the general recommendations for asthma as defined in the Global Initiative for Asthma (GINA) guidelines. Patients with OA should be thoroughly informed about the possibilities for compensation, and established cases should be reported to the appropriate public health authorities, according to national regulations. Patients should be considered as permanently and completely impaired for jobs involving exposure to the sensitizing agent that caused their OA. Evaluation for impairment and disability should take into account all of the special features of asthma and should be based on the level of airway obstruction, the degree of nonspecific bronchial hyperresponsiveness or airway reversibility, the minimum amount of medication required for maintaining control of asthma, and the effects of asthma on quality of life.

Data on the optimal management of IrIA are limited, because most cases occur in isolation. Some evidence from case series indicates that subjects with IrIA should benefit rapidly from treatment with oral and/or inhaled corticosteroids, although the dose and duration of treatment remain unknown. Unlike persons with immunologic OA, workers with acute IrIA may be able to continue in their usual jobs if the risk of accidental high-level exposures is prevented through engineering controls. Persons who develop IrIA may subsequently experience worsening of their asthma symptoms on exposure to irritants in the workplace, which may substantially reduce their capacity to work in polluted or dusty environments.

CONTROVERSIES AND PITFALLS

It is important to have objective evidence that the patient's asthma is due to occupational exposure. Many pitfalls may be encountered in confirming the diagnosis of OA. Although lists of agents causing OA found in published articles and databases are useful to alert the physician, the absence of an agent on such lists does not exclude the possibility of OA, because new proteinaceous materials and chemicals are constantly being introduced into the marketplace. Patients often are asked to leave the job when the diagnosis is suspected. However, one of the objective tests for OA is serial monitoring of PEF by the patient for a period at work and a period away from work. Unless the patient has severe symptoms, it is best to obtain objective evidence first before recommending permanent removal from a specific workplace (i.e., job resignation). PEF monitoring also has limitations, as discussed previously. It should be done properly according to a protocol and with use of a logging device, or together with serial measurements of nonallergic bronchial hyperresponsiveness and airway inflammation. Specific challenge tests have been said to be the "gold standard" modality for diagnosis of OA. When a new agent is suspected, investigators often use several methods to confirm the diagnosis. Some evidence suggests that work-related asthma remains largely unrecognized and inappropriately investigated. A crucial step for enhancing the diagnosis of OA is to promote the prompt referral of workers suspected of having work-related asthma to specialists who have the expertise and facilities for conducting appropriate investigations. In addition, the relative cost and effectiveness of various diagnostic approaches should be further assessed.

Considerable controversy continues regarding whether exposure to a low level of irritant gases or fumes in the workplace or in the environment can actually induce asthma de novo. Despite a great deal that has been learned about OA over the past several years, many gaps remain in current knowledge. Future research priorities should include further improvement in diagnostic, surveillance methods, and control of exposures to prevent the development of the disease and curtail the psychosocioeconomic impact.

Section 7
AIRWAY DISEASES

Chapter 41
Chronic Obstructive Pulmonary Disease: Epidemiology, Pathophysiology, and Clinical Evaluation

William MacNee

Chronic obstructive pulmonary disease (COPD) is a preventable and treatable chronic lung condition characterized by airflow limitation that is not fully reversible. COPD is increasingly recognized as a major global problem that places a burden on both patients who suffer from this disabling condition and health care resources. Despite significant advances in our understanding of the pathogenesis, physiology, clinical features, and management of COPD in recent years, much remains to be discovered about this condition.

Although hidden by the generic term "chronic obstructive pulmonary disease," COPD is a heterogeneous collection of syndromes with overlapping manifestations, which has led to major difficulties in obtaining an acceptable definition of the condition. In addition, as with many chronic inflammatory conditions, COPD is associated with extrapulmonary effects and comorbidities that affect both morbidity and mortality.

The acceptance that symptoms of breathlessness, cough, and sputum production are part of aging or an inevitable consequence of cigarette smoking, and not related to a disease, results in underdiagnosis despite the diagnosis of COPD being easily made. This underdiagnosis is exacerbated by the belief, reinforced by many definitions, that COPD is an "irreversible" condition and that there is nothing "to reverse" with treatment. This leads not only to underdiagnosis but also to undermanagement.

It is now well recognized that significant responses to treatment do occur, which has led to a much more positive approach to the diagnosis and treatment of COPD. Whereas previous treatments largely focused on patients at the severe end of the disease spectrum, recent guidelines recognize that diagnosis and treatment at an earlier stage can offer significant benefits for patients. Although unable to cure COPD, current treatments can reduce symptoms, improve function, and reduce exacerbations in patients as well as decrease the enormous health care costs associated with COPD.

DEFINITIONS AND DIAGNOSTIC CONSIDERATIONS

In defining COPD, several problems must be considered. First, COPD is not just one disease but a group of diseases. Second, it is difficult to differentiate COPD from asthma; the persistent airways obstruction in older patients with chronic asthma is often difficult or even impossible to distinguish from that of COPD patients, who may demonstrate partial reversibility of their airflow limitation. Indeed, some patients with asthma may develop COPD, or these two common conditions may coexist in the same individual. Therefore the problem often is not whether the patient has asthma *or* COPD, but rather whether *either* asthma or COPD is present.

Chronic bronchitis is defined clinically by the American Thoracic Society (ATS) and the United Kingdom (UK) Medical Research Council as "the production of sputum on most days for at least three months in at least two consecutive years when a patient with another cause of chronic cough has been excluded." This definition does not require the presence of airflow limitation. Chronic bronchitis results from inflammation in the larger airways, with bronchial gland hypertrophy and mucus cell hyperplasia.

Emphysema is defined pathologically as "abnormal, permanent enlargement of the distal air spaces, distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis." As with chronic bronchitis the definition of emphysema does not require the presence of airflow limitation. As emphysema progresses, the consequent loss of lung elastic recoil contributes to the airflow limitation in COPD.

Bronchiolitis or *small airways disease* also occurs in COPD, where chronic inflammation in the smaller bronchi and bronchioles less than 2 mm in diameter leads to airway remodeling, resulting in airflow limitation. Although relatively little is known of the natural history, bronchiolitis may contribute increasingly, as it progresses, to the airflow limitation in COPD.

The relative contributions made by large or small airways abnormalities or emphysema to the airflow limitation, in individual patients with COPD, is difficult to determine. Thus the term "chronic obstructive pulmonary disease" was introduced in the 1960s to describe patients with incompletely reversible airflow limitation caused by a combination of airways disease and emphysema, without defining the contribution of these conditions to the airflow limitation.

In the statement on the standards for diagnosis and care of patients with COPD by ATS and European Respiratory Society (ERS), COPD is defined as "a preventable and treatable disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and is associated with an abnormal inflammatory response in the lungs to noxious particles or gases, primarily caused by cigarette smoking. Although COPD affects the lungs, it also produces significant systemic consequences." This is similar to the definition produced by the World Health Organization (WHO) Global Initiative on Obstructive Lung Disease (GOLD), which first introduced the concept of COPD as an inflammatory disease into its definition.

The diagnosis of COPD should be considered in any person with the following:

- A history of chronic progressive symptoms: cough, wheeze, and/or breathlessness, with little variation in these symptoms
- A history of exposure to risk factors: cigarette smoke, occupational and environmental dust, and gaseous exposure

The diagnosis requires objective evidence of airflow limitation assessed by spirometry. A postbronchodilator forced expiratory volume in the first second (FEV_1)/forced vital capacity (FVC) ratio of less than 0.7 confirms the presence of airflow limitation that is not fully reversible.

A number of specific causes of airflow limitation, such as cystic fibrosis, bronchiectasis, and bronchiolitis obliterans, are not included in the definition of COPD, but these should be considered in its differential diagnosis. COPD is considered primarily as a lung disease. However, the extrapulmonary effects and comorbidities should also be considered in patients with COPD.

PATHOLOGY

The pathologic changes in COPD are complex and occur in the central conducting airways, the peripheral airways, the lung parenchyma, and the pulmonary vasculature.

Inflammation initiated by exposure to particles or gases underlies most of the pathologic lesions associated with COPD and represents the innate and adaptive immune responses to a lifetime exposure to noxious particles, fumes, and gases, particularly cigarette smoke. Enhanced inflammation also contributes to disease exacerbations, in which acute inflammation is superimposed on the chronic disease. There is good evidence that all smokers have inflammation in their lungs. However, there is individual susceptibility in the inflammatory response to tobacco smoking, and those who develop COPD show an enhanced or abnormal inflammatory response to inhaled toxic agents.

Although the clinical and physiologic presentation of chronic asthma may be indistinguishable from COPD, the pathologic changes are distinct from those in most cases of COPD, largely because of cigarette smoking. The histologic features of COPD in the 15% to 20% of COPD patients who are nonsmokers have not yet been studied in detail. Although complex, the pathology of COPD can be simplified by considering separate disease sites in which pathologic changes occur in smokers to produce a clinical pattern of largely fixed airflow limitation (Box 41-1). The clinicopathologic picture is complicated because chronic bronchitis, bronchiolitis, and emphysema may exist in an individual patient, resulting in the clinical and pathophysiologic heterogeneity seen in patients with COPD.

CHRONIC BRONCHITIS

Mucus is produced by mucous glands present in the larger airways and by goblet cells in the airway epithelium. Chronic bronchitis is characterized by hypertrophy of the mucous glands (Figure 41-1). Goblet cells that occur predominantly in the surface epithelium of the larger airways increase in number and change in distribution, extending more peripherally. Bronchial biopsy studies confirm findings in resected lungs and show bronchial wall inflammation in chronic bronchitis. Activated T lymphocytes are prominent in the proximal airway walls, with a predominance of the CD8 suppressor T lymphocyte subset, rather than the CD4 subset, as seen in asthma. Macrophages are also prominent. Sputum volume correlates with the degree of inflammation in the airway wall. Neutrophils are present, particularly in the bronchial mucus-secreting glands (Figure 41-1), and become more prominent as the disease progresses. In stable chronic bronchitis, the high percentage of intraluminal

Box 41-1 Chronic Obstructive Pulmonary Disease (COPD): Pathologic Changes

Proximal Airways (cartilaginous airways >2 mm in diameter)
Macrophages and CD8 T lymphocytes
Few neutrophils and eosinophils (neutrophils increase with progressive disease)
Submucosal bronchial gland enlargement and goblet cell metaplasia (results in excessive mucus production or chronic bronchitis)
Cellular infiltrates (neutrophils and lymphocytes) of bronchial glands
Airway epithelial squamous metaplasia, ciliary dysfunction, increased smooth muscle and connective tissue

Peripheral Airways (noncartilaginous airways <2 mm in diameter)
Bronchiolitis at early stage
Macrophages and T lymphocytes ($CD8^+ > CD4^+$)
Few neutrophils or eosinophils
Pathologic extension of goblet cells and squamous metaplasia into peripheral airways
Luminal and inflammatory exudates
B lymphocytes, lymphoid follicles, and fibroblasts
Peribronchial fibrosis and airway narrowing with progressive disease

Lung Parenchyma (respiratory bronchioles and alveoli)
Macrophages and $CD8^+$ T lymphocytes
Alveolar wall destruction caused by loss of epithelial and endothelial cells
Development of emphysema (abnormal enlargement of air spaces distal to terminal bronchioles)
Microscopic emphysematous changes
  Centrilobular (dilation and destruction of respiratory bronchioles, often found in smokers and predominantly in upper zones)
  Panacinar (destruction of whole acinus, typically found in α_1-antitrypsin deficiency and more common in lower zones)
Macroscopic emphysematous changes
  Microscopic changes progress to bullae formation, defined as an emphysematous air space >1 cm in diameter.

Pulmonary Vasculature
Macrophages and T lymphocytes

Early Changes
Intimal thickening
Endothelial dysfunction

Late Changes
Vascular smooth muscle
Collagen deposition
Destruction of capillary bed
Development of pulmonary hypertension and cor pulmonale

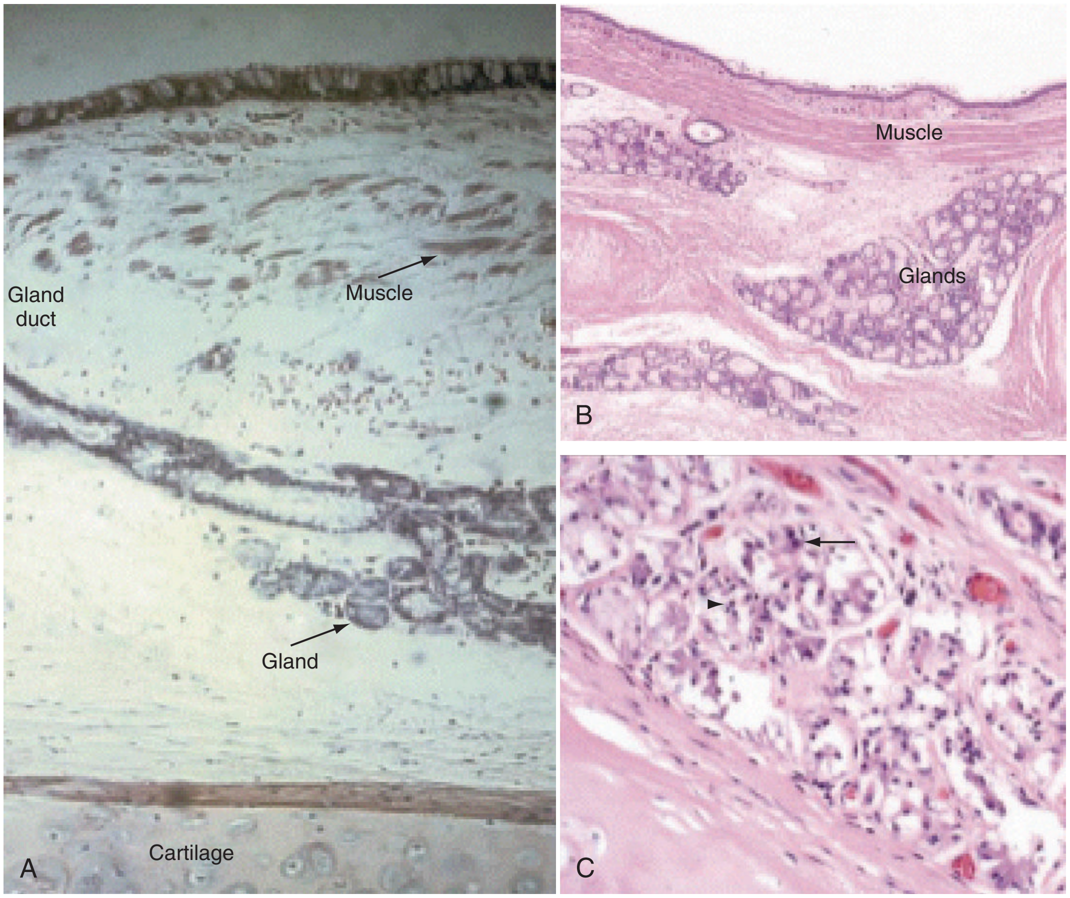

Figure 41-1 **A,** Central bronchus from lung of cigarette smoker with normal lung function. Only small amounts of muscle are present, and epithelial glands are small. This contrasts sharply with **B,** bronchus from patient with chronic bronchitis, where the muscle appears as a thick bundle and the glands are enlarged. **C,** Enlarged glands at higher magnification, showing evidence of chronic inflammation in glands involving polymorphonuclear leukocytes *(arrowhead)* and mononuclear cells, including plasma cells *(arrow)*. *(Courtesy Dr. J. C. Hogg.)*

neutrophils is associated with the presence of neutrophil chemotactic factors, including interleukin-8 (IL-8) and leukotriene B_4 (LTB_4). Elastase released from these cells is a potent stimulant for the secretion of mucus. Macrophages and $CD8^+$ T cells also accumulate in the mucous glands.

Evidence indicates that the airway inflammation in patients with chronic bronchitis persists after smoking cessation, particularly if the production of sputum persists, although cough and sputum improve in most smokers who quit. Airway wall changes include squamous metaplasia of the airway epithelium, loss of cilia and ciliary function, and increased smooth muscle and connective tissue.

SMALL AIRWAYS DISEASE AND BRONCHIOLITIS

The smaller bronchioles (<2 mm in internal diameter) normally contribute relatively little to the total airway resistance, because there are so many airways of this size in parallel. Considerable narrowing of these airways can occur before pulmonary function becomes impaired and symptoms develop. Small airways inflammation is one of the earliest changes in asymptomatic cigarette smokers. The inflammatory cell profiles in the small airways are similar to those in larger airways, including the predominance of $CD8^+$ lymphocytes, increase in CD8/CD4 ratio, and increased macrophages. Mucosal ulceration, goblet cell hyperplasia, and squamous cell metaplasia may be present, as well as mesenchymal cell accumulation and fibrosis. With progression of the condition, structural remodeling may occur, characterized by increased collagen content and scar tissue formation that narrows the airways and produces fixed airway obstruction (**Figure 41-2**).

EMPHYSEMA

Pulmonary emphysema is defined as abnormal permanent enlargement of air spaces distal to the terminal bronchioles, accompanied by destruction of bronchiolar walls. The major types of emphysema are recognized according to the distribution of enlarged air spaces within the *acinar unit*, the part of lung parenchyma supplied by a single terminal bronchiole, as follows:

- Centrilobular (or centriacinar) emphysema, in which large air spaces are initially clustered around the terminal bronchiole (Figure 41-3, *A*).
- Panlobular (or panacinar) emphysema, where the large air spaces are distributed throughout the acinar unit (Figure 41-3, *B*).

Air space enlargement can be identified macroscopically when the enlarged space reaches 1 mm. A *bulla* is a localized area of emphysema, conventionally defined as greater than 1 cm in size.

Centrilobular and panlobular emphysema can occur alone or in combination. The association with cigarette smoking is clearer for centrilobular than panlobular emphysema, although smokers can develop both types. Those with centrilobular emphysema appear to have more abnormalities in the small

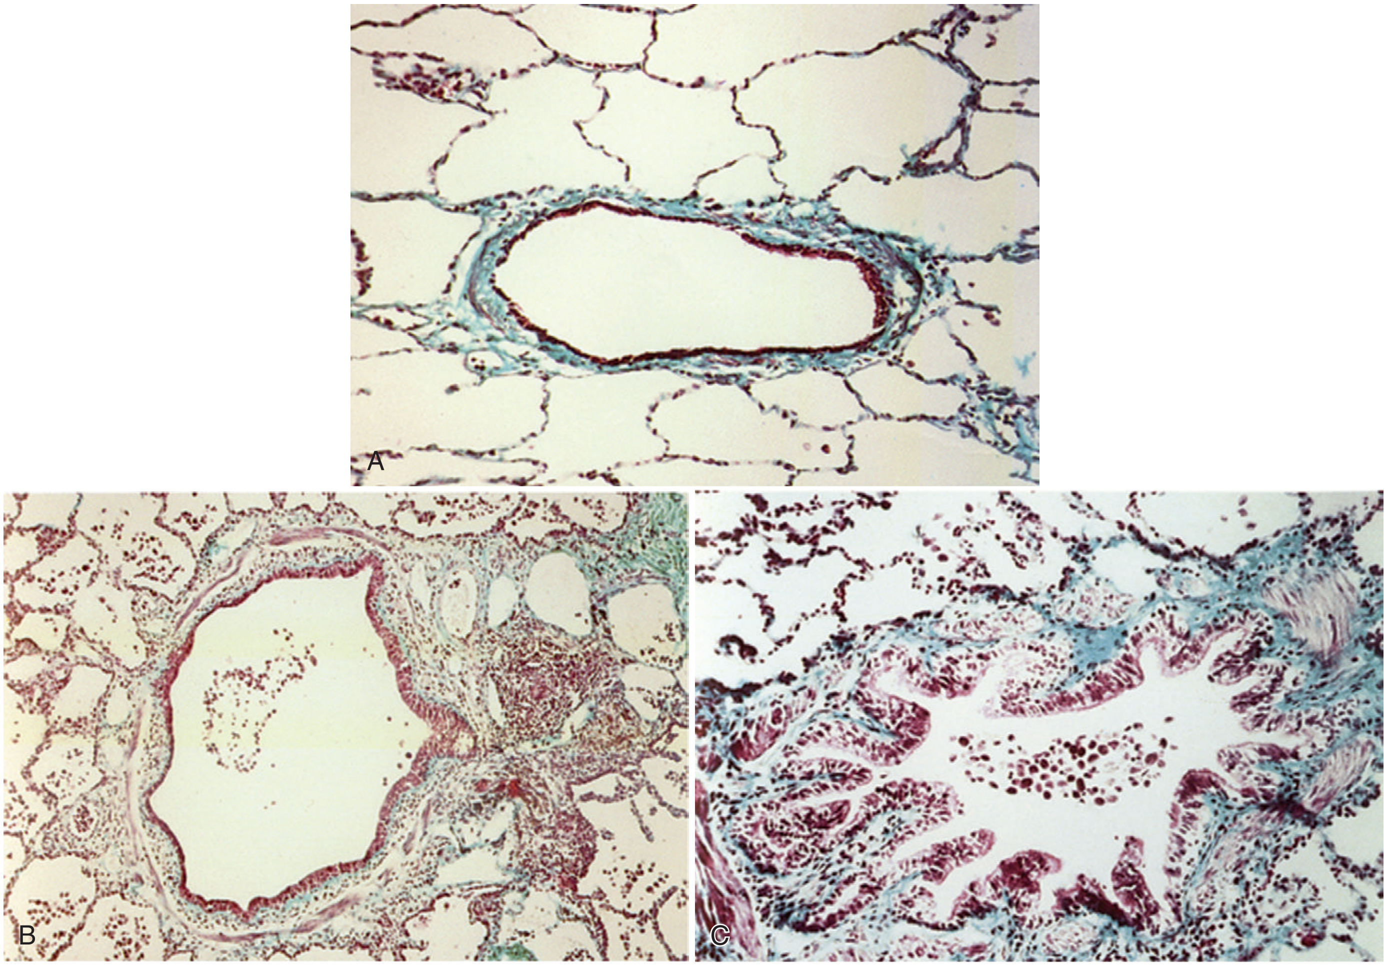

Figure 41-2 Histologic sections of peripheral airways. **A,** Section from cigarette smoker with normal lung function, showing near-normal airway. **B,** Section from patient with small airways disease, showing inflammation in wall and inflammatory exudate in airway lumen. **C,** More advanced case of small airways disease, with reduced lumen, structural reorganization of airway wall, increased smooth muscle, and deposition of peribronchiolar connective tissue. *(Courtesy Dr. J. C. Hogg.)*

airways than those with panlobular emphysema. Panacinar emphysema appears more severe in the lower lobes, in contrast to centriacinar emphysema, which usually concentrates in the upper lobes. Panlobular emphysema is associated with α_1-antitrypsin deficiency, but can also be found in patients with no identified genetic abnormality.

Other types include *paraseptal* (periacinar or distal acinar) emphysema, in which enlarged air spaces occur along the edge of the acinar unit, but only where it abuts against a fixed structure such as the pleura or a vessel. Mixed types of emphysema occur in COPD patients.

The bronchioles and small bronchi are supported by attachment to the outer aspect of adjacent alveolar walls. This arrangement maintains the tubular integrity of the airways. Loss of these attachments and consequent loss of lung elastic recoil may lead to distortion or irregularities of the airways, which contributes to the airflow limitation. The inflammatory cell profile in the alveolar walls is similar to that described in the airways and persists throughout the disease.

PULMONARY VASCULATURE

Changes in the pulmonary vasculature occur early in the course of COPD; thickening of the intima is followed by increase in smooth muscle and infiltration of the vessel wall with inflammatory cells, including macrophages and $CD8^+$ T lymphocytes. As the disease progresses, greater amounts of smooth muscle, proteoglycans, and collagen accumulate, thickening the arterial wall. The development of chronic alveolar hypoxia in patients with COPD results in hypoxic vasoconstriction and subsequently leads to structural changes in the pulmonary vasculature, pulmonary hypertension, and right ventricular hypertrophy and dilation (cor pulmonale).

ETIOLOGY

RISK FACTORS

Cigarette Smoking

Cigarette smoking is the single most important identifiable etiologic factor in COPD. The cause-and-effect relationship between cigarette smoking and COPD derives from several well-controlled population studies over the last four decades.

Maternal smoking is associated with low birth weight and decreased lung function at birth, which may lead to decreased level of function in early adulthood, increasing the risk of developing COPD depending on lifestyle, particularly smoking history. Further, smoking by either parent is associated with an increase in respiratory illness in the first 3 years of life, which may contribute to airflow limitation in later life.

CT scans show patchy centrilobular emphysema. **B,** Panlobular (panacinar) emphysema, showing confluent, even involvement of acinar unit. CT scans show diffuse, low-attenuation areas of panlobular emphysema.

Mild airflow limitation and a reduced increase in lung function occur in smoking adolescents. In addition, the plateau FEV_1 in the third decade of life is also shortened considerably by cigarette smoking, which results in the initiation of FEV_1 decline years earlier than in those who do not smoke.

In adulthood the effect of smoking on FEV_1 decline is well known. In general there is a significant dose-response effect, with smokers having lower lung function the more and the longer they smoke. There is, however, considerable variation. Most longitudinal studies indicate that the decline in FEV_1 in smokers ranges from 45 to 90 mL per year, in contrast to the normal 30 mL/yr (Figure 41-4). However, values vary considerably among individuals, and some experience significantly greater decline, at least temporarily, which may explain why COPD may seem to surface over a short period in the fifth and sixth decades of life. Some nonsmokers have impaired lung function, and 15% to 20% of COPD patients are lifelong nonsmokers. Conversely, some heavy smokers are able to maintain normal lung function, although the frequently quoted "15% to 20%" of smokers who are thought to develop clinically significant COPD is probably an underestimate. About 35% of smokers with normal lung function initially developed COPD during a 25-year follow-up in the Copenhagen City Heart Study.

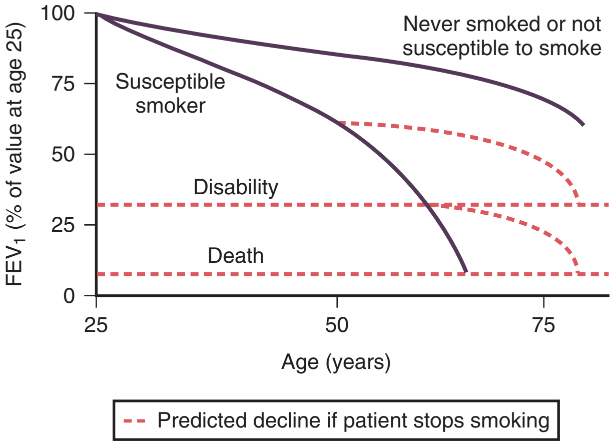

Figure 41-4 Decline in forced expiratory volume in 1 second (FEV_1) in smokers and nonsmokers. Horizontal dashed lines represent level of FEV_1 consistent with disability or death; curved dashed lines represent change in FEV_1 decline with smoking cessation.

Pipe and cigar smokers have significantly greater morbidity and mortality from COPD than nonsmokers, although the risk is less than that from cigarettes. There is a trend to an increased relative risk of chronic airflow limitation from passive smoking, but the effect is not powerful enough to demonstrate clinical significance. Epidemiologic studies have associated cessation of smoking with a decrease in the prevalence of respiratory symptoms and improvement in the subsequent decline in FEV_1 (Figure 41-4). The first effect on lung function after smoking cessation is a small increase of 50 to 100 mL in FEV_1. There is some debate on whether decline in FEV_1 after smoking cessation completely normalizes, although in general those who quit smoking continue to have an FEV_1 decline slightly larger than in those who never smoked.

Air Pollution

Air pollution has been recognized as a risk factor in chronic respiratory disease in association with various air pollution episodes in the past. The introduction of air quality standards in the 1950s and 1960s led to a decrease in smoke and sulfur dioxide levels, which produced less discernible peaks of pollution related to morbidity and mortality. However, more recent studies show an association between respiratory symptoms, general practitioner consultations and hospital admissions in patients with airways disease, including COPD, at levels of particulate air pollution below 100 $\mu g/m^3$, levels currently experienced in many urban areas in Western countries.

The role of long-term exposure to *outdoor* air pollution as a risk factor for the development of COPD is still debated. Air pollution does appear to be a risk factor for mucus hypersecretion, although the association with airflow limitation and accelerated decline in FEV_1 is less clear. Air pollution may affect the development of lung function in childhood, which may influence the risk of COPD in adulthood. It is also recognized that *indoor* air pollution, derived from the combustion of biomass fuel in fires and stoves, is an important etiologic factor in COPD and is a particular problem among women in developing countries. Exposure to biomass smoke is thought to increase the risk of COPD two-fold to three-fold.

Occupational Exposure to Dusts

There is a causal link between occupational dust exposure and the development of mucus hypersecretion. In addition, longitudinal studies in workforces exposed to dust show an association between dust exposure and a more rapid decline in FEV_1. Selection bias must be considered in these associations, resulting from the "healthy worker effect," with those having respiratory symptoms or lower lung function excluded before entering the occupation. An estimated 15% to 20% of COPD cases are caused by occupational dusts, which increases to 30% in never-smokers. A study of male workers in the Paris area exposed to occupational dusts showed a 5 to 15 mL/yr successive decline in FEV_1 from dust exposure. Exposure to welding fumes is also associated with a small but significant risk of developing COPD, from a study in shipyard workers. Workers exposed to *cadmium* have an increased risk of emphysema.

Chronic Mucus Hypersecretion

Population studies of respiratory symptoms indicate a higher prevalence of cough and sputum among smokers than nonsmokers. Cessation of smoking is associated with cessation of sputum production in most cases. Earlier studies of working men in London showed that smoking accelerated the decline in FEV_1, but failed to show a correlation between the degree of mucus hypersecretion and an accelerated decline in FEV_1 or mortality. By contrast, mortality was strongly related to the development of a low FEV_1. Data from a more general population study in Copenhagen between 1976 and 1994 suggested that mucus hypersecretion was associated with increased risk of hospital admission and excessive decline in FEV_1 of 10 to 15 mL. Moreover, as FEV_1 decreases, the association between mucus hypersecretion and mortality becomes stronger.

Chronic Bronchopulmonary Infection

The "British hypothesis" suggested that chronic sputum production (chronic bronchitis) predisposed patients to recurrent bronchopulmonary infections, which subsequently resulted in biologic changes in the airways and alveoli, causing the progression of chronic airflow limitation. In the 1960s and 1970s, Fletcher and Peto refuted this hypothesis, showing no relationship between recurrent infective exacerbations of bronchitis and the decline in lung function in men with chronic bronchitis. This has been challenged more recently in the Lung Health Study, which showed an association in continued smokers between lower respiratory tract infection and a faster rate of decline in lung function. This is supported by more recent studies of patients with COPD.

Cough and sputum production in adulthood is more often reported in those with a history of chest illness in childhood. The association between childhood respiratory illness and ventilatory impairment in adulthood is probably multifactorial. Low economic status, greater exposure to passive smoking, poor diet and housing, and residence in areas of high pollution may all contribute to this finding.

HOST FACTORS

Lung Growth

Several studies indicate that mortality from chronic respiratory diseases and adult ventilatory function correlate inversely with birth weight and weight at 1 year of age. Thus, impaired growth in utero may be a risk factor for the development of chronic respiratory diseases, including COPD. Any factor that affects lung growth during gestation or in childhood, and thus subsequent attainment of maximum lung function, has the potential to increase the risk of developing COPD.

Diet

Diet may influence the development of COPD. Because oxidative stress is thought to have a role in the pathogenesis of COPD, dietary antioxidants such as vitamins A, C, and E should have a protective effect in smokers. The Seven Countries Study found an inverse relationship between baseline intake of fruit and fish and subsequent COPD mortality. In the U.S. Third National Health and Nutrition Examination Survey (NHANES-III), dietary factors, particularly a low intake of vitamin C and low plasma levels of ascorbic acid, were related to a diagnosis of bronchitis. Two British studies also showed that dietary intake of vitamins C and E influences lung function in adults. Studies further suggest a decreased risk of COPD in subjects with a high intake of omega-3 fatty acids.

Atopy and Airway Hyperresponsiveness

The “Dutch hypothesis” proposed that smokers with chronic, largely irreversible airflow limitation and subjects with asthma shared a common constitutional predisposition to allergy, airway hyperresponsiveness, and eosinophilia. Smokers tend to have higher levels of immunoglobulin E (IgE) and higher eosinophil counts than nonsmokers, but not as high a level as in asthmatic patients. Studies in middle-aged smokers with a degree of airflow limitation found a positive correlation between accelerated decline in FEV_1 and increased airway responsiveness to either methacholine or histamine. Over a range of studies, the presence of airway hyperresponsiveness adds approximately 10 mL/yr to decline in FEV_1.

Bronchodilator reversibility has been suggested as a proxy for airway hyperresponsiveness, and some studies suggest reversibility as a predictor of FEV_1 decline. However, these studies have not been adjusted for the actual value of the post-bronchodilator FEV_1; when this is done, minimal association appears to exist between reversibility and FEV_1 decline.

Whether airway hyperresponsiveness is a cause or consequence of COPD remains a subject of debate. Although asthma has been considered confusingly as a risk factor for COPD, good evidence supports that asthmatic patients have a more rapid decline in FEV_1 than nonasthmatic patients, as well as an increased mortality, primarily from COPD. Poorly controlled asthma will likely lead to airway remodeling and fixed airflow obstruction, fulfilling the definition of COPD.

Genetic Factors

Chronic obstructive pulmonary disease is a prime example of a condition of gene-environment interaction. The observation of a familial association for an increased risk of airflow limitation in smoking siblings of subjects with severe COPD suggests a genetic component to this disease. Genetic linkage analysis has identified several sites in the genome that may contain susceptibility genes, such as chromosome 2q. Genetic association studies show that a number of candidate genes are associated with the development of COPD or with rapid decline in FEV_1. However, the associations are not consistent in different populations (Box 41-2).

Because COPD is a complex and heterogeneous condition, COPD-related phenotypes may differ between different genetic subtypes of COPD. Several studies suggest polymorphisms in various genes related to emphysema severity or distribution of emphysema. A genetic predisposition to the development of COPD exacerbations has also been suggested.

Many genes with unknown functions likely contribute to the pathogenesis of COPD, and until recently, it has not been practical to interrogate the entire genome. Genome-wide association studies may provide a better alternative to candidate gene approaches. Recent genome-wide association studies have identified a single nucleotide polymorphism (SNP) on chromosome 15 that has a significant association with COPD. Multiple genes of interest are present near the most likely associated SNP, including subunits of the nicotinic acetylcholine receptor (CHRNA3 and CHRNA5) and an iron-binding protein (IREB2). A further genome-wide association study identified four SNPs on chromosome 4q, which is strongly associated with FEV_1/FVC. Thus, although genome-wide association studies are at an early stage, chromosome 4 and 15 genetic associations appear to be most significant in COPD.

Table 41-1 Alpha$_1$-Antitrypsin Phenotypes: Frequency in UK Population, Concentration, and Emphysema Risk

Phenotype	Frequency (%)	Average Concentration* (g/L)	Risk Factor for Emphysema
MM	86	2	No
MS	9	1.6	No
MZ	3	1.2	No
SS	0.25	1.2	No
SZ	0.2	0.8	Yes
ZZ	0.03	0.4	Yes

*Serum α_1-protease inhibitor.

The most consistent association with COPD is *alpha$_1$-antitrypsin* (α_1-proteinase inhibitor) *deficiency*. Alpha$_1$-antitrypsin is a glycoprotein that is the major inhibitor of serine proteases, including neutrophil elastase. More than 75 biochemical variants of α_1-antitrypsin have been described relating to their electrophoretic properties, giving rise to the *phase inhibitor* (Pi) nomenclature (Table 41-1). The most common allele in all populations is PiM, and the most common genotype is PiMM, which occurs in 93% of the alleles in subjects of Northern European descent. PiMZ and PiMS are the next two most common genotypes and are associated with α_1-proteinase inhibitor levels of 15% to 75% of the mean levels of PiMM subjects. Similar levels occur in the much less common PiSS type. The most important other type is PiSZ, in which basal levels are 35% to 50% of normal values. The threshold point for increased risk of emphysema is a level of about 80 mg/dL, which is about 30% of normal.

The homozygous PiZZ type, in which serum levels are 10% to 20% of the average normal value, is the strongest genetic risk factor for the development of emphysema. This recessive trait is most frequently seen in individuals of Northern European descent. Such individuals, particularly if they smoke, are likely to develop COPD, usually panlobular emphysema, at an early age. The onset of disease occurs at a median age of 50 in nonsmokers and 40 years in smokers.

The defect resulting in α_1-antitrypsin deficiency is related to a single point mutation at position 342, where the nucleotide sequence for this codon is changed from GAG to AAG, resulting in an amino acid change from glutamic acid to lysine. In the PiZZ subject, α_1-antitrypsin protein accumulates in the endoplasmic reticulum of the liver. The structure of the protein reveals that the defect results in the development of abnormal protein polymers, which prevents the α_1-antitrypsin passing through the endoplasmic reticulum and thus prevents the secretion of the protein. These polymers may also be chemotactic for inflammatory cells and may thus contribute to the increased elastase burden. It is postulated that a deficiency in α_1-proteinase inhibitor results in excess activity of neutrophil elastase and therefore tissue destruction and emphysema.

Studies of U.S. blood donors identify a 1 : 2700 prevalence of PiZZ subjects, the majority of whom had normal spirometry. An estimated 1 : 5000 UK children are born with the homozygous deficiency (PiZZ). However, the number of subjects identified with disease is much lower than predicted from the known prevalence of the deficiency. It is therefore by no means inevitable that all individuals with homozygous deficiency will develop respiratory disease.

OTHER FACTORS

An association between COPD patients' economic status, education, and lung function and COPD hospitalization has been shown in a Danish study, despite relatively small differences among social classes. However, social risk factors are likely multifactorial and may relate to intrauterine exposure, childhood infections, childhood environment, diet, housing conditions, and occupational factors.

The role of gender as a risk factor for COPD remains unclear. Previous studies typically showed greater COPD mortality in men than women, but more recent studies show that COPD now has almost equal prevalence in men and women, probably reflecting the change in tobacco smoking. Women may be more susceptible to the effects of tobacco smoke than men, but this is still debated.

EPIDEMIOLOGY

Although COPD is a leading cause of morbidity and mortality worldwide, its prevalence varies across countries. The imprecise, variable definitions of COPD and the lack of spirometry to confirm the diagnosis make it difficult to quantify morbidity and mortality. In addition, prevalence data underestimate the total disease burden because COPD typically is not diagnosed until it is clinically recognized, usually at a moderately advanced stage. Mortality from COPD is also likely to be underestimated because it is often cited as a "contributory factor" rather than a cause of death.

PREVALENCE

In the past, imprecise definitions of COPD and underdiagnosis have resulted in underreporting of the condition. Prevalence studies of COPD vary depending on the survey method employed, including self-report of physician diagnosis of COPD, prebronchodilator or postbronchodilator spirometry, and respiratory symptom questionnaires. The lowest prevalence figures come from physician self-reporting; most national surveys indicate that about 6% of the general population has been diagnosed with COPD. This figure probably reflects the underrecognition of COPD, particularly in the early stages, when symptoms are not recognized as representing a disease.

Studies based on standardized spirometry suggest that 25% of subjects over age 40 have airflow limitation (FEV_1/FVC <0.7). However, prevalence data vary depending on the spirometric criteria used to define COPD. The use of a postbronchodilator, fixed FEV_1/FVC (<0.7) leads to potential underdiagnosis in younger adults and overdiagnosis in older adults (>50). Other prevalence studies are based on percent predicted FEV_1. In a UK population survey, 10% of men and 11% of women age 18 to 64 years had an FEV_1 greater than 2 standard deviations (SD) below their predicted values; the numbers increased with age, particularly in smokers. In current smokers 40 to 65 years old, 18% of men and 14% of women had an FEV_1 greater than 2 SD below normal, compared with 7% and 6% of male and female nonsmokers, respectively.

Approximately 14 million people in the United States have COPD, increasing by 42% since 1982. The best data available come from the 1988-1994 NHANES-III study. Prevalence of mild COPD (defined as $FEV_1/FVC <0.7$ and $FEV_1 >80\%$ predicted) was 6.9% and prevalence of moderate COPD (defined as $FEV_1/FVC <0.7$ and $FEV_1 \leq 80\%$ predicted) was 6% for those age 25 to 75. The prevalence of both mild and moderate COPD was higher in males than females, in whites than in blacks, and increased steeply with age. Airflow limitation affected an estimated 14.2% of current white male smokers, 6.9% of ex-smokers, and 3.3% of never-smokers. Airflow limitation occurred in 13.6% of white female smokers, 6.8% of ex-smokers, and 3.1% of never-smokers. Less than 50% of COPD patients, based on the presence of airflow limitation, had a physician diagnosis of COPD.

Data from five Latin American cities in five different countries showed the presence of COPD (FEV_1/FEC ratio <0.7) increased sharply with age. The highest prevalence was in the over-60 age-group and ranged from 18.4% in Mexico City to 31.1% in Montevideo, Uruguay. In 12 Asian-Pacific countries, prevalence of moderate to severe COPD in those over age 30 was 6.3%. However, prevalence rates ranged from 3.5% to 6.7% across the Asia-Pacific region.

The UK national study reported abnormally low FEV_1 in 10% of males and 11% of females age 60 to 65 years. In England and Wales, an estimated 900,000 people have a diagnosis of COPD, although because of underdiagnosis, the true number is likely closer to 1.5 million. The mean age at diagnosis in the UK was 67 years, and prevalence increased with age. COPD was more common in men than in women and was associated with socioeconomic deprivation. The prevalence of diagnosed COPD has increased in the UK in women from 0.8% in 1990 to 1.4% in 1997, but did not change over the same period in men. Similar trends are found in the United States, again probably reflecting differences in smoking habits. National surveys of consultations in British general practices found a modest decline in the number of middle-aged men with symptoms of COPD and a slight increase in middle-aged women. These trends are confounded by changes over the years in the application of the diagnostic labels for this condition, particularly the overlap between COPD and asthma.

MORBIDITY AND SOCIOECONOMIC IMPACT

Morbidity data in patients with COPD are less available and less reliable than mortality data, but the number of physician visits, emergency department (ED) visits, and hospitalizations in COPD patients increases with age, is greater in men than women, and is likely to increase with the aging population.

The ERS White Book provides data on the mean number of consultations for major respiratory diseases across 19 European countries. In most, consultations for COPD equal the number for asthma, pneumonia, lung cancer, and tuberculosis combined. In the United States in 2000, there were 8 million physician office/hospital outpatient visits for COPD, 1.5 million ED visits, and 673,000 hospitalizations.

The disability-adjusted life years (DALYs) for a condition is the sum of years lost because of premature mortality and years of life lived with disability, adjusted for the severity of the disability. In 1990, COPD was the 12th leading cause of DALYs in the world, about 2.1% of the total. COPD is projected to be the fifth leading cause of DALYs worldwide in 2020.

In the UK, emergency admissions for exacerbations of COPD increased from 0.5% of all hospital admissions in 1991 to 1% in 2000. Morbidity from COPD increases with age and is greater in men than women. COPD morbidity also may be affected by comorbidities (e.g., ischemic heart disease, diabetes mellitus) and may impact health status. Airway diseases (chronic bronchitis and emphysema, COPD, and asthma) account for a calculated 24.4 million lost working days per year in the UK, which represents 9% of all certified sickness absence among men, and 3.5% of the total in women. Respiratory diseases in the UK rank as the third most common cause of days of certified incapacity, with COPD accounting for 56% of these days lost in men and 24% in women. Most admissions are in the over-65 age-group and patients with advanced disease, although admissions recur at all stages. About 25% of patients diagnosed with COPD are admitted to the hospital, and 15% of all outpatients are admitted each year. In 2002-2003, there were 110,000 hospital admissions for COPD exacerbations in England, representing 8% of all emergency admissions. The burden in primary care is even greater, providing 86% of COPD care. Patients with COPD average six or seven visits annually to their general practitioner.

MORTALITY

Chronic obstructive pulmonary disease is the fourth leading cause of death in the United States and Europe and is projected to be the third leading cause of death (now fifth) worldwide by 2020, a result of the increase in smoking in the developing world and the changing demographics in those countries with increasing longevity of their populations. Large international variations in mortality for COPD cannot be entirely explained by differences in diagnostic patterns, diagnostic labels, or smoking habits. Death certification figures underestimate mortality because as previously stated, COPD is often cited as a contributory factor to the cause of death. COPD death rates are low under age 45 and increase steeply with age. Although mortality from COPD in men has been falling slightly, mortality in women has increased. U.S. data (2000-2005) indicate that COPD accounts for 5% of all deaths, with age-standardized mortality rate stable at approximately 64 deaths per 100,000 population; however, mortality in males fell from 83.8 in 2000 to 77.3 per 100,000 in 2005 and increased in females from 54.4 to 56.0 per 100,000.

In the UK in 2003, an estimated 26,000 persons (14,000 men, 12,000 women) died from COPD, 4.9% of all deaths, 5.4% of all male deaths, and 4.2% of all female deaths. Mortality from COPD in the UK has fallen in men but risen in women over the last 25 years, except in the over-75 age-group. In American women the decline in mortality which was recorded until 1975 has reversed and has increased substantially between 1980 and 2000, from 20.1 to 56.7 per 100,000, whereas the increase in men has been more modest, from 73.0 to 82.6 per 100,000. These trends presumably relate to the later peak prevalence of cigarette smoking in women compared with men. In the UK, age-adjusted death rates from chronic respiratory diseases vary by a factor of 5 to 10 in different geographic locations. Mortality rates tend to be higher in urban areas than in rural areas.

In the UK, COPD reduces life expectancy by an average of 1.8 years (76.5 vs. 78.3). The reduction in life expectancy increases with age, from 1.1 year in mild disease to 1.7 years in moderate disease and 4.1 years in patients with severe disease.

NATURAL HISTORY AND PROGNOSIS

Chronic obstructive pulmonary disease is generally progressive, particularly if the patient's exposure to noxious agents continues. However, the natural history of COPD is variable; not all individuals follow the same course. Stopping exposure to noxious agents, such as cigarette smoke, may result in some improvement in lung function and may slow or halt progression of the disease.

The airway obstruction in susceptible smokers develops slowly because of an accelerated rate of decline in FEV_1 that continues for years. As noted previously, impaired lung function development during childhood and adolescence as a result of recurrent infections or exposure to tobacco smoke may lead to lower maximally attained lung function in adulthood. This failure in lung growth, often combined with a shortened plateau phase in teenage smokers, increases the risk of COPD (**Figure 41-5**). In never-smokers the FEV_1 declines at a rate of 20 to 30 mL/yr (see Figure 41-4). Smokers as a population have a faster rate of decline, and reported changes in FEV_1 in patients with COPD exceed 50 mL/yr. However, decline in COPD patients varies considerably. The initial level of FEV_1 is related to the annual rate of decline in FEV_1, and individuals in the highest or lowest FEV_1 percentiles remain in the same percentiles over subsequent years. This suggests that susceptible cigarette smokers can be identified in early middle age by a reduction in FEV_1.

Longitudinal data from the Lung Health Study in the United States show that stopping smoking, even after significant airflow limitation is present, can result in some improvement in function, and that it will slow or even stop the progression of airflow limitation. Men who quit smoking at the beginning of the study had an FEV_1 decline of 30.2 mL/yr, whereas for those who continued to smoke throughout the study, the decline was 66.1 mL/yr. Similar findings were seen in women.

The FEV_1 is a strong predictor of survival. Less than 50% of patients whose FEV_1 has fallen to 30% of the predicted values are alive 5 years later. The best association between FEV_1 and survival is the postbronchodilator FEV_1, rather than prebronchodilator. Other clinical parameters shown to be important prognostic indicators independent of FEV_1 include weight loss, a poor prognostic sign. Other unfavorable prognostic factors include severe hypoxemia, raised pulmonary arterial pressure,

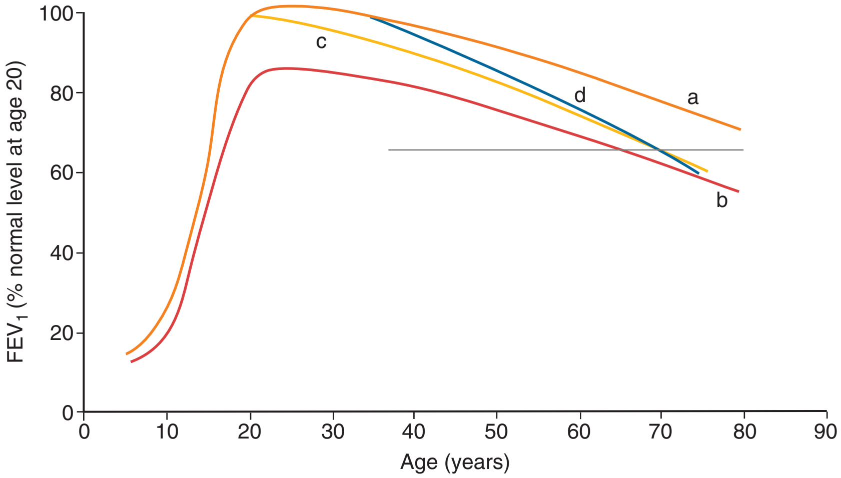

Figure 41-5 Different patterns of obtaining abnormally low forced expiratory volume in 1 second (FEV$_1$) in middle age. FEV$_1$ plotted as a percentage of maximal at age 20 against years of age. Line *a*, normal age-related decline in FEV$_1$ in healthy subjects; *b*, abnormal growth rate but normal age-related decline in FEV$_1$; *c*, premature or early decline; *d*, accelerated decline in lung function. *(From Weiss ST, Ware JH:* Am J Respir Crit Care Med *154:s208–s211, 1996.)*

and low carbon monoxide transfer, which become apparent in patients with severe disease.

PATHOGENESIS

Central to the pathogenesis of COPD is an enhanced inflammatory response to inhaled particles or gases. The following pathogenic processes are involved in this inflammatory response (Figure 41-6):

- Increased air space inflammation
- Increased protease burden and decreased antiprotease function
- Oxidant/antioxidant imbalance and oxidative stress
- Defective lung repair

AIR SPACE INFLAMMATION

Inflammation is present in the lungs, particularly in the small airways, of all smokers. This inflammatory response is thought to be a normal, protective, innate immune response to inhaled toxins. This response is amplified in patients who develop COPD, through mechanisms not fully understood. COPD does develop in some patients who do not smoke, but the inflammatory response in these patients is not well characterized. The abnormal inflammatory response in COPD leads to tissue destruction, impairment of defense mechanisms that limit such destruction, and defective repair mechanisms. In general, the inflammatory and structural changes in the airways increase with disease severity and persist even after smoking cessation.

The *innate* inflammatory immune system provides primary protection against the continuing insult from inhalation of toxic gases and particles. The first line of defense consists of the mucociliary clearance apparatus and macrophages that clear foreign material from the lower respiratory tract; both are impaired in COPD. The second line of defense of the innate immune system is the exudation of plasma and circulating cells into both large and small conducting airways and the alveoli. This process is controlled by an array of proinflammatory chemokines and cytokines (Box 41-3). COPD is characterized by increased neutrophils, macrophages, T lymphocytes (CD8 > CD4), and dendritic cells in various parts of the lungs (see Box 41-2). Generally, the extent of inflammation is related to degree of airflow limitation. These inflammatory cells are capable of releasing a variety of cytokines and mediators that participate in the disease process. This inflammatory cell pattern is greatly different from that found in asthma.

Box 41-3 Inflammatory Mediators in COPD

Leukotriene B_4 (LTB_4)
  Neutrophil and T cell chemoattractant
  Produced by macrophages, neutrophils, and epithelial cells
Chemotactic factors
  CXC chemokines, interleukin-8 (IL-8), growth-related oncogene-α
  Produced by macrophages and epithelial cells
  Attract cells from circulation; amplify proinflammatory responses
Proinflammatory cytokines
  Tumor necrosis factor alpha (TNF-α)
  Interleukin-1beta (IL-1β) and IL-6
Growth factors
  Transforming growth factor beta (TGF-β)
  May cause fibrosis in airways directly or through release of another cytokine, connective tissue growth factor

COPD, chronic obstructive pulmonary disease.

An *adaptive* immune response is also present in the lungs of patients with COPD, as shown by the presence of mature lymphoid follicles, which increase in number in the airways according to disease severity. Their presence has been attributed to the large antigen load associated with bacterial colonization or frequent low respiratory tract infections, or possibly an autoimmune response. Dendritic cells are major antigen-presenting cells, are increased in the small airways, and provide a link between the innate and adaptive immune responses.

Both central airways and peripheral airways are inflamed in smokers with COPD. Smokers with chronic bronchitis have greater inflammation in bronchial glands. Recent studies characterizing the inflammation show increased infiltration of mast cells, macrophages, and neutrophils in smokers with chronic bronchitis (see Box 41-1). An increase in T lymphocytes, mainly in the $CD8^+$ subset, occurs, in contrast to the predominance of the CD4 T cell subset in asthma. CD8 lymphocytes may have a role in apoptosis and destruction of alveolar wall epithelial cells, through the release of perforins and tumor necrosis factor alpha (TNF-α). Excessive recruitment of CD8 T lymphocytes may occur in response to repeated viral infections, damaging the lungs in susceptible smokers.

Figure 41-6 Overview of pathogenesis of chronic obstructive pulmonary disease. Cigarette smoke activates macrophages in epithelial cells to produce chemotactic factors that recruit neutrophils and CD8$^+$ cells from the circulation. These cells release factors that activate fibroblasts, resulting in abnormal repair processes and bronchiolar fibrosis. Imbalance between proteases released from neutrophils and macrophages and antiproteases leads to alveolar wall destruction (emphysema). Proteases also cause the release of mucus. Increased oxidant burden resulting from smoke inhalation or release of oxidants from inflammatory leukocytes causes epithelial and other cells to release chemotactic factors, inactivates antiproteases, directly injures alveolar walls, and causes mucus secretion. Several processes are involved in amplifying the inflammatory responses in COPD. *TGF-β*, Transforming growth factor beta; *CTG*, connective tissue growth factor. *(From MacNee W: Pathology and pathogenesis. PROTEINASE/ANTIPROTEINASE IMBALANCE

Important for understanding the pathogenesis of COPD, an association was seen between α_1-antitrypsin deficiency and development of early-onset emphysema. Alpha$_1$-antitrypsin is a potent inhibitor of serine proteases and has greatest affinity for the enzyme neutrophil elastase. It is synthesized in the liver and increases from its usual plasma concentration as part of the acute-phase response. The activity of this protein is critically dependent on the methionine-serine sequence at its active site. Table 41-1 provides the average α_1-antitrypsin plasma levels for the more common phenotypes.

A deficiency in alpha$_1$-antitrypsin levels, particularly the inability to increase levels in the acute response, results in unrestrained proteolytic damage to lung tissue, leading to emphysema, which develops at an earlier age than in the patient with the more common emphysema in COPD. Cigarette smoking is a cofactor in the development of emphysema in alpha$_1$-antitrypsin–deficient patients, probably as a result of oxidation and thus inactivation of the remaining functional α_1-antitrypsin by oxidants in cigarette smoke. Hypothetically, under normal circumstances, the release of proteolytic enzymes from inflammatory cells, which migrate to the lungs to fight infection or after cigarette smoke inhalation, does not cause damage because of inactivation of these proteolytic enzymes by an excess of inhibitors. In conditions of excessive enzyme load or with absolute or functional deficiency of antiproteinases, however, an imbalance develops between proteinases and antiproteinases that favors proteinases, leading to uncontrolled enzyme activity and degradation of lung connective tissue in alveolar walls, resulting in emphysema. Cigarette smoke and inflammation produce oxidative stress, which primes several inflammatory cells to release a combination of proteases and to inactivate several antiproteases by oxidation.

This simplified protease/antiprotease theory is complicated by the presence of other antiproteases (e.g., antileukoprotease) and other proteases (e.g., metalloproteases) released from macrophages (Table 41-2).

ELASTASE SYNTHESIS AND REPAIR

An abnormality of elastin synthesis and repair may be involved in the pathogenesis of emphysema. Severe starvation has been reported to cause COPD in both humans and animals;

Table 41-2 Proteinases and Antiproteinases in COPD

Proteinases	Antiproteinases
Serine proteinases	α_1-Antitrypsin
Neutrophil elastase	α_1-Antitrypsin
Cathepsin G	Secretory leukoprotease inhibitor
Proteinase 3	Elafin
Cysteine proteinases	Cystatins
Cathepsins: B, K, L, S	
Matrix metalloproteinases (MMP-8, MMP-9, MMP-12)	Tissue inhibitor of MMPs (TIMP-1 to TIMP-4)

COPD, chronic obstructive pulmonary disease.

in addition, starvation can exacerbate proteinase-induced emphysema in animal models. Whether the milder malnutrition that occurs in emphysematous patients has a role in the pathogenesis is unknown.

Certain disorders of connective tissues, including Ehlers-Danlos syndrome and cutis laxa (generalized elastolysis), have been associated with the development of emphysema. Emphysema also develops in some animal models with genetic defects in tissue metabolism.

OXIDANT/ANTIOXIDANT IMBALANCE

Considerable evidence supports the presence of an imbalance between oxidants and antioxidants that favors the oxidants (oxidative stress) in patients with COPD. Cigarette smoke itself produces a huge oxidant burden in the air spaces, and oxidants are released in increased amounts from the activated inflammatory cells that migrate into the air spaces in response to smoking, as noted earlier. Important antioxidants such as glutathione may also be affected by inhalation of cigarette smoke. Smoking initially depletes glutathione, but a subsequent rebound of levels occurs, presumably as a protective mechanism against the effects of cigarette smoking.

Studies have measured increased markers of oxidative stress, such as products of lipid peroxidation reactions, in biologic fluids of patients with COPD as indirect measurements of reactive oxygen species activity. Evidence shows increased markers of oxidative stress in bronchoalveolar lavage (BAL) fluid, sputum, exhaled breath, and breath condensate as well as systemically in the blood and skeletal muscle in patients with COPD, supporting a role for oxidative stress in its pathogenesis. Oxidative stress can directly damage cells, increase air space epithelial permeability, inactivate antiproteases, and importantly, trigger an enhanced inflammatory response by activating redox-sensitive transcription factors (e.g., NF-κB, AP-1). Also, oxidative modification of target molecules occurs more in the lungs in patients with COPD than in smokers without COPD.

Histone deacetylase-2 (HDAC2) is modified by oxidative stress in COPD, resulting in decreased level and activity. Decrease in HDAC2 results in acetylation of the lysine residues and DNA, resulting in uncoiling of DNA and increasing the accessibility of transcription factors and RNA polymerase to the transcriptional machinery, thus increasing gene transcription. Studies of resected lungs indicate that HDAC2 protein and activity is reduced in lung tissue in COPD as a result of oxidative modification of the molecule and is associated with an increase in histone-4 acetylation at the IL-8 promoter and increased IL-8 mRNA expression. This mechanism may be responsible for perpetuating inflammation in COPD.

The transcription factor *nuclear erythroid-related factor 2* (Nrf2) controls the expression of several of the most important antioxidant enzymes. COPD lungs have decreased expression of Nrf2 transcriptional activity, which may result in reduced protection against oxidative stress.

OTHER MECHANISMS

Autoimmunity, apoptosis, and cell senescence also may be involved in the pathogenesis of emphysema (Figure 41-6). Studies show that *apoptosis* occurs in emphysematous lungs, predominantly involving endothelial cells in the alveolar walls and resulting from a decrease in vascular endothelial growth factor (VEGF) or VEGF signaling, also shown to occur in association with emphysema in human lungs. These data led to the concept of an "alveolar maintenance program" required for the structural preservation of the lungs. Cigarette smoke is thought to cause disruption of this maintenance program, resulting in emphysema. The lung destruction or tissue destruction of emphysema is therefore caused by the mutual interaction of alveolar cell apoptosis, oxidative stress, and protease/antiprotease imbalance.

Similar features between pulmonary emphysema and lung aging led to the hypothesis that both conditions share underlying mechanisms, including oxidative stress, inflammation, and apoptosis. The cellular equivalent of aging is *senescence*, which is characterized by a nonproliferative stage in which cells are metabolically active and apoptosis resistant. Mechanisms associated with cell senescence include accumulation of DNA damage, impairment of DNA repair, epigenetic modifications in nuclear DNA, protein damage, oxidative stress, and telomere attrition. Telomere length is decreased in cells from emphysematous lungs, as are antiaging molecules such as sirtuins, suggesting a role for accelerated aging and cell senescence in the pathogenesis of emphysema.

Considerable evidence supports the role of the adaptive immune response in the progression of COPD. The presence of autoantibodies to lung structural cells and elastase suggests involvement of autoimmune mechanisms in pathogenesis of COPD.

Both oxidants and proteases such as elastase are important secretagogues for mucus and thus may be involved in the hypersecretion of mucus that occurs in chronic bronchitis. Airway mucus synthesis is regulated by the epidermal growth factor receptor (EGFR) system. Cigarette smoke upregulates EGFR expression and activates EGFR tyrosine phosphorylation, causing mucus synthesis in epithelial cells by a mechanism that probably involves oxidative stress.

PATHOPHYSIOLOGY

AIRFLOW LIMITATION AND HYPERINFLATION

The characteristic physiologic abnormality in COPD is a decrease in maximum expiratory flow, which results from (1) loss of lung elasticity and (2) increase in airway resistance in small airways.

The main site of airflow limitation in COPD occurs in the small conducting airways (<2 mm in diameter) and results from inflammation, narrowing (airway remodeling), and inflammatory exudates in the small airways, features that correlate

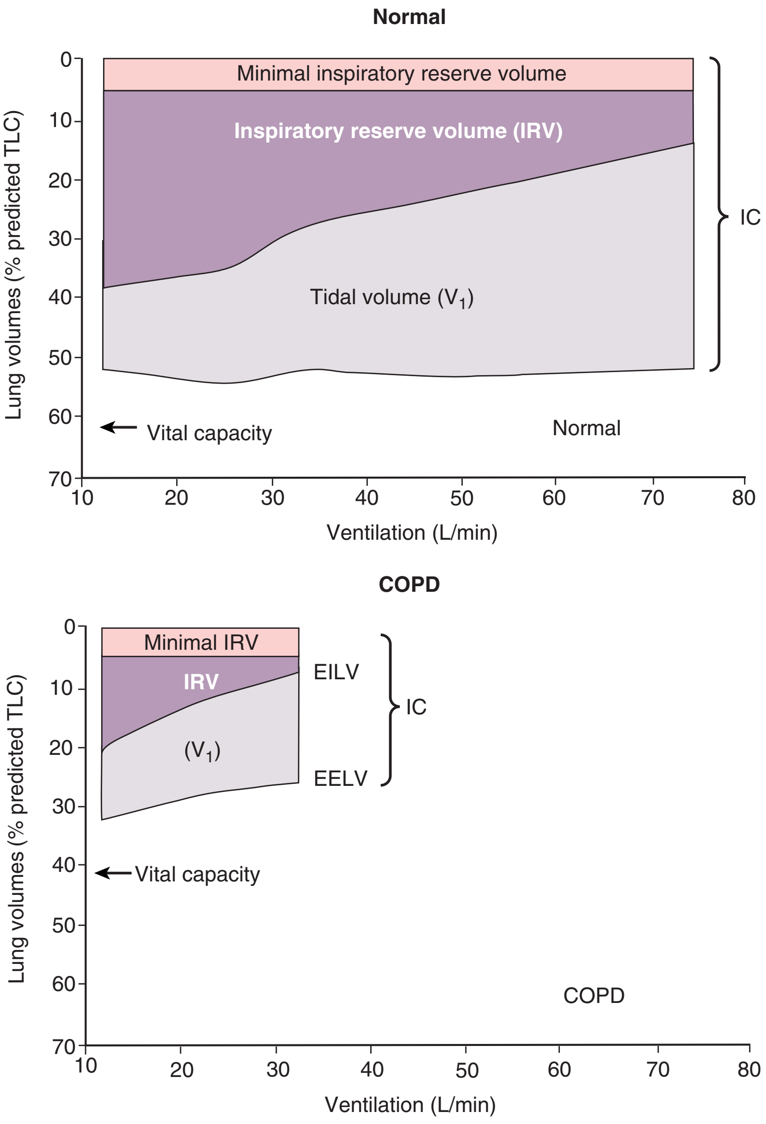

Figure 41-7 In health, the body meets the increased oxygen demand produced by exercise by using some of the inspiratory reserve volume of the lungs to increase tidal volume. *COPD*, chronic obstructive pulmonary disease. *EELV*, end-expiratory lung volume; *EILV*, end-inspiratory lung volume; *IC*, inspiratory capacity; *IRV*, inspiratory reserve volume; *TLC*, total lung capacity. *(Data from O'Donnell DE et al:* Am J Respir Crit Care Med *164:770, 1999.)*

with the reduction in FEV_1. Other factors contributing to the airflow limitation include loss of the lung elastic recoil (caused by destruction of alveolar walls) and destruction of alveolar support (from alveolar attachments). The resultant airway obstruction causes progressive trapping of the air during expiration, resulting in hyperinflation at rest and dynamic hyperinflation during exercise. Lung hyperinflation reduces the inspiratory capacity, and thus functional residual capacity (FRC) increases, particularly during exercise (Figure 41-7). These features are thought to occur early in the course of the disease and result in the breathlessness and limited exercise capacity typical of COPD. Bronchodilators reduce air trapping and thus decrease lung volumes, improving symptoms and exercise capacity. Tests of overall lung mechanics (e.g., FEV_1, airway resistance) are usually abnormal in patients with COPD when breathlessness develops.

Residual volume, FRC, and (in some cases) total lung capacity (TLC) increase. Maximum expiratory flow-volume curves show a characteristic convexity toward the volume axis, with preservation of peak expiratory flow initially. The uneven distribution of ventilation in advanced COPD causes a reduction in "ventilated" lung volume, and thus the carbon monoxide transfer factor (TLco) is almost always reduced, although the lung diffusing capacity for carbon monoxide (DLco), normalized to ventilated alveolar volume (DLco/VA/Kco), may remain relatively well preserved in patients without emphysema.

The ability to draw air through the conducting airways during inspiration depends on the strength of the respiratory muscles, which in turn depends on their resting length; the compliance of the respiratory system (lung and chest wall); and the resistance of the airways. Exhalation is normally passive and results from the elastic recoil of the lungs. The characteristic changes in the static pressure-volume curve of the lungs in COPD are an increase in static compliance and a reduction in static transpulmonary pressure at any given lung volume. These changes are generally thought to indicate emphysema.

The resistance to airflow depends on the length and diameter of the airways and the physical properties of the respirable gas. At a constant airway diameter, airflow on inhalation is proportional to the difference between atmospheric gas pressure and alveolar pressure. During exhalation, airflow depends on the difference between alveolar and atmospheric pressures. Throughout inhalation and during the initial portion of exhalation, this relationship is constant. However, at a certain point during exhalation, flow cannot increase despite further

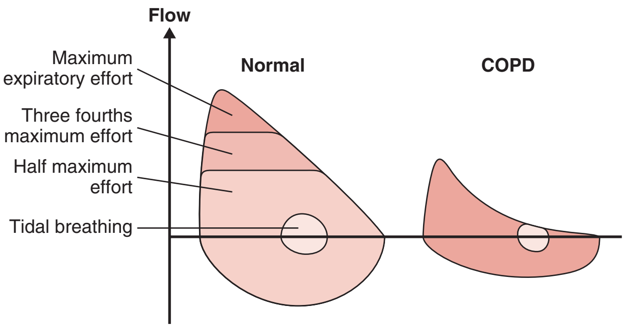

Figure 41-8 Flow-volume loop over normal individual and patient with chronic obstructive pulmonary disease (COPD). Patients who have COPD may reach airflow limitation even during tidal breathing. *(From Celli B. In Albert R, Spiro SG, Jett JR, editors:* Comprehensive respiratory medicine, *St Louis, 1999, Mosby.)*

increases in alveolar pressure. This is a result of dynamic compression of the airways, which limits flow, as illustrated by the flow-volume loop (Figure 41-8). During exhalation from TLC, flow increases to a point beyond which additional expiratory effort has no effect. During tidal breathing, expiratory flow is well below that attainable during maximum expiration. In COPD, however, the flow-volume loop is different. The major site of the fixed airway narrowing in COPD is in peripheral airways of diameter less than 2 mm. Loss of lung elastic recoil pressure is also an important mechanism of airway obstruction, resulting from a reduction in the distending force applied to the intrathoracic airways. Dynamic expiratory compression of the airways is enhanced by loss of lung recoil and by atrophic changes in the airways and loss of support from the surrounding alveolar walls, allowing flow limitation at lower driving pressure and flow.

In addition to a decrease in peak expiratory flow, the later expiratory portion of the flow-volume curve is concave relative to the volume axis in patients with COPD. In severe disease the flow generated during tidal breathing may actually reach the maximum possible flow (Figure 41-8). Such patients, in response to the increased metabolic demands of exercise, for example, are unable to increase ventilation. Increased respiratory rate results in gas trapping from incomplete alveolar emptying, so-called dynamic overinflation. This increased lung volume increases the elastic recoil and is associated with an increase in the end-expiratory alveolar pressure. The result is an increase in the work of breathing because pleural pressure must drop below alveolar pressure before inspiration of air can occur.

PULMONARY GAS EXCHANGE

Ventilation-perfusion (V/Q) mismatching (as a result of decreased alveolar ventilation without a corresponding reduction in perfusion) is the most important cause of impaired pulmonary gas exchange in COPD. Other causes, such as impaired alveolar-capillary diffusion of oxygen and increased shunt, are much less important. In general, gas exchange worsens as the disease progresses. The distribution of ventilation is uneven in patients with COPD. Mechanisms that reduce blood flow include local destruction of vessels in alveolar walls as a result of emphysema, hypoxic vasoconstriction in areas of severe alveolar hypoxemia, and passive vascular obstruction from increased alveolar pressure and distention.

RESPIRATORY MUSCLES

In patients with severe COPD, a combination of lung overinflation and malnutrition results in muscle weakness, reducing the capacity of the respiratory muscles to generate pressure over the range of tidal breathing. In addition, the load against which the respiratory muscles need to act is increased because of the increase in airway resistance. Overinflation of the lungs leads to shortening and flattening of the diaphragm, impairing its ability to generate force to lower pleural pressure. During quiet tidal breathing in normal subjects, expiration is largely passive and depends on the elastic recoil of lungs and chest wall. Patients with COPD increasingly need to use their rib cage muscles and inspiratory accessory (e.g., sternocleidomastoid) muscles, even during quiet breathing. During exercise, this pattern may be even more distorted and may result in paradoxical motion of the rib cage.

Patients with COPD have impaired values of global function of the respiratory muscles, such as maximum inspiratory mouth pressure (PE_{max}), although these measurements are effort-dependent. Diaphragmatic function can be assessed during inspiration by measurement of transdiaphragmatic pressure (Pdi), using balloon-tipped catheters with small transducers in the esophagus and stomach. Pdi values are reduced in patients with COPD.

PULMONARY HYPERTENSION

Pulmonary hypertension complicating COPD is generally defined by a mean *pulmonary artery pressure* (Ppa) greater than 20 mm Hg. This is different from the definition of idiopathic hypertension (Ppa >25 mm Hg). In the natural history of COPD, pulmonary hypertension is often preceded by an abnormally large increase in Ppa (>30 mm Hg) during exercise.

The term *cor pulmonale* is often used synonymously with pulmonary hypertension in COPD. However, cor pulmonale is defined as right ventricular (RV) hypertrophy (enlargement) resulting from disease that affects the structure or function of the lungs. This is a pathologic definition and thus of limited value in clinical practice, because the diagnosis of RV hypertrophy is difficult to make. Pulmonary hypertension is the cause of cor pulmonale, so it is best to use the term *pulmonary hypertension* in COPD rather than cor pulmonale.

There are few data on the prevalence of pulmonary hypertension resulting from COPD, because large studies of right-sided heart catheterization or Doppler echocardiography have not been undertaken. An estimate of the prevalence of pulmonary hypertension in COPD can be obtained from calculating the number of subjects with significant hypoxemia who require long-term oxygen therapy. Significant hypoxemia (PaO_2 <55 mm Hg, FEV_1 <50% of predicted) occurs in 0.3% of the UK population 45 or older. Extrapolation from this figure suggests that in England and Wales, 60,000 patients may be at risk of pulmonary hypertension and eligible for long-term oxygen therapy. Extrapolating these figures to the United States, 300,000 COPD patients are at risk of pulmonary hypertension. Box 41-4 lists the factors leading to pulmonary hypertension in patients with COPD.

Pulmonary artery hypertension occurs late in the course of COPD, concurrent with the development of hypoxemia. Alveolar hypoxia is the most important functional factor in the development of pulmonary hypertension in COPD. Acute hypoxia causes pulmonary vasoconstriction, and chronic

Box 41-4 Factors Leading to Increased Pulmonary Vascular Resistance in COPD

Functional Factors
- Alveolar hypoxia
  - Acute hypoxia (vasoconstriction)
  - Chronic hypoxia (remodeling of pulmonary vascular bed)

- Thromboembolic lesions
- Fibrosis
- Emphysema
- Compression of alveolar vessels

COPD, chronic obstructive pulmonary disease.

hypoxia induces structural changes or remodeling of the pulmonary vasculature, leading to sustained pulmonary hypertension.

The pulmonary hypertension in COPD is precapillary, because of an increased pressure difference between Ppa and pulmonary capillary wedge pressure, reflecting the increased pulmonary vascular resistance. Pulmonary hypertension in COPD is mild to moderate, with a resting Ppa in the stable stage of the disease ranging between 20 and 35 mm Hg. Ppa of 40 mm Hg or greater is unusual in COPD patients, except when measured during an acute exacerbation or during exercise; approximately 1% of patients exhibit severe pulmonary hypertension (Ppa >40 mm Hg). These patients are characterized by less severe airflow limitation but profound hypoxemia and hypocapnia. These patients may have an increased reactivity of the pulmonary arteries to hypoxia or coexisting idiopathic pulmonary hypertension. COPD patients with severe pulmonary hypertension in COPD have a poorer prognosis.

The progression of pulmonary hypertension is slow in COPD patients, and Ppa may remain stable for several years. The mean change in Ppa in a cohort of COPD patients is small (0.5 mm Hg/yr). Also, symptoms and physical signs are of little help in the diagnosis of pulmonary hypertension in COPD patients. The sensitivity of electrocardiography in diagnosing pulmonary hypertension is poor as well. Doppler echocardiography is the best method for the noninvasive diagnosis of pulmonary hypertension. However, right-sided heart catheterization remains the “gold standard” for diagnosing pulmonary hypertension.

The Ppa value is a good indicator of prognosis in patients with COPD. Five-year survival in a group of patients with initial Ppa less than 25 mm Hg was 66%, whereas in those with initial Ppa greater than 25 mm Hg, survival was only 36%.

The development of structural changes in the pulmonary arteries results in persistent pulmonary hypertension and RV hypertrophy/enlargement and dysfunction. Cor pulmonale is the major cardiovascular complication of COPD and is associated with a poor prognosis. Peripheral edema results from a combination of increased venous pressure and renal hormonal changes, leading to increased salt and water retention.

SYSTEMIC EFFECTS AND COMORBIDITIES

Although primarily a disease of the lungs, it is increasingly recognized that, as in many chronic diseases, COPD results in important systemic features that may affect morbidity and mortality. Comorbid conditions are frequently observed in patients with COPD at all stages, and many patients have multiple comorbidities.

The prevalence of COPD morbidity varies among studies. In a cohort of 1522 patients with COPD, 50% had one or two comorbidities, 15.8% had three or four comorbidities, and 6% had five or more. Comorbidities not only are highly prevalent but also have important prognostic implications. In the Lung Health Study of patients with mild to moderate COPD, deaths from respiratory disease were relatively uncommon (7%); lung cancer was the most common cause of death (33%). Coronary artery disease (CAD) accounted for 10.5%, and cardiovascular disease (including CAD) accounted for 22% of deaths. In a large, pharmacologic intervention study, with cause of death assessed by independent review panel, 27% of deaths were related to COPD, 26% to cardiovascular disease, and 21% to lung cancer.

In a large cohort of COPD patients, the presence of diabetes, hypertension, or cardiovascular disease significantly increased the risk of hospitalization or mortality. Furthermore, combinations of multiple comorbid diseases in an individual resulted in an even higher risk of death. Systemic inflammation in patients with COPD is thought to contribute to these systemic effects and comorbidities.

SKELETAL MUSCLE DYSFUNCTION/WASTING AND WEIGHT LOSS

Peripheral muscle dysfunction is a prominent contributor to exercise limitation, increases health care utilization, and is an independent indicator of morbidity and mortality in COPD.

Weight loss is common in patients with COPD. A decreased body weight is reported in 49% of patients referred to a UK center for pulmonary rehabilitation. The prevalence of muscle wasting in COPD is probably underestimated, as extrapolated from body weight measurements, because fat-free mass (FFM) may be reduced despite preservation of body weight. Independent of body mass index (BMI) and disease severity, FFM index can predict mortality in COPD patients. The prevalence of FFM depletion was about 30% in patients with an FEV_1 of 30% to 70% of predicted and is associated with impaired peripheral muscle strength. Weight loss and loss of muscle mass result from the effects of systemic inflammation, an imbalance between muscle protein synthesis and breakdown, muscle apoptosis, and muscle disuse. Increased systemic inflammatory mediators (e.g., TNF-α, IL-6, O_2 free radicals) may mediate some systemic effects.

Osteoporosis is recognized as one of the systemic effects of COPD. In the TORCH study (Towards a Revolution in COPD Health), 18% of men and 30% of women had osteoporosis, and 42% of men and 41% of women had osteopenia, based on bone mineral density (BMD) assessments. The etiology of osteoporosis in COPD is complex. Several risk factors for osteoporosis are common features in COPD patients, including aging, limited physical activity, vitamin D deficiency, cigarette smoking, hypogonadism, and systemic corticosteroid use. A consequence of osteoporosis is that prevalence of vertebral fractures in COPD patients is 20% to 30%. This can result in increased kyphosis, compromising pulmonary function.

Osteoporosis is related to emphysema and to arterial wall stiffness. Moreover, the osteoprotegerin (OPG)/receptor activator of nuclear factor κB (RANK)/RANK ligand (RANKL) system has been identified as a possible mediator of arterial calcification, suggesting common links between osteoporosis and vascular diseases.

CARDIOVASCULAR DISEASE

Cardiovascular disease is one of the most important comorbidities related to COPD. A study that included 11,943 COPD patients reported a two-fold to four-fold increase in mortality risk from cardiovascular disease over a 3-year follow-up compared with an age-matched and gender-matched control group without COPD. In a cohort of patients with mild COPD in the Lung Health Study, cardiovascular complications accounted for 22% of all deaths during follow-up and for 42% of first hospitalizations. In this study, for every 10% increase in FEV_1, cardiovascular mortality increased by 28%, and nonfatal cardiovascular events increased by almost 20%, after adjustments for relevant confounders such as age, gender, smoking status, and treatment. There is strong epidemiologic evidence that reduced FEV_1 is a marker of cardiovascular mortality. A systematic review and meta-analysis included more than 80,000 patients identified and almost a twofold risk of cardiovascular mortality in patients with the lowest versus the highest lung function quintiles. COPD is an important risk factor for atherosclerosis, ischemic heart disease, cerebrovascular accident (stroke), and sudden cardiac death. Underlying mechanisms that contribute to the increased risk of atherosclerosis in COPD patients are not well understood and probably multifactorial, including low-grade systemic inflammation, endothelial dysfunction, and arterial stiffness.

ANEMIA

Although hypoxemia in COPD can be associated with secondary polycythemia, as a compensatory mechanism to improve oxygen transport to the tissues, polycythemia is present in only 6% of COPD patients, whereas anemia is present in 13% to 33%. The anemia in COPD is normochromic, normocytic, and is likely mediated by shortened red blood cell survival, decreased erythropoietin, and dysregulation of iron homeostasis. Anemia contributes to impaired oxygen transport to the tissues and exercise intolerance and has been associated with increased mortality in COPD patients.

DEPRESSION

Depression has been reported in 10% to 80% of patients with COPD, 2% to 5% higher than in the normal age-matched population. Depression is part of a vicious cycle involving poor health status, isolation, sedentary lifestyle, and worsening health status, resulting in the development of a *reactive* depression. Depression may also precede the development of COPD. Systemic inflammation may also contribute to development of depression.

LUNG CANCER

Lung cancer is three to four times more common in COPD patients than in the general population and constitutes an important mortality risk in COPD patients. Patients with COPD have a higher incidence of lung cancer independent of the history of cigarette smoking. COPD is associated with the risk of developing small cell and squamous cell carcinoma, although no relationship seems to exist between COPD and the risk of developing adenocarcinoma.

DIABETES

The prevalence of diabetes in COPD patients has ranged from 1% to 16% of patients in different studies. Smoking is also a risk factor, and quitting smoking reduces the risk of diabetes. A reduction in lung function has also been associated with diabetes. Inflammatory markers such as TNF-α, IL-6, and C-reactive protein (CRP) have been associated with diabetes, and these inflammatory markers are elevated in COPD and may mediate insulin resistance by blocking signaling through the insulin receptor. The metabolic syndrome also appears to be more common in COPD patients, reflecting concomitant diabetes and cardiovascular disease with airway obstruction.

GASTROESOPHAGEAL REFLUX

An increase in gastroesophageal reflux disease (GERD) has been identified in COPD patients, being more common in those patients with an FEV_1 less than 50% predicted. GERD also appears to be a precipitant of exacerbations of COPD.

CLINICAL FEATURES

SYMPTOMS

Patients with COPD characteristically complain of the symptoms of breathlessness on exertion, chest tightness, wheeze, chronic cough, and lower respiratory tract infections. The cough is often, but not invariably, productive. *Breathlessness* is the symptom that usually causes the patient to seek medical attention and is the most disabling symptom.

Patients often date the onset of their illness to an acute exacerbation of *cough* with sputum production, which leaves them with a degree of chronic breathlessness. Close questioning, however, usually reveals a cough with small amounts of mucoid sputum (usually <60 mL/day), often in the morning for many years. A productive cough occurs in up to 50% of cigarette smokers and may precede the onset of breathlessness. Many patients may dismiss this as simply "smoker's cough." The frequency of nocturnal cough does not appear to be increased in stable COPD. Paroxysms of coughing in the presence of severe airflow limitation generate high intrathoracic pressures, which can produce syncope and "cough fractures" of the ribs.

Breathlessness is usually first noticed on climbing hills or stairs, or hurrying on level ground, which later becomes progressive and persistent. It usually heralds at least moderate impairment of expiratory flow. Patients may adapt their breathing pattern and their behavior to minimize the sensation of breathlessness. The perception of breathlessness varies greatly among patients with the same impairment of ventilatory capacity. However, when the FEV_1 has fallen to 35% or less of the predicted value, breathlessness is usually present on minimal exertion. Severe breathlessness is often affected by changes in environmental temperature or occupational exposure to dust and fumes. Some patients have severe orthopnea, relieved by leaning forward, whereas others find greatest ease when lying flat. The impact of breathlessness can be assessed on the UK Medical Research Council (MRC) Dyspnea Scale (Table 41-3).

Wheeze (wheezing) is common but not specific to COPD because it results from turbulent airflow in large airways from any cause.

Chest tightness is also common in patients with COPD, resulting from the disease itself, underlying ischemic heart disease, or GERD. Chest tightness is a frequent complaint

Table 41-3 Modified MRC Dyspnea Scale for Assessing Breathlessness

Grade	Degree of Breathlessness Related to Activities
1	Not troubled by breathlessness, except on strenuous exercise.
2	Short of breath when hurrying or walking up a slight hill.
3	Walks slower than contemporaries on level ground because of breathlessness, or has to stop for "breather" when walking at own pace.
4	Stops for breath after walking about 100 m or after a few minutes on level ground.
5	Too breathless to leave the house, or breathless when dressing or undressing.

Data from UK Medical Research Council.

Table 41-4 Modified Borg Scale for Assessing Breathlessness

Scale	Severity Experienced by Patient
0	Nothing at all
0.5	Very, very slight (just noticeable)
1	Very slight
2	Slight (light)
3	Moderate
4	Somewhat severe
5	Severe (heavy)
6	Very severe Very, very severe (almost maximal) Maximal

during periods of worsening breathlessness, particularly during exercise and exacerbations, and this is sometimes difficult to distinguish from ischemic cardiac pain. Pleuritic chest pain may suggest concurrent pneumothorax, pneumonia, or pulmonary infarction. Hemoptysis can be associated with purulent sputum and may be caused by inflammation or infection. However, blood-tinged sputum should also suggest bronchial carcinoma.

OTHER ASPECTS OF THE HISTORY

As part of the assessment of patients with COPD, the following factors need to be determined from the history:

- Current medications
- History of other medical conditions
- Symptoms of anxiety and depression
- Sleep quality
- Frequency of exacerbations; number of courses of corticosteroids and antibiotics in preceding year
- Hospital admissions
- Occupational and environmental exposure to dust, chemicals, gases, and fumes
- Exposure to biomass fuel
- Previous respiratory problems (chronic asthma or tuberculosis)
- Number of days missed from work
- Social and family support
- Anorexia and weight loss
- Current smoking status and number of pack-years (1 pack-year is defined as 20 cigarettes [1 pack] smoked per day for 1 year)

Several conditions should be considered in the differential diagnosis in patients with COPD. Asthma can be particularly difficult; scales (e.g., the modified Borg scale) can be used to assess the degree of breathlessness (Table 41-4).

CLINICAL SIGNS

Patients with COPD typically present in the fifth decade of life. The physical examination may be completely negative early in the disease course. The physical signs are not specific and depend on the degree of airflow limitation and pulmonary overinflation. Because of the heterogeneity of COPD, patients may show a range of phenotypic clinical presentations. The sensitivity of physical examination to detect or exclude moderately severe COPD is rather poor.

PATIENT ASSESSMENT

GENERAL EXAMINATION

The respiratory rate may be increased. A breathing pattern with a prolonged expiratory phase, with or without pursing of the lips, is characteristic of patients with COPD. A forced expiratory time greater than 5 seconds strongly suggests the presence of airflow limitation. Use of accessory muscles of respiration, particularly the sternocleidomastoids, is often seen in advanced disease, and these patients often adopt a posture in which they lean forward, supporting themselves with their arms to fix the shoulder girdle. This allows use of the pectoral muscles and the latissimus dorsi muscle to increase chest wall movement.

Tar-stained fingers indicate the smoking habit in many patients. In advanced disease, cyanosis may be present, indicating hypoxemia, but it may be masked by anemia or accentuated by polycythemia, and is a fairly subjective sign. The "flapping tremor" associated with hypercapnia is neither sensitive nor specific, and papilledema associated with severe hypercapnia is rare.

As described earlier, weight loss may also be apparent in advanced disease, as well as a reduction in muscle mass. The body mass index (BMI; weight/height^2) should be calculated. Finger clubbing is not a feature of COPD and should suggest the possibility of complicating bronchial neoplasm, pulmonary fibrosis, or bronchiectasis.

CHEST EXAMINATION

In the later stages of COPD, the chest is often barrel-shaped with a kyphosis, resulting in an increased anterior/posterior chest diameter, horizontal ribs, prominence of the sternal angle, and a wide subcostal angle. The distance between the suprasternal notch and the cricoid cartilage (normally 3 fingerbreadths) may be reduced because of the elevation of the sternum. These are all signs of overinflation. An inspiratory tracheal tug may be detected, attributed to contraction of the low, flat diaphragm. The horizontal position of the diaphragm also acts to pull the lower ribs in during inspiration (Hoover sign). The xiphisternal angle widens, and abdominal protuberance results from forward displacement of the abdominal contents, giving the appearance of weight gain. Increased intrathoracic pressure swings may result in indrawing of the suprasternal and supraclavicular fossae and intercostal muscles.

Decreased hepatic and cardiac dullness on percussion indicates overinflation. A useful sign of gross overinflation is the absence of a dull percussion note, normally caused by the underlying heart, over the lower end of the sternum. Breath sounds may have a prolonged expiratory phase or may be uniformly diminished, particularly in the advanced stages of COPD. Wheezing may be present both on inspiration and expiration but is not an invariable sign. Crackles may be heard, particularly at the lung bases, but are usually scant and vary with coughing.

CARDIOVASCULAR EXAMINATION

Air trapping decreases venous return and compresses the heart. Accordingly, tachycardia is common in COPD patients. The presence of positive alveolar pressure at the end of exhalation (i.e., intrinsic positive end-expiratory pressure, or auto-PEEP) results in the need to create a more negative pleural pressure than usual, manifested by paradoxical pulse. Overinflation makes it difficult to localize the apex beat and reduces the cardiac dullness. The characteristic signs that indicate the presence or consequences of pulmonary hypertension may be detected in advanced cases. The heave of RV hypertrophy may be palpable at the lower left sternal edge or in the subxiphoid regions. Heart sounds are usually soft, although the pulmonary component of the second heart sound may be exaggerated in the second left intercostal space, indicating pulmonary hypertension. An RV gallop rhythm may be detected in the fourth intercostal space to the left of the sternum. The jugular venous pressure can be difficult to estimate in patients with COPD because it swings widely with respiration and is difficult to discern if there is prominent accessory muscle activity. There may be evidence of functional tricuspid incompetence, producing a pansystolic murmur at the left sternal edge. The liver may be tender and pulsatile, and a prominent *v* wave may be visible in the jugular venous pulse. The liver may also be palpable below the right costal margin as a result of overinflation of the lungs.

Peripheral vasodilation accompanies hypercapnia, producing warm peripheries with a high-volume pulse. Pitting peripheral edema may also be present as a result of fluid retention.

PHYSIOLOGIC ASSESSMENT

The degree of airflow limitation cannot be predicted from the symptoms and signs noted on clinical evaluation. Accordingly, the degree of airflow limitation should be assessed in every patient. At an early stage of the disease, conventional spirometry may reveal no abnormality. Results of tests of small airways function, such as the frequency dependency of compliance and closing volume, may be abnormal. However, these tests are difficult to perform, have high coefficient of variation (CV), and are valid only when lung elastic recoil is normal and there is no increase in airway resistance. These tests therefore are *not* recommended in normal clinical practice.

Spirometry

Spirometry is the best test of airflow limitation in patients with COPD. Spirometric measurements have a well-defined range of normal values. A postbronchodilator FEV_1/VC ratio less than 0.7 is a diagnostic criterion for COPD. The rate of decline of the FEV_1 can be used to assess susceptibility in cigarette smokers and progression of disease.

It is important that a volume plateau is reached when performing the FEV_1 maneuver, which can take 15 seconds or more in patients with severe airway obstruction. If this maneuver is not carried out, the vital capacity (VC) can be underestimated. FEV_1 within ±20% of predicted value is considered in the normal range. Thus, an FEV_1 of 80% or more of the predicted value is normal. Under usual circumstances, 70% to 80% of the total volume of the air in the lungs (FVC) should be exhaled in the first second. When the FEV_1/FVC ratio falls below 0.7, airflow limitation is present. The reproducibility of the FEV_1 varies by less than 200 mL between maneuvers.

Spirometric measurements are evaluated by comparison of the results with appropriate reference values based on age, gender, height, and race. The presence of a postbronchodilator FEV_1/FVC ratio <0.7 confirms the presence of airflow limitation that is not fully reversible. However, in older adults, values of FEV_1/FVC between 0.65 and 0.7 may be normal. Thus, use of a fixed ratio of FEV_1/FVC <0.7 postbronchodilator leads to overdiagnosis of COPD in elderly patients. FEV_6 measures the volume of air that can be forcibly exhaled in 6 seconds. It approximates the FVC, although in healthy individuals the FEV_6 and FVC are identical. Use of FEV_6 instead of FVC may be helpful in patients with more severe airflow limitation. To avoid the effect of airway collapse in patients with COPD during forced expiration, the clinician should use a slow or relaxed VC measurement, which allows patients to exhale at their own pace. The slow VC is often 0.5 L greater than the FVC.

The FEV_1 as a percentage of the predicted value can be used to assess the severity of disease (**Table 41-5**). FEV_1 does not fully capture the impact of COPD on the patient's functional capabilities, however, and thus other measurements in addition to spirometry are required to assess the effect of COPD on functional ability. Breathlessness can be gauged by the MRC scale (see Table 41-3). Exercise capacity can be objectively measured by a reduction in self-paced walking distance (e.g., 6-minute walking distance [6MWD]), which is a strong predictor of health status impairment and prognosis. A combination of these variables to give a more detailed indication of disease severity has been proposed as the *BODE index*, a composite score of ***b***ody mass index, airways ***o***bstruction, ***d***yspnea, and ***e***xercise that appears to be a better predictor of subsequent survival than any of the individual components (**Table 41-6**).

Expiratory Flow

Expiratory flows measured at 75% or 50% of VC have also been used to identify patients with COPD. These measurements

Table 41-5 Spirometric Classification of COPD Severity

Stage	Characteristics
I: Mild	FEV_1/FVC <0.7 FEV_1 ≥80% predicted
II: Moderate	FEV_1/FVC <0.7 50% ≤ FEV_1 <80% predicted
III: Severe	FEV_1/FVC <0.7 30% ≤ FEV_1 <50% predicted
IV: Very severe	FEV_1/FVC <0.7 FEV_1 <30% predicted or FEV_1 <50% predicted plus chronic respiratory failure

Table 41-6 Variables and Point Values in Computation of BODE* Index

	Points on BODE Index			
Variable	**0**	**1**	**2**	**3**
FEV_1 (% of predicted)	≥65	50-64	36-49	≤35
Distance walked in 6 minutes (m)	≥350	250-349	150-249	≤149
MMRC dyspnea scale†	0-1	2	3	4
Body mass index	>21	≤21	—	—

*Body mass index, degree of airflow obstruction and dyspnea, and exercise capacity.

†See Table 41-3.

are less reproducible than the FEV_1, such that an abnormal value must fall below 50% of predicted value. Flows at lung volume less than 50% of VC were previously considered to be an indicator of small airways function, but probably provide no more clinically useful information than measurements of the FEV_1.

Peak expiratory flow can either be read directly from the flow-volume loop or measured with a handheld peak flowmeter. Flowmeters are relatively easy to use and are particularly useful in subjects with asthma, who have variations in serial measurements. In patients with COPD, however, many of the variations are often within the error of the measurement. The peak expiratory flow may underestimate the degree of airflow limitation in COPD and is thus not used as a routine assessment.

Reversibility Testing

Assessment of reversibility to bronchodilators was performed in COPD patients (1) to help distinguish patients with marked reversibility who have underlying asthma and (2) to establish the postbronchodilator FEV_1, which is the best predictor of long-term prognosis.

There is no agreement on a standardized method of assessing reversibility, but this is usually quantified on the basis of a change in the FEV_1 or peak expiratory flow. However, there may be changes in other lung volumes after bronchodilators (e.g., inspiratory capacity, residual volume) which may explain why some symptoms improve in some patients after a bronchodilator without a change in spirometry. An improvement in FEV_1 in response to a bronchodilator is not a good predictor of a symptomatic response.

Bronchodilator reversibility can vary from day to day, depending on the degree of bronchomotor tone. A change in FEV_1 that exceeds 200 mL is considered greater than random variation. Therefore, changes should be reported as significant only if they exceed 200 mL. In addition to this absolute change of 200 mL in FEV_1, a percentage change of 12% over baseline has been suggested as significant by the ERS/ATS and GOLD guidelines.

Approximately 30% of patients with COPD show significant reversibility of their airflow limitation in response to a bronchodilator. It is usually recommended that reversibility be assessed using a large bronchodilator dose, either with repeated doses from a metered dose inhaler or by nebulization, because this results in more patients with a significant response. In some cases, addition of a second drug, such as an anticholinergic agent to a β_2-agonist, further increases FEV_1. Reversibility testing with a bronchodilator is usually indicated only at diagnosis. Although not a requirement for the diagnosis of COPD, postbronchodilator spirometry is recommended to assess for chronic airflow limitation (see earlier discussion). A formal assessment of steroid reversibility is not included in the most recent guidelines for assessment and management of COPD. The most common method is to measure FEV_1 before and after treatment with 30 mg of prednisolone for 2 weeks. Although patients with previous response to nebulized bronchodilators are more likely to respond to steroids, individual patient responses cannot be predicted.

Lung Volumes

Static lung volumes such as TLC, residual volume (RV) and FRC, and the ratio RV/TLC are measured in patients with COPD, to assess the degree of overinflation and gas trapping, and are usually increased. These measurements are not necessary in every patient. The standard method of measuring static lung volumes, using the helium dilution technique during rebreathing, may underestimate lung volumes in COPD, particularly in patients with bullous disease, because the inspired helium may not have sufficient time to equilibrate properly in the enlarged air spaces. Body plethysmography uses Boyle's law to calculate lung volumes from changes in mouth and plethysmographic pressures. This technique measures trapped air in the thorax, including poorly ventilated areas, and therefore gives higher readings than the helium dilution technique.

Gas Transfer for Carbon Monoxide

A low D_{LCO} is present in many patients with COPD. Although there is a relationship between the D_{LCO} and the extent of microscopic emphysema, the severity of the emphysema in an individual patient cannot be predicted from the D_{LCO}, and a low D_{LCO} is not specific for emphysema. The usual method is the *single-breath technique*, which uses alveolar volume calculated from the helium dilution during a single-breath test. This method underestimates alveolar volume in patients with severe COPD, however, producing a lower value for the D_{LCO}. This test can be useful to distinguish patients with COPD from those with asthma because a low D_{LCO} excludes asthma.

Arterial Blood Gases

Arterial blood gases (ABGs) are needed to confirm the degree of hypoxemia and hypercapnia that develops in patients with COPD. Hypoxemia and hypercapnia are not usually observed until the FEV_1 falls below 50% of predicted. It is essential to record the fraction of inspired oxygen concentration (F_{IO_2}) when reporting ABGs. It may take at least 30 minutes for a change in F_{IO_2} to have its full effect on the arterial oxygen partial pressure (Pa_{O_2}), because of long time constants for alveolar gas equilibration in COPD, particularly during exacerbations. Pulse oximetry is increasingly used to measure the level of oxygenation, but it should not replace ABG assessment in patients with FEV_1 below 50% predicted, because measurements of Pa_{CO_2} are often required. ABG abnormalities may worsen during exercise and sleep and during exacerbations.

Exercise Tests

Although exercise testing is rarely needed to diagnose COPD, useful functional information may be obtained from doing any of three types of tests.

Progressive symptom-limited exercise tests require the patient to maintain exercise on a treadmill or a cycle until symptoms prevent the person from continuing, while the workload is continuously increased. A maximum test is usually defined as a heart rate greater than 85% of predicted or ventilation greater than 90% predicted. The results are particularly useful when simultaneous electrocardiography and blood pressure monitoring are performed, to assess whether coexisting cardiac or psychological factors contribute to exercise limitation.

Self-paced exercise tests are simple to perform and give information on sustained exercise that may be more relevant to activities of daily living. The 6MWD has approximately 8% CV. A learning effect, however, may influence the result of repeated tests. The 6MWD test is useful only in patients with moderately severe COPD (FEV_1, <1.5 L) who would be expected to have an exercise tolerance of less than 600 m in 6 minutes. There is a weak relationship between 6MWD and FEV_1, although walking distance is a predictor of survival in COPD patients. An alternative test is the *shuttle walking test*, in which the patient performs a paced walk between two points 10 m apart (the shuttle). The pace of the walk is increased at regular intervals, as dictated by bleeps on a tape recording, until the patient is forced to stop because of breathlessness. The number of completed shuttles is recorded.

S*teady-state exercise* tests involve exercise at a sustainable percentage of maximum capacity for 3 to 6 minutes, during which ABGs are measured, enabling calculation of dead space/tidal volume ratio (V_D/V_T) and shunt. This assessment is seldom required in patients with COPD.

OTHER TESTS

Lung pressure-volume curves are difficult to measure, requiring assessment of esophageal pressure with an esophageal balloon, and are not part of the routine assessment of patients with COPD. These tests may be necessary in special circumstances.

Measurements of small airways function with nitrogen washout test, helium flow-volume loops, or frequency dependence of compliance have poor reproducibility in patients with COPD. Although these tests can differentiate smokers from nonsmokers, they are not useful for predicting in which smokers COPD will develop, and thus are not used in routine practice.

Respiratory Muscle Function Test

The usual tests of respiratory muscle function in COPD are maximum inspiratory and expiratory mouth pressures. These tests can be useful in cases where breathlessness or hypercapnia is not fully explained by other lung function testing or when peripheral muscle weakness is suspected (see Chapter 42).

Sleep Studies

Selected patients should be assessed for the presence of nocturnal hypoxemia. Finding nocturnal hypoxemia, however, provides no further prognostic or clinically useful information in the assessment of patients with COPD, unless coexisting sleep apnea syndrome is suspected.

HEALTH STATUS

Health-related or health status quality of life is a measure of the impact of the disease on daily life and well-being. Breathlessness in patients with COPD limits exercise, reduces expectation, diminishes daily activity, restricts social activities, disturbs mood, and impairs well-being. Several questionnaires are available to assess health status and are used in hospital rehabilitation programs and research. The Chronic Respiratory Disease Index Questionnaire is sensitive to change but is time-consuming and requires training to administer properly. The Breathing Problems Questionnaire is a self-completed test that is easy to complete but relatively insensitive to change.

The *St. George's Respiratory Questionnaire* is a self-completed test with three components—*symptoms* (distress caused by respiratory symptoms), *activity* (disturbance in daily activities), and *impact* (psychosocial function)—summed to give a total score of overall health status. This is the most validated health status tool in COPD. However, a rather poor relationship exists between the St. George's Respiratory Questionnaire and the FEV_1. It is clear from various studies that there can be improvement in health status without any improvement in FEV_1 in response to treatment. An example of this is the response to pulmonary rehabilitation. The threshold of clinical improvement is a change of four units in the St. George's Respiratory Questionnaire. Exacerbations of COPD have a clear detrimental effect on health status.

More recently, the C*OPD Assessment Test* (CAT) has been shown to correlate well with the more detailed St. George's Respiratory Questionnaire. The CAT may be useful clinically in assessing functional status, health status, and response to treatment.

OTHER MEASUREMENTS

Erythrocythemia or polycythemia is important to identify in patients with COPD because it predisposes to peripheral vascular, cardiovascular, and cerebrovascular events. *Erythrocythemia* does not develop until there is clinically important hypoxemia (PaO_2 <55 mm Hg) and is not inevitable even at this level. *Polycythemia* should be suspected when the hematocrit is greater than 47% in women and 52% in men, and/or the hemoglobin is greater than 16 g/dL in women or 18 g/dL in men, provided other causes of spurious polycythemia from decreased plasma volume (dehydration, diuretics) can be excluded. A complete blood count may reveal the anemia of chronic disease that occurs in COPD.

$Alpha_1$-antitrypsin deficiency screening with measurements of the level and determination of allelic phenotype are indicated for patients (<45 years old) with early onset of emphysema and in those with a family history of premature emphysema. Because of the potential importance for other family members, some experts recommend that all patients with COPD be screened.

Electrocardiography is not routinely required in the assessment of patients with COPD, except when coexisting cardiac morbidity is suspected. It is an insensitive technique for the diagnosis of cor pulmonale.

Overinflation of the chest increases the retrosternal air space, which transmits sound waves poorly, making echocardiography difficult in patients with COPD. Thus, an adequate examination can be achieved in only 65% to 85% of patients with COPD. Two-dimensional echocardiography has been used in the investigation of right ventricular dimensions. Pulsed-wave Doppler echocardiography is used to assess ejection flow dynamics of the right ventricle in patients with pulmonary hypertension. The tricuspid gradient can be used to calculate the right ventricular systolic pressure. The technique estimates the pressure gradient across the tricuspid regurgitant jet recorded by Doppler ultrasound. The maximum velocity of the regurgitant jet is measured from the continuous-wave Doppler recordings, and the simplified Bernoulli equation is used to calculate the maximum pressure gradient between the right ventricle and the right atrium, $P_{RV} - P_{RA} = 4v^2$, where P_{RV} and P_{RA} are the right ventricular and right atrial pressures and v is the maximum velocity. The right atrial pressure is estimated from clinical examination of the jugular venous pressure.

IMAGING

Plain Chest Radiography

All patients with suspected COPD should have a posteroanterior (PA) chest radiograph performed at diagnosis. COPD does not produce any specific features on plain chest radiography unless features of emphysema are present. There may be no abnormalities, however, even in patients with severe disability. A chest x-ray film is used to discount other causes of respiratory symptoms and to identify complications with COPD, such as bulla formation. The most reliable radiographic signs of emphysema can be divided into those caused by overinflation, by vascular changes, and by bullae (see Computed Tomography). The following radiologic features are indicative of *overinflation:*

- Low, flattened diaphragm; the border of the diaphragm in the midclavicular line on the PA film is at or below the anterior end of the seventh rib, and it is flattened if the perpendicular height from a line drawn between the costal and cardiophrenic angles to the border of the diaphragm is less than 1.5 cm.
- Increased retrosternal air space, visible on the lateral film at a point 3 cm below the manubrium; it is present when the horizontal distance from the posterior surface of the aorta to the sternum exceeds 4.5 cm.
- Obtuse costophrenic angle on the PA or lateral chest radiograph.
- Inferior margin of the retrosternal air space 3 cm or less from the anterior aspect of the diaphragm.

The *vascular changes* associated with emphysema result from loss of alveolar walls and are shown on the plain chest radiograph by the following:

- Reduction in the number and size of pulmonary vessels, particularly at the lung periphery
- Vessel distortion, producing increased branching angles and excess straightening or bowing of vessels
- Areas of increased lucency

Critical to the assessment of vascular loss in emphysema is the quality of the chest radiograph, because increased transradiancy (translucency) may be only an overexposure. The accuracy of diagnosing emphysema on plain chest radiography increases with severity of the disease, reported at 50% to 80% in patients with moderate to severe disease. However, the sensitivity is as low as 24% in patients with mild to moderate COPD.

Computed Tomography

Computed tomography (CT) has been used to detect and quantify emphysema. Techniques can be divided into (1) those that provide a visual assessment of low-density areas on the CT scan, which can be semiquantitative or quantitative, and (2) those that use CT lung density to quantify areas of low x-ray attenuation. These techniques are used to measure macroscopic and microscopic emphysema, respectively. A visual assessment of emphysema on CT scanning shows the following:

- Areas of low attenuation without obvious margins or walls
- Attenuation and pruning of the vascular tree
- Abnormal vascular configurations

Areas of low attenuation correlate best with areas of macroscopic emphysema. Visual inspection of the CT scan can be used to locate macroscopic emphysema, although assessing the extent is insensitive and subject to high intraobserver and interobserver variability. The CT scan can be used to assess different types of emphysema; centrilobular emphysema produces patchy areas of low attenuation prominent in the upper zones, whereas those of panlobular emphysema are diffuse throughout the lung zones (see Figure 41-3).

A more quantitative approach to assessing macroscopic emphysema is by highlighting picture elements (pixels) in the lung fields in a predetermined low-density range, between −910 and −1000 Hounsfield units, the "density mask" technique. Although the choice of the density range is arbitrary, there is good correlation between pathologic emphysema score and the CT density score. This technique may still miss areas of mild emphysema.

Microscopic emphysema can be quantified by measuring CT lung density. CT density is measured on a linear scale in Hounsfield units (water = 0 H; air = −1000 H). CT lung density is a direct measure of physical density, and thus, as emphysema develops, a decrease in alveolar surface area occurs as alveolar walls are lost, associated with an increase in distal air space size, which would decrease lung CT density. A standardized protocol on either an inspiratory or an expiratory CT scan of the chest is required to measure lung density accurately.

A *bulla* is defined arbitrarily as an emphysematous space greater than 1 cm in diameter. On the plain chest radiograph, a bulla appears as a localized avascular area of increased lucency, usually separated from the rest of the lung by a thin, curvilinear wall. Marked compression of the surrounding lung may be seen, and bullae may also depress the diaphragm. CT is much more sensitive than plain radiography in detecting bullae and can be used to determine the number, size, and position. CT can quantify the extent and distribution of emphysema as part of surgical assessment in bullous disease and for lung volume reduction.

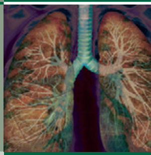
Section 7
AIRWAY DISEASES



Chapter 42
Treatment of the Stable Patient with Chronic Obstructive Pulmonary Disease

Bartolome R. Celli

The airflow obstruction of chronic obstructive pulmonary disease (COPD), as defined by the forced expiratory volume in 1 second (FEV_1), is thought to be only partially irreversible. This physiologic fact has been perpetuated over the years and has generated an unjustified negativist therapeutic attitude in many health care providers. The evidence suggests that the airflow obstruction of COPD *does* reverse with therapy, and that therapies aimed at the extrapulmonary manifestations of the disease *do* improve patient outcomes. An optimistic attitude toward these patients helps relieve fears and misconceptions. In contrast to many other diseases, some forms of intervention in COPD improve survival, such as smoking cessation, long-term oxygen therapy in hypoxemic patients, lung volume reduction surgery in certain patients with inhomogeneous upper lobe emphysema, and even pharmacologic therapy. Other interventions, such as pulmonary rehabilitation, lung transplantation, and bronchodilator therapy, improve symptoms and the quality of a patient's life once the diagnosis of COPD has been established.

Box 42-1 summarizes the available therapeutic options for patients with COPD. This chapter reviews medical management of COPD that centers on three goals: (1) prevent deterioration in lung function, (2) alleviate symptoms, and (3) treat complications as they arise. Once diagnosed, patients with COPD should be encouraged to participate actively in their management; collaborative management improves their self-reliance and self-esteem. All patients should be encouraged to lead a healthy life and exercise regularly. Preventive care is extremely important, and all patients should receive immunizations, including pneumococcal vaccine every 5 years and yearly influenza vaccine. Figure 42-1 provides an algorithm detailing this comprehensive approach.

MULTICOMPONENT DISEASE

Increasing evidence shows that independent of the degree of airflow limitation, the lung volumes are important in the development of symptoms in patients with more advanced COPD. Studies have demonstrated that dyspnea perceived during exercise, including walking, more closely relates to development of dynamic hyperinflation than to changes in FEV_1. Further, the improvement in exercise brought about by several therapies, including bronchodilators, oxygen, lung reduction surgery, and even rehabilitation, is more closely related to delaying dynamic hyperinflations than by changing the degree of airflow obstruction. *Hyperinflation*, expressed as the ratio of inspiratory capacity to total lung capacity, was shown to predict survival better than the FEV_1. This not only provides new insights into pathogenesis, but also opens the door for novel ways to alter lung volumes and perhaps impact COPD progression.

The association between COPD and important systemic manifestations in patients with more advanced disease is now accepted. Because of a persistent systemic inflammatory state or other, yet-unproven mechanisms (e.g., imbalanced oxidative stress, abnormal immunologic or reparative response), many patients with COPD may have decreased fat-free mass (FFM), impaired systemic muscle function, anemia, osteoporosis, depression, pulmonary hypertension, and cor pulmonale, all of which are important determinants of outcome. Indeed, dyspnea measured with a simple tool such as the UK Modified Medical Research Council (MMRC) scale, the body mass index (BMI; kg/m^2), and the 6-minute walking distance (6MWD) are all better predictors of mortality than the FEV_1. The incorporation of these variables into the multidimensional *BODE index* (BMI, airflow obstruction, dyspnea, exercise capacity) predicts survival even better. The BODE index is also responsive to exacerbations and, more importantly, acts as a surrogate marker of future outcome after interventions, thus providing clinicians with a useful tool to help determine the comprehensive severity of the disease. Other multidimensional indices (e.g., age, dyspnea, and obstruction [ADO]; dyspnea, obstruction, smoking, and exacerbation [DOSE]), have also shown important outcome predictive capacity and could be used to test novel forms of therapy.

Based on the multidimensional nature of COPD and the availability of multiple effective therapies, the approach shown in Figure 42-1 may more accurately help clinicians evaluate patients and choose therapies than the current approach, using primarily the FEV_1 percentage from reference values.

TREATABLE DISEASE

Current evidence suggests that besides smoking cessation, long-term oxygen therapy in hypoxemic patients, mechanical ventilation in acute respiratory failure, and lung volume reduction surgery for patients with upper lobe emphysema and poor exercise capacity improve survival. The TORCH study (Towards a Revolution in COPD Health) in more than 6000 patients showed not only that the combination of salmeterol and fluticasone improved lung function and health status, but also that the relative mortality risk over the 3 years of the study decreased by 17.5%. This is not exclusive of this drug combination; the Understanding Potential Long-Term Impacts on Function with Tiotropium (UPLIFT) study also observed a decrease in mortality risk over 4 years in patients taking tiotropium, a long-acting

anticholinergic. Other therapies, such as pulmonary rehabilitation and lung transplantation, improve symptoms and quality of life (QOL) once the diagnosis has been established.

RESPIRATORY MANIFESTATIONS

Once diagnosed, the patient with COPD should be encouraged to participate in disease management, confident that if not cured, COPD can certainly be treated.

SMOKING CESSATION AND SMOKE POLLUTANTS

Smoking is the major cause of COPD, and thus smoking cessation is the most important component of therapy for patients who still smoke. Because secondhand smoke is known to damage lung function, limitation of exposure to involuntary smoke, particularly in children, should be encouraged.

Many factors cause patients to smoke, including the addictive nature of nicotine, conditional responses to stimuli surrounding smoking, psychosocial problems such as depression, poor education and low income, and forceful advertising campaigns. Therefore, smoking cessation programs should also involve multiple interventions. The clinician should always participate in the treatment of smoking addiction, because a physician's advice and the appropriate medications (nicotine patch, gum, or inhalers; bupropion; varenicline) help obtain successful results.

Decreased Exposure to Biomass Fuel

The significant burden of COPD in patients exposed to biomass fuel in certain areas of the world should improve by changing to more efficient and less polluting sources of energy.

PHARMACOLOGIC THERAPY OF AIRFLOW OBSTRUCTION

Most patients with COPD require pharmacologic therapy. This should be organized according to the severity of symptoms, the degree of lung dysfunction, and the tolerance of the patient to specific drugs. A stepwise approach similar to that developed for systemic hypertension may be helpful, because medications alleviate symptoms, improve exercise tolerance and QOL, and may decrease mortality. Tables 42-1 and 42-2 summarize the evidence supporting the effect of individual and combined therapies on outcomes of importance in patients with COPD. Because most patients with COPD are elderly, care must be taken when prescribing drugs for this population. Comorbidities are frequently present in patients with COPD,

Table 42-1 Effect of Single Pharmacologic Agents on Important Outcomes in Chronic Obstructive Pulmonary Disease Patients

Drug	FEV_1	Lung Volume	Dyspnea	QOL	AE	Exercise Endurance	Disease Modifier by FEV_1	Mortality	Side Effects

mandating caution to ensure that therapy takes these into account.

Bronchodilators

Several important concepts guide the use of bronchodilators. In some patients, changes in FEV_1 may be small, and the symptomatic benefit may result from other mechanisms, such as a decrease in hyperinflation of the lung. Some older COPD patients cannot effectively activate metered dose inhalers (MDIs), and clinicians should work with the patient to achieve mastery of the MDI. If this is not possible, use of a spacer or nebulizer to facilitate inhalation of the medication will help achieve the desired results. Mucosal deposition in the mouth will result in local side effects (e.g., thrush with inhaled steroids) or general absorption and its consequences (e.g., tremor after β_2-agonists). The inhaled route is preferred over oral administration, and long-acting bronchodilators are more effective than short-acting agents. The currently available bronchodilators are described next.

Beta$_2$-Agonists

The β_2-adrenoceptor agonists increase cyclic adenosine monophosphate (cAMP) within many cells and promote airway smooth muscle relaxation. Other nonbronchodilator effects have been observed, but their significance is uncertain. In the minority of COPD patients with mild intermittent symptoms, it is reasonable to initiate drug therapy with an MDI of a short-acting β_2-agonist as needed for relief of symptoms. Patients with persistent symptoms should receive long-acting β_2-agonists twice daily or once daily if the new ultra-long-acting agents are available. These prevent nocturnal bronchospasm, increase exercise endurance, and improve QOL. The safety profile of salmeterol in the TORCH trial and *formoterol fumarate* in the SUN and SHINE studies, as well as that of the longer-acting *indacaterol*, is reassuring to clinicians, who frequently prescribe selective long-acting β_2-agonists for their patients with COPD.

Anticholinergics

Anticholinergic drugs act by blocking muscarinic receptors known to be functional in COPD. The appropriate dosage of the short-acting *ipratropium bromide* is 2 to 4 puffs three or four times daily, but some patients require and tolerate larger doses. The therapeutic effect is a decrease in exercise-induced increased lung inflation or dynamic hyperinflation. The long-acting *tiotropium* (Spiriva) is effective in inducing prolonged bronchodilation and decreasing lung volume in patients with COPD. In addition, tiotropium improves dyspnea, decreases exacerbations, and improves health-related QOL compared with placebo and even ipratropium. The results of the large UPLIFT trial confirmed the effectiveness of tiotropium as a disease-modifying agent in that it improved QOL, decreased exacerbation rate, and provided more bronchial dilation when used with regular treatment. These results place tiotropium as a good first-line agent for COPD patients with persistent symptoms. Other new long-acting anticholinergic agents, such as aclidinium bromide and glycopyrrolate, are being developed and will become available to clinicians worldwide.

Phosphodiesterase Inhibitors

Theophylline is a nonspecific phosphodiesterase inhibitor that increases intracellular cAMP within airway smooth muscle. The bronchodilator effects of these drugs are best seen at high doses, which also carry a higher risk of toxicity. Theophylline's potential for toxicity has led to a decline in its popularity. Theophylline is of particular value for less compliant or less capable patients who cannot use aerosol therapy optimally. The previously recommended therapeutic serum levels of 15 to 20 mg/dL are too close to the toxic range and are frequently associated with side effects. Therefore, a lower target range of 8 to 13 mg/dL is safer and still therapeutic in nature. Some research suggests that theophylline could help reestablish the corticosteroid sensitivity that appears to be absent in patients with COPD.

The specific phosphodiesterase E4 (PDE4) inhibitor *roflumilast* has antiinflammatory and bronchodilator effects, with minimal gastrointestinal irritation. Roflumilast has proved useful in decreasing exacerbations in COPD patients with cough and sputum production.

Other Antiinflammatory Therapy

In contrast to their value in asthma management, antiinflammatory drugs have not been documented to have a significant role in the routine treatment of patients with stable COPD. Cromolyn and nedocromil have not been established as useful agents, although they could possibly be helpful if the patient has associated respiratory tract allergy. One study using monoclonal antibodies against interleukin-8 (IL-8) and tumor necrosis factor alpha (TNF-α) failed to detect a response. However, patients were selected according to the degree of airflow obstruction, not the presence or level of the specific targeted molecule. The groups of leukotriene inhibitors useful in asthma have not been adequately tested in COPD, so a conclusion about their potential use cannot be drawn.

Corticosteroids

Glucocorticoids act at multiple points within the inflammatory cascade, although their effects in COPD appear to be more modest compared with bronchial asthma. In outpatients, COPD exacerbations necessitate a course of oral steroids, as discussed later, but it is important to wean patients quickly; older COPD patients are susceptible to complications such as skin damage, cataracts, diabetes, osteoporosis, and secondary infections. These risks do not accompany standard doses of inhaled corticosteroid aerosols, which may cause thrush but pose a negligible risk for other outcomes, such as cataract and osteoporosis.

Several large multicenter trials evaluated the role of inhaled corticosteroids (ICS) in preventing or slowing the progressive course of symptomatic COPD. The results of these earlier studies showed minimal, if any, benefits in the rate of decline of lung function. On the other hand, in the one study that evaluated it, inhaled fluticasone decreased exacerbations and the rate of loss of health-related QOL. Recent retrospective analysis of large databases suggesting a possible effect of ICS on improving survival was not confirmed in the TORCH trial, in which the ICS-only arm did not show improved survival compared with placebo, whereas the combination arm was significantly more effective than ICS alone. In TORCH the combination was superior in terms of all outcomes evaluated. Along with the more frequent development of pneumonia in the patients receiving ICS, this suggests that ICS should not be prescribed alone but rather with a long-acting β_2-agonist (LABA).

Combination Therapy

All the studies on combinations of agents show significant improvements over single agents alone, and clinicians should now consider combination therapy as first-line therapy. Initially, the combination of inhaled ipatroprium and albuterol proved effective in the management of COPD. More recently, the combination of tiotropium and formoterol, even when administered once daily, was almost as effective as tiotropium once daily added to the recommended twice-daily dose of formoterol. Similarly, the combination of theophylline and salmeterol was significantly more effective than either agent alone.

The TORCH study showed better effects of the salmeterol-fluticasone combination on survival, FEV$_1$, exacerbation rate, and QOL than placebo and the individual components alone, confirming earlier studies evaluating the combination of beta agonists and corticosteroids. Recent trials compared tiotropium plus placebo with tiotropium plus salmeterol and with tiotropium plus the combination of salmeterol and fluticasone in a large patient group. The number of hospitalizations related to exacerbations, health-related QOL, and lung function were significantly better in the group receiving triple therapy (LABA, long-acting muscarinic antagonist [LAMA], ICS). Thus, the institution of triple therapy for COPD is consistent with good medicine, if the patient has failed less intense therapy.

Mucokinetic Agents

The mucokinetic drugs decrease sputum viscosity and adhesiveness to facilitate expectoration. The only controlled study in the United States suggesting a value for mucokinetics in the chronic management of bronchitis was a multicenter evaluation of organic iodide, which demonstrated symptomatic benefits. Oral acetylcysteine is favored in Europe for its antioxidant effects; however, a recent large trial failed to document any substantial benefit. Genetically engineered ribonuclease seems to be useful in cystic fibrosis but is of no value in COPD patients.

Antibiotics

In patients with evidence of respiratory tract infection, such as fever, leukocytosis, and a change in the chest radiograph, antibiotics have proved effective. If recurrent infections occur, particularly in winter, continuous or intermittent, prolonged courses of antibiotics may be useful. The major bacterial strains to be considered are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella (Branhamella) catarrhalis*. The antibiotic choice will depend on local experience, supported by sputum culture and sensitivities if the patient is moderately ill or requires hospital admission. Two recent randomized multicenter trials of the macrolide antibiotic *clarithromycin* show a beneficial impact on exacerbations, likely from the drug's antiinflammatory action.

Alpha$_1$-Antitrypsin

Although supplemental weekly or monthly administration of the enzyme α_1-antitrypsin may be indicated in nonsmoking, younger patients with genetically determined emphysema, such therapy is difficult to initiate in practice. Evidence shows that the administration of α_1-antitrypsin is relatively safe. Although not entirely clear, the most likely candidates for replacement therapy would be patients with mild to moderate COPD.

VACCINATION

Ideally, infectious complications of the respiratory tract should be prevented in patients with COPD by using effective vaccines. Thus, routine prophylaxis with pneumococcal and influenza vaccines is recommended.

SYSTEMIC MANIFESTATIONS

The systemic manifestations of COPD include peripheral muscle dysfunction, malnutrition, cardiovascular compromise, osteoporosis, depression, anemia, and lung cancer. Some may be responsive to pulmonary and exercise therapy and may benefit patients with minimal response to conventional pharmacologic therapy.

PULMONARY REHABILITATION

Pulmonary rehabilitation has gradually become the "gold standard" treatment for patients with symptomatic COPD. By definition, rehabilitation services are provided to patients with symptoms, most of them with advanced lung disease. Because new therapeutic strategies such as surgical and nonsurgical lung volume reduction and lung transplantation require well-conditioned patients, pulmonary rehabilitation is becoming a crucial component of the overall treatment strategy of many patients previously deemed untreatable.

The most important concept in pulmonary rehabilitation is that any program must attempt to treat each patient enrolled as an individual. The variation that arises from the need to individualize therapy from one patient to another is one factor that makes the objective evaluation of each group of patients enrolled in a rehabilitation program difficult.

Because pulmonary rehabilitation is multidisciplinary and uses different therapeutic components, it is difficult to attribute improved global outcomes to the effect of individual elements of a program. Independent of the study design used, conventional pulmonary function tests do not usually change after pulmonary rehabilitation. Nevertheless, well-controlled studies show significant improvement in different outcomes, including increased exercise capacity, improved health-related QOL, and decreased dyspnea and hospital admissions.

Objectives and Goals

The definition of pulmonary rehabilitation provides three major objectives:

1. Control, alleviate, and as much as possible, reverse the symptoms and pathophysiologic processes leading to respiratory impairment.
2. Improve the quality of life, and attempt to prolong the patient's life.
3. Reduce health care use and costs.

Patient Selection

Any patient symptomatic from a respiratory disease with some functional limitation is a candidate for rehabilitation. It is preferable to choose patients with moderate to moderately severe disease, to prevent the disabling effects of end-stage respiratory failure. This is an important issue because it seems intuitive that patients with minimal functional limitation benefit minimally from programs designed to improve function. On the other hand, patients who are "too" advanced along the course of their illness could be considered "unlikely to benefit" from rehabilitation. This is not true; patients with the most severe degree of lung disease, such as those awaiting lung transplantation and lung volume reduction surgery, have shown significant functional improvement and increased exercise endurance after pulmonary rehabilitation.

The mild COPD state may not justify the intense effort employed to rehabilitate disabled patients. Other barriers to successful rehabilitation are disabling diseases (e.g., severe heart failure, arthritis), low educational level, hazardous occupation, lack of support, and most importantly, motivation. Although it is customary not to consider patients with cancer as candidates for pulmonary rehabilitation, its inclusion in the preoperative conditioning of patients undergoing lung transplantation or lung volume reduction surgery has expanded the list of indications for rehabilitation.

THERAPEUTIC MODALITIES THAT IMPROVE PATIENT PERFORMANCE

Exercise Conditioning

Exercise conditioning is based on three physiologic principles: *specificity* of training, which attributes improvement only for the type of exercise practiced; *intensity* of training, which establishes that only a load higher than baseline will induce a training effect; and *reversal* of the training effect, which states that once discontinued, the training effect will disappear. The first two have been extensively applied in the rehabilitation of patients with severe COPD.

Lower Extremity Exercise

Several controlled trials prove that pulmonary rehabilitation is more effective than conventional treatment in symptomatic COPD patients. Exercise training is the most important component of a pulmonary rehabilitation program. A rehabilitation program that includes lower extremity exercise is better than other forms of therapy, such as optimization of medication, education, breathing retraining, and group therapy.

All studies report an increase in exercise endurance, a modest but significant improvement in work rate or oxygen uptake, and a decrease in the perception of dyspnea. One study randomized 119 patients to education (62) and education with exercise training (57). After 6 months, the trained patients significantly increased their exercise endurance time and peak O_2 uptake and reported an improvement in the perception of dyspnea and self-assessed efficacy for walking compared with controls. A follow-up showed that the gains were lost after 1 year, and that a once-a-month follow-up training visit was not sufficient to maintain the gained effects.

With exercise, patients with COPD may become desensitized to the dyspnea induced by the ventilatory load. However, randomized studies have documented evidence for a true training effect. Muscle biopsies of trained patients, but not those of the controls, manifested significant increases in all enzymes responsible for oxidative muscle function, with important physiologic outcomes, as supported by a reduction in exercise lactic acidosis and minute ventilation after training.

All willing symptomatic patients capable of some exercise are candidates for rehabilitation. In 50 patients with severe COPD evaluated before and after exercise training, an inverse relationship was seen between the baseline 12-minute walking distance and O_2 uptake and the improvement.

Upper Extremity Exercise

Most knowledge about exercise conditioning is derived from programs emphasizing leg training. This is unfortunate, because the performance of many everyday tasks requires not only the hands but also the concerted action of other muscle groups that are also used in upper torso and arm positioning. Some of these serve a dual function (respiratory and postural), and arm exercise will decrease the capacity to participate in ventilation. These observations suggest that if the arms are trained to perform more work, or if the ventilatory requirement for the same work is decreased, as previously shown, this could improve the capacity to perform activities of daily living.

Arm training results in improved performance, which is primarily task-specific. One study compared two forms of arm exercise—gravity resistance and modified proprioceptive neuromuscular facilitation—with no arm exercise in 45 patients with COPD. The 20 patients who completed the program improved performance on the tests specific for the training. The patients also reported a decrease in fatigue for all tests performed.

Unsupported arm training (against gravity) decreases O_2 uptake at the same workload compared with arm-cranking training. Unsupported arm exercise may be more effective to train patients in activities similar to those of daily living. Cystic fibrosis patients who underwent upper extremity training (swimming and canoeing for 1½ hours daily) exhibited increased upper extremity endurance after 6 weeks; most importantly, their increase in maximal sustainable ventilatory capacity was similar to that obtained with ventilatory muscle training. This suggests that arm exercise training programs can train ventilatory muscles.

Because simple arm elevation results in significant increases in minute ventilation (V_E), oxygen uptake (V_{O_2}), and carbon dioxide production (V_{CO_2}), my group studied 14 patients with COPD before and after 8 weeks of three-times-weekly 20-minute sessions of unsupported arm and leg exercise. Our study was part of a comprehensive rehabilitation program to test whether arm training decreases the ventilatory requirement for arm activity. There was a 35% decrease in the rise of V_{O_2} and V_{CO_2} brought about by arm elevation, associated with a significant decrease in V_{O_2}. Because the patients also trained their legs, we could not conclude that the improvement resulted from the arm exercise. To answer this question, we had 25 patients with COPD undergo either unsupported arm training (11) or resistance breathing training (14). After 24 sessions, arm endurance increased only for the unsupported arm training group. Interestingly, maximal inspiratory pressure increased significantly for both groups, indicating that training the arms may induce ventilatory muscle exercise for rib cage muscles that hinge on the shoulder girdle.

PHYSICAL MODALITIES OF VENTILATORY THERAPY

Physical modalities include controlled breathing techniques (diaphragmatic breathing exercise, pursed-lip breathing, bending forward), chest physical therapy (postural drainage, chest percussion, vibration position), and respiratory muscle endurance or strength training. The benefits of these modalities include less dyspnea, fewer anxiety and panic attacks, and improved well-being. Although strength and endurance training of the respiratory muscle is associated with an increase in exercise endurance, the clinical significance of these effects remains debatable. These modalities require careful instruction by specialists and should be initiated under close supervision until the patient shows thorough understanding of the techniques. It is often necessary to involve the family because many of these modalities require the assistance of another person (e.g., chest percussion).

Breathing Training

Breathing training is aimed at controlling the respiratory rate and breathing pattern, thus decreasing air trapping. It also attempts to decrease the work of breathing and improve the position and function of the respiratory muscles. The simplest maneuver is *pursed-lip breathing.* Patients inhale through the nose and exhale between 4 and 6 seconds through lips pursed in a whistling-kissing position. The exact mechanism by which this maneuver decreases dyspnea is unknown. *Diaphragmatic breathing* is a technique to change the breathing pattern from having the rib cage muscles as the predominant pressure generators to a more normal pattern in which the pressures are generated with the diaphragm. Diaphragmatic breathing is usually practiced for at least 20 minutes two to three times daily. Although most patients report improvement in dyspnea and perception of dyspnea, this technique results in minimal if any changes in oxygen uptake and resting lung volume. Similar to pursed-lip breathing, there is usually a fall in respiratory rate, minute ventilation, and increased tidal volume with diaphragmatic breathing.

Chest Physical Therapy

The goal of chest physiotherapy is that of removing airway secretions, thereby decreasing airflow resistance and bronchopulmonary infection. These techniques include postural drainage, chest percussion, vibration, and directed cough. *Postural drainage* uses gravity to help drain the individual lung segments. *Chest percussion* should be performed with care in patients with osteoporosis or bone problems. The single most important criterion for chest physical therapy is the presence of sputum production.

Ventilatory Muscle Strength and Endurance Training

It has been shown that in normal individuals the respiratory muscles, as with their skeletal counterparts, can be specifically trained to improve their strength or endurance. Subsequently, several studies showed that a training response will occur if there is sufficient stimulus. An increase in inspiratory muscle strength (and perhaps endurance) should result in improved respiratory muscle function by decreasing the ratio of the pressure required to breathe (P_I) and the maximal pressure that the respiratory system can generate ($P_{I_{max}}$). The $P_I/P_{I_{max}}$ ratio, which represents the effort required to complete each breath as a function of the force reserve, is the most important determinant of fatigue in loaded respiratory muscles. Because patients with COPD have reduced inspiratory muscle strength, considerable efforts have been made to define the role of respiratory muscle training in these patients.

Studies show an increase in $P_{I_{max}}$ when the respiratory muscles have been specifically trained for strength. Decreasing $P_I/P_{I_{max}}$ through respiratory muscle strength training does not appear to be clinically important. However, respiratory muscle strength often increases as a byproduct of endurance training achieved using resistive loads. Some benefits observed after endurance training may relate to the increased strength. Endurance is achieved through low-intensity, high-frequency training programs; the three types are flow resistive loading, threshold loading, and voluntary isocapneic hyperpnea.

Because many studies have not been controlled, it is difficult to attribute their results to the training. Many show an increase in the endurance time during which the ventilatory muscles could tolerate a known load; some show a significant increase in strength and a decrease in dyspnea during the performance of inspiratory load and exercise. Studies of systemic exercise performance found a minimal increase in walking distance or constant-load exercise endurance. Ventilatory muscle training with resistive breathing clearly results in improved ventilatory muscle strength and endurance. In COPD, however, it is not clear whether this effort results in decreased morbidity or mortality or offers any clinical advantage. In many studies, compliance has been low, with up to 50% of all pulmonary patients failing to complete the programs. Larger multicenter studies with clinical outcomes are needed to select the appropriate patients who may benefit from this labor-intensive form of therapy. Currently, ventilatory muscle training is recommended for patients with symptoms and evidence of ventilatory muscle weakness.

Respiratory muscle training results in increased strength and capacity of the muscles to endure a respiratory load. Whether it also results in improved exercise or performance of activities of daily living is debatable. Knowing the respiratory muscle factors that may contribute to ventilatory limitation in COPD might help predict that increases in strength and endurance should help respiratory muscle function. However, this may be important only in the capacity of the COPD patient to handle inspiratory loads, such as during acute exacerbations. It is less likely that ventilatory muscle training will substantially affect systemic exercise performance.

Respiratory Muscle Resting

Respiratory muscles that must work against a large enough load may become fatigued. Experimentally, this has occurred in both normal volunteers and patients with COPD. Clinically, respiratory muscle fatigue seems to play an important role in the acute respiratory failure of patients with COPD. *Noninvasive ventilation* (NIV) should be helpful in patients with acute or chronic respiratory failure and impending respiratory muscle fatigue, as confirmed by several randomized trials evaluating different outcomes, including the rate of intubation, length of intensive care unit (ICU) and hospital stay, dyspnea, and mortality. Although not all showed the same results in mortality, there was uniform agreement that positive-pressure NIV was effective in reversing acute respiratory failure. The most successfully treated patients were able to cooperate and had elevated partial pressure of carbon dioxide in arterial blood ($Pa{CO_2}$) but no other important comorbid problems (no sepsis or severe pneumonia). Because positive-pressure NIV is potentially dangerous, patients considered for this therapy should be closely monitored and treated by clinicians familiar with these ventilatory techniques.

The possibility that the respiratory muscles of patients with stable severe COPD were functioning close to the fatigue threshold led numerous investigators to explore the role of muscle resting using negative-pressure and positive-pressure NIV. With one exception, the controlled trials using both forms of ventilation showed no benefit in most of the outcomes studied. Therefore, routine use of NIV in stable COPD patients remains controversial.

NUTRITION EVALUATION

Many patients with emphysema appear thin and emaciated and may have anemia, leading to a poor prognosis. Although no evidence suggests a plan that would result in unequivocal benefits for the respiratory system, most authorities agree that any deficiencies should be corrected. Correction of factors such as anemia (to improve oxygen-carrying capacity) and electrolyte imbalances (sodium, potassium, phosphorus, magnesium) could result in improved cardiopulmonary performance. Similarly, simple measures such as encouraging the patient to take small amounts of food at more frequent intervals result in less abdominal distention and decrease dyspnea after meals. My group also recommends evaluating oxygen saturation ($Sa{O_2}$) during meals. If hypoexmia is present, this can be alleviated by supplementing O_2 at feeding time.

PSYCHOLOGICAL SUPPORT

Most patients with advanced lung disease have minor psychological problems, mainly *reactive depression* and *anxiety*. Fortunately, these problems are likely to improve as the patients become involved in a rehabilitation program that improves activity and performance. Simple measures, such as being able to exercise under the supervision of supportive specialists, frequently result in desensitization to symptoms, including dyspnea and fear. From 15 to 20 rehabilitation sessions that include education, exercise, physical therapy, breathing techniques, and relaxation are more effective in reducing anxiety than a similar number of psychotherapy sessions. Occasionally, patients have major psychological problems and require primary psychiatric evaluation and treatment.

HOME OXYGEN THERAPY

Therapeutic oxygen has been used systemically since the association between hypoxemia and right-sided heart failure was first recognized and the benefit of continuous O_2 delivery to patients with severe COPD was documented. Since then, much has been learned about the effects of oxygen and hypoxemia, and progress has been made in the area of mechanical O_2 delivery devices. The results of the Nocturnal Oxygen Therapy Trial and UK Medical Research Council studies established that continuous home oxygen improves survival in hypoxemic COPD patients, and that survival is related to the number of hours of supplemental O_2 per day. Other beneficial effects of long-term O_2 include reduction in polycythemia (perhaps resulting more from lowered carboxyhemoglobin levels than improved arterial saturation), reduction in pulmonary artery pressure (Ppa), dyspnea, and rapid eye movement–related hypoxemia during sleep. Oxygen also improves sleep and may reduce nocturnal arrhythmias. Importantly, O_2 can also improve neuropsychiatric testing and exercise tolerance, attributed to central mechanisms causing reduced minute ventilation at the same workload, thereby delaying ventilatory limitation. The improved arterial oxygenation enables greater O_2 delivery, reversal of hypoxemia-induced bronchoconstriction, and the effect of O_2 on respiratory muscle recruitment.

Prescribing Home Oxygen

Patients are evaluated for long-term O_2 therapy by measuring the partial pressure of oxygen in arterial blood ($Pa{O_2}$). Therefore the recommendation is that $Pa{O_2}$ measurement, not pulse oximetry for $Sa{O_2}$, should be the clinical standard for initiating long-term O_2 therapy, particularly during rest. Oximetry may be used to adjust O_2 flow settings over time. If hypercapnia or acidosis is suspected, arterial blood gases (ABGs) must be measured. Some COPD patients who were not hypoxemic before their exacerbation will eventually recover to the point they no longer need oxygen. It is therefore recommended that the need for long-term O_2 be reassessed in 30 to 90 days, when the patient is clinically stable and receiving adequate medical management. O_2 therapy can be discontinued if the patient does not meet ABG criteria.

As with any drug, oxygen may have deleterious effects, particularly in older patients. The hazardous effects of O_2 therapy can be considered under three broad headings. First, *physical risks* include fire hazard or tank explosion, trauma from catheters or masks, and drying of mucous membranes caused by high flow rates and inadequate humidification. Second, *functional effects* are related to increased CO_2 retention and absorptive atelectasis. Elevated Pa_{CO_2} in response to supplemental O_2 is a well-recognized complication in a minority of patients, traditionally attributed to reductions in hypoxic ventilatory drive. In many patients, however, the decrease in minute ventilation is minimal. The most consistent finding is a worsening of the pulmonary ventilation/perfusion distribution, with an increase in the dead space/tidal volume ratio. This presumably results from oxygen's blockage of local hypoxic vasoconstriction, thereby increasing perfusion of poorly ventilated areas. Third, although possible, *cytotoxic effects* and atelectasis have not been clearly demonstrated with the low flow rates (1-5 L/min; fraction of inspired oxygen [F_{IO_2}] of 24%-36%) typically used for chronic home O_2 therapy in COPD patients.

Oxygen Delivery Systems

Long-term home O_2 therapy is available from three different delivery systems: oxygen concentrators, liquid systems, and compressed gas. Each system has advantages and disadvantages, and the correct system for each patient depends on patient limitations and the clinical application. Oxygen systems were recently compared on the basis of weight, cost, portability, ease of refilling, and availability; the first three factors may be of particular importance in elderly, often debilitated patients.

Administration Devices

Oxygen is typically administered with continuous flow by a nasal cannula. However, because alveolar delivery occurs during a small portion of a spontaneous respiratory cycle (approximately the first sixth), with the rest of the cycle used to fill dead space and for exhalation, the majority of continuously flowing O_2 is not used by the patient and is wasted into the atmosphere. To improve efficiency and increase patient mobility, several devices are available that focus on O_2 conservation and delivery during early inspiration, including reservoir cannulas, demand-type systems, and transtracheal catheters.

Reservoir nasal cannulas and pendants store oxygen during expiration and deliver a 20-mL bolus during early inspiration. Because more alveolar O_2 is delivered, flows may be reduced proportionally, resulting in a 2:1 to 4:1 O_2 savings at rest and with exercise. Cosmetic considerations have traditionally limited patient acceptance of these devices.

Demand valve systems have an electronic sensor that delivers O_2 only during early inspiration or provides an additional pulse early in inspiration as an adjuvant to the continuous flow. By restricting or accentuating O_2 during inspiration, wasted delivery into dead space or during exhalation is minimized. This results in a 2:1 to 7:1 O_2 savings. The effect of mouth breathing on efficacy is not yet clear.

Transtracheal oxygen therapy introduces a thin flexible catheter into the lower trachea for delivery of continuous (or pulsed) O_2. Because O_2 is delivered directly into the trachea, dead space is reduced, and the upper trachea serves as a reservoir of undiluted O_2. This provides a 2:1 to 3:1 O_2 savings over a nasal cannula. However, the widespread use of transtracheal O_2 has been limited by the rate of complications, requiring administration in specialized centers.

EXACERBATIONS, HOSPITALIZATION, AND DISCHARGE CRITERIA

Although acute exacerbations are difficult to define and their pathogenesis is poorly understood, impaired lung function can lead to respiratory failure, requiring intubation and mechanical ventilation. In addition, repeated exacerbations are associated with poor outcome. The purpose of acute treatment is to manage the patient's decompensation and comorbid conditions to prevent further deterioration and readmission (see Chapter 43).

The therapy of an exacerbation is based on the administration of the same medications that are given in the stable patient, with preference for nebulized medications. In addition, the administration of systemic corticosteroids has resulted in improved outcomes. If a bacterial infection is suspected, antibiotics are administered based on the local prevalence of bacteria.

Traditionally, the decision for hospital admission derives from subjective interpretation of clinical features, such as the severity of dyspnea, determination of respiratory failure, short-term response to emergency department (ED) therapy, presence of right-sided heart failure, and presence of complications (e.g., severe bronchitis, pneumonia, comorbidities). This approach to decision making is less than ideal in that up to 28% of patients with an acute exacerbation of COPD discharged from an ED have recurrent symptoms within 14 days. Additionally, 17% of patients discharged after ED management of COPD will relapse and require hospitalization. Few clinical studies have investigated patient-specific objective clinical and laboratory features that identify patients with COPD who require hospitalization. A general consensus supports the need for hospitalization in patients with severe acute hypoxemia or acute hypercarbia; less extreme ABG abnormalities, however, do not assist with decision making.

Other factors that identify high-risk patients include a previous ED visit within 7 days, number of doses of nebulized bronchodilators, use of home oxygen, previous relapse rate, administration of aminophylline, and use of corticosteroids and antibiotics at ED discharge.

Once improved, clinical assessment plans for modifying drug regimens, use of home oxygen, or potential benefits from pulmonary rehabilitation programs should be prepared. The duration of hospitalization for the COPD patient depends at least partly on a multidisciplinary team present to direct respiratory management.

Because of the complex management issues in caring for COPD patients with impending or frank respiratory failure, physician specialists with extensive COPD experience should participate in the care of hospitalized patients who present with underlying severe disease. This includes patients who require invasive or noninvasive mechanical ventilation or who develop hypoxemia unresponsive to F_{IO_2} of 0.50 or have new-onset hypercarbia, as well as those who require steroids more than 48 hours to maintain adequate respiratory function, undergo thoracoabdominal surgery, or require specialized techniques to manage copious airway secretions.

The indications for hospital admission vary according to local practices and regulations. The expert consensus considers the severity of the underlying respiratory dysfunction, progression of symptoms, response to outpatient therapy, existence of comorbid conditions, necessity of surgical interventions that may affect pulmonary function, and the availability of adequate home care. The severity of respiratory dysfunction dictates the need for ICU admission. Depending on available resources, patients with severe exacerbations of COPD may be admitted to intermediate or special respiratory care units to identify and manage acute respiratory failure successfully. Limited data support the discharge criteria, but the patient's capacity to function independently and lack of comorbidities help in the decision.

CONTROVERSIES AND PITFALLS

The paradigm that COPD is a disease associated with poor therapy response has shifted to the general sense that patients do respond to therapy. However, the following controversies still remain:

1. Should asymptomatic patients who are diagnosed with airflow obstruction by spirometry be treated?
2. Should symptomatic patients with mild obstruction be treated, and if so, what is the best initial choice for therapy?
3. Should most patients with persistent symptoms be treated with double- or triple-drug therapy?
4. If double-agent therapy is selected, is it better to treat with a β_2-agonist plus inhaled corticosteroids or a long-acting β_2-agonist (LABA) and long-acting muscarinic antagonist (LAMA)?
5. For which patients is pulmonary rehabilitation more effective?
6. Do maintenance programs of pulmonary rehabilitation need to be developed? Are they useful?
7. Is there a definitive role for chronic antibiotic therapy for patients with COPD, and if so, which agents in which schedule?

Although such questions remain unanswered, studies are unraveling the mechanistic processes that result in COPD to develop therapies capable of reversing disease progression. Recent evidence proving the presence of stem cells in the lungs indicates that regenerative therapy may help repair damaged lungs.

CONCLUSION

Knowledge of COPD has increased significantly in recent years. Smoking cessation campaigns have resulted in a significant decrease in smoking prevalence in the United States. Similar efforts worldwide should have the same impact. The consequence should be a future decrease in the incidence of COPD. The widespread application of long-term oxygen therapy for hypoxemic patients has resulted in increased survival. An expanded drug therapy armamentarium has effectively improved dyspnea and quality of life, and pulmonary rehabilitation has documented benefits. Noninvasive ventilation has offered new alternatives for the patient with acute or chronic respiratory failure. Surgical and more innovative nonsurgical volume reduction may serve as an alternative to lung transplantation for patients with severe COPD who are still symptomatic after maximal medical therapy. All these options offer new hope for the patient with chronic obstructive pulmonary disease.

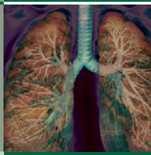
AIRWAY DISEASES



Chapter 43

Management of Exacerbations in Chronic Obstructive Pulmonary Disease

John R. Hurst • Jadwiga A. Wedzicha

EPIDEMIOLOGY

It would be difficult to exaggerate the importance of exacerbations in patients with chronic obstructive pulmonary disease (COPD). COPD is the fifth leading cause of death worldwide, and the mortality and morbidity are often associated with episodes of symptom deterioration termed *exacerbations*. Furthermore, whereas death rates in other prevalent conditions are falling, mortality from COPD continues to rise. Exacerbations of COPD account for about 1 in 10 emergency medical admissions to the hospital, and the in-hospital mortality is 10%. Exacerbations are consequently responsible for 70% of the direct costs attributable to COPD.

Exacerbations generally become both more frequent and more severe as the severity of the underlying COPD progresses. On average, patients with moderate to severe COPD, typical of those attending secondary care, will have one or two exacerbations requiring additional treatment annually. However, annual exacerbation incidence rates differ greatly among individual patients, and those prone to more frequent exacerbations experience a particular burden of disease (Figure 43-1). The best determinant of future exacerbation history is *past* exacerbation frequency, such that some patients appear more intrinsically susceptible and some more resistant to these important events.

PATHOPHYSIOLOGY

The World Health Organization defines COPD as a disease state having a pulmonary component characterized by airflow limitation that is progressive, not fully reversible, and associated with an abnormal inflammatory response to noxious particles or gases. Airway inflammation is even greater at exacerbation, and the assumption has been that this additional inflammation provokes symptoms such as worsening dyspnea and sputum production, through mechanisms relating to airway tone, airway wall edema, and mucus production. The resultant air trapping increases the work of breathing and causes additional impairment to respiratory muscle function. Triggers of increased airway inflammation are therefore the causes of exacerbation, predominantly tracheobronchial infection, with a lesser role for pollutants. However, the effects of increased inflammation at exacerbation require further clarification, because a direct relationship between the clinical severity of the exacerbation and the degree of airway inflammation has never been conclusively demonstrated.

Defining the role of airway infection in causing COPD exacerbation is problematic. Recent advances in molecular biology have isolated respiratory viruses and potentially pathogenic bacteria from the airways of most patients during exacerbations (Box 43-1). However, certainly for patients with more severe underlying disease, bacteria also are often present in the stable state (bacterial colonization). Therefore the presence of an organism at exacerbation does not assume a role in causing that exacerbation. More recent studies suggest that a change in the colonizing bacterial strain may be the precipitating cause. However, not all strain changes are associated with exacerbation, and vice versa. Reflecting this, as discussed later, antibiotics are not of universal benefit during exacerbations. Rhinovirus is the most often identified viral pathogen, and thus exacerbations are more common during the winter months, when viral circulation in the community is higher. The role of atypical organisms such as *Chlamydia* and *Mycoplasma* species appears minimal.

Regarding pollutants in causing COPD exacerbation, large epidemiologic studies link rises in pollutant levels with increases in hospital admission for respiratory disease. Particulate matter less than 10 μm in size (PM_{10}) appears particularly important. Pollutants and microorganisms may interact to amplify the risk of exacerbation.

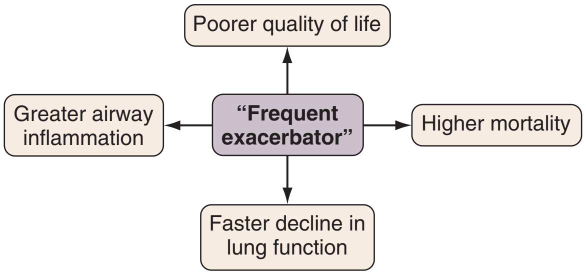
Because some COPD patients seem more susceptible to exacerbations, there may be genetic determinants of exacerbation frequency. In support of this, susceptibility to exacerbation has a familial component, but no single polymorphism has yet been reported to explain the variance in exacerbation frequency observed in COPD patients.

It is now recognized that COPD is associated with upregulated systemic inflammation, and there is now ample evidence to demonstrate heightened systemic inflammation during exacerbations. This may be important given the association between cardiovascular death and elevated systemic inflammatory markers, and because many patients with COPD die from cardiovascular disease. This systemic inflammation is thought to represent "spillover" from the lung.

Understanding the pathophysiology of exacerbations in COPD explains the rationale for the various therapies employed. Bronchodilators may be helpful for increased bronchoconstriction and hyperinflation, corticosteroids may reduce airway inflammation, and antibiotics may be appropriate in exacerbations caused by bacteria (Figure 43-2).

CLINICAL FEATURES

The cardinal feature of COPD exacerbation is an increase in respiratory symptoms beyond what is usual for the patient.



Poorer quality of life
Greater airway inflammation
"Frequent exacerbator"
Higher mortality
Faster decline in lung function

Figure 43-1 Consequences of exacerbations in COPD.

Box 43-1 Common Organisms Isolated at Exacerbation of COPD

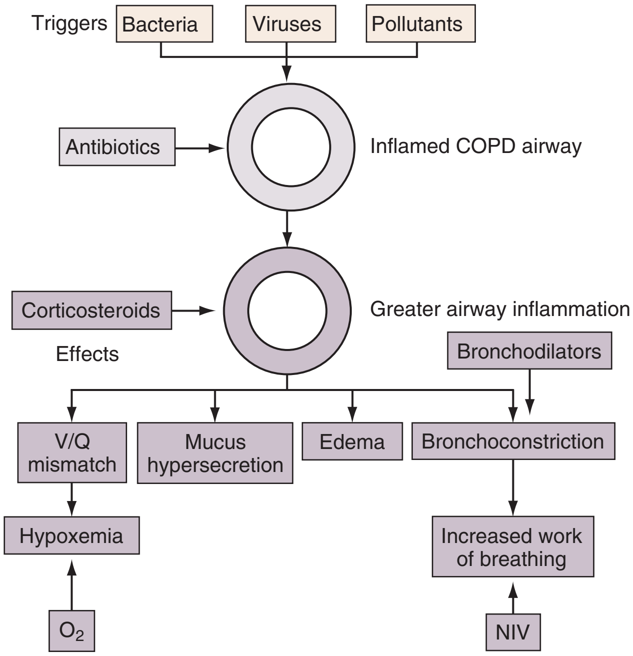
Bacteria

Haemophilus influenzae
Moraxella (Branhamella) catarrhalis
Streptococcus pneumoniae
*Pseudomonas aeruginosa**

Respiratory Viruses

Rhinovirus
Influenza
Parainfluenza
Coronavirus
Respiratory syncytial virus
Adenovirus

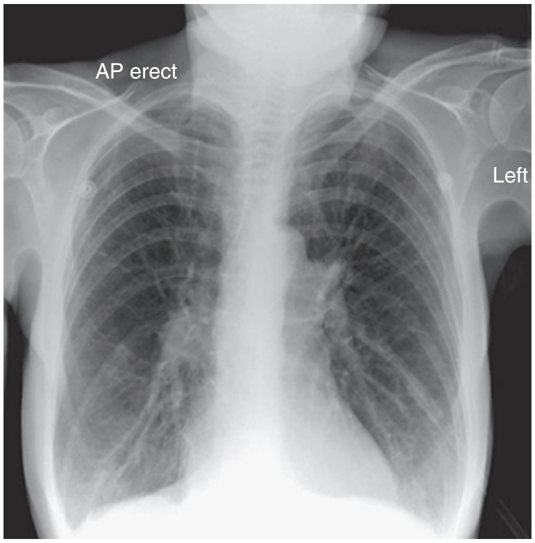
*In patients with more severe underlying COPD.



Triggers
Bacteria
Viruses
Pollutants
Antibiotics
Inflamed COPD airway
Corticosteroids
Greater airway inflammation
Effects
Bronchodilators
V/Q mismatch
Mucus hypersecretion
Edema
Bronchoconstriction
Hypoxemia
Increased work of breathing
O2
NIV

Figure 43-2 Pathophysiology of COPD exacerbation provides rationale for understanding therapies for exacerbations. *NIV*, noninvasive ventilation; *V/Q*, ventilation/perfusion ratio.

Typically, such symptoms include dyspnea, sputum volume, sputum purulence, cough, and wheezing, perhaps accompanied by upper respiratory tract symptoms such as rhinorrhea. Clinical signs are nonspecific but may include tachycardia, tachypnea, cyanosis, use of accessory respiratory muscles, polyphonic expiratory wheeze or crackles on auscultation, and features of carbon dioxide retention or cor pulmonale.



AP erect
Left

Figure 43-3 Typical chest radiograph at exacerbation of COPD. Note the features of underlying COPD, including hyperexpansion and prominent pulmonary vasculature suggestive of pulmonary hypertension, but no evidence of conditions that may mimic or complicate exacerbation (e.g., pneumothorax, pneumonia, cardiac failure).

Exacerbations are heterogeneous events, and the clinical features vary widely. It may be best to consider the *severity* of the presentation, which represents the combined severity of the underlying COPD and the exacerbation. Patients with mild underlying disease may experience no more than a troublesome worsening of symptoms, whereas those with more severe COPD are at significant risk of respiratory failure. Furthermore, other conditions occurring in patients with underlying COPD may mimic or complicate exacerbations. Proper assessment, as described next, is therefore important.

DIAGNOSIS

Exacerbation of COPD is a clinical syndrome, and there is no confirmatory diagnostic test. Although controversy surrounds how exactly to define an exacerbation, and such differences are important when interpreting study results, it is now widely accepted that an exacerbation is a sustained worsening of a patient's symptoms that is acute in onset, is beyond day-to-day variation, and may necessitate a change in therapy.

Although investigations are not helpful in the diagnosis of exacerbation, diagnostic tests help assess the severity of the presentation and exclude other conditions in patients with underlying COPD that may mimic or complicate exacerbation. Such diagnoses include pneumonia, pneumothorax, pulmonary embolus, and cardiac failure, and appropriate investigations include chest radiography, electrocardiography, oxygen saturation (SaO_2) values, and arterial blood gas (ABG) analysis. Simple venous blood tests include complete blood count, urea and electrolytes, and C-reactive protein. A typical chest radiograph at exacerbation (Figure 43-3) should appear much the same as the patient's radiograph in the stable state. Spirometry is not generally helpful because absolute values may be misleading, changes at exacerbation are small, and patients acutely dyspneic have difficulty performing the maneuvers. Sputum microscopy and culture may help to refine empirical antibiotic therapy in those not initially improving. For the patient with mild exacerbation responding to an increase in inhaled bronchodilators, it may be appropriate to omit further investigation.

There is no accepted method of assessing exacerbation severity because it represents the combined severity of the underlying disease and the exacerbation insult. Quantifying changes in symptoms or lung function requires knowledge of the patient at baseline and is difficult to achieve and not generally helpful. Consequently, the degree of health care utilization has been used as a surrogate assessment of severity: *mild* exacerbations require no more than an increase in inhaled bronchodilators, *moderate* exacerbations require antibiotics and corticosteroids in the community, and patients with *severe* exacerbations require hospital admission. The pH is the best indicator of an acute change in alveolar ventilation, and most exacerbations associated with respiratory failure will require hospital assessment. However, the decision to admit a patient depends on more than the severity of the exacerbation and would include, for example, the social circumstances and support available to the patient at home.

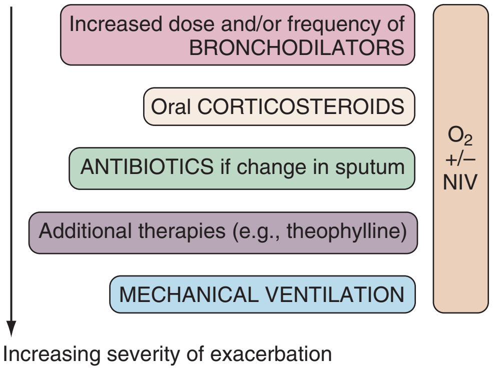
TREATMENT

PHARMACOTHERAPY

The principles of therapy at the time of COPD exacerbation are twofold: to modify the course of the event and to support the patient's respiratory function so that disease-modifying therapies can work. Treatment is given in proportion to the clinical severity of the event, and the sequential approach is illustrated in Figure 43-4. Many guidelines exist to guide appropriate therapy, including recently updated evidence-based statements from the UK National Institute for Clinical Excellence (NICE). Attention to comorbidities is also important, and in the recovery phase the clinician should consider interventions that may reduce the risk of subsequent exacerbations.

Inhaled Bronchodilators

An increase in the dose or frequency of inhaled short-acting bronchodilators is the mainstay of COPD exacerbation therapy. The bronchodilator effect is similar between the β_2-agonist *albuterol* (salbutamol) and the anticholinergic drug *ipratropium bromide.* Although often used in combination, there is little evidence to suggest an additive benefit. Also, no evidence indicates that nebulization is more effective than administering these drugs by inhaler and large-volume spacer. However, nebulizers are often preferred in dyspneic patients and may be less demanding on nursing time. Nebulizers for COPD should be driven on compressed air.



Increased dose and/or frequency of BRONCHODILATORS
Oral CORTICOSTEROIDS
ANTIBIOTICS if change in sputum
Additional therapies (e.g., theophylline)
MECHANICAL VENTILATION
O2 +/– NIV
Increasing severity of exacerbation

Figure 43-4 Summary of stepwise therapeutic approach to COPD exacerbation, with increasing severity of the exacerbation presentation. *NIV*, noninvasive ventilation.

Patients prescribed long-acting bronchodilators normally continue these therapies, but evidence is minimal to support the introduction of long-acting agents as exacerbation therapy, and short-acting drugs are preferred. The recommended approach is therefore to increase the dose and frequency of either a short-acting β_2-agonist or an anticholinergic, with both drugs used together in the event of inadequate clinical response.

Corticosteroids

Systemic corticosteroids are indicated in all COPD exacerbations except milder events that respond to an increase in inhaled bronchodilators alone. A number of randomized trials, now summarized in systematic reviews, demonstrate a more rapid improvement in FEV_1 after administration of steroids, although effects on outcomes such as oxygenation, hospitalization, and length of stay are more variable, with no definite evidence of a mortality benefit. Guidelines vary in their specific recommendations, generally suggesting oral *prednisone,* 30 to 40 mg for 10 to 14 days. Prolonged courses provide no additional benefit (and increase the risk of side effects), and no evidence suggests that tapering the dose is advantageous. Some physicians choose to give the first dose of prednisone intravenously. Nebulized *budesonide* results in similar improvements in lung function to oral dosing but is more expensive than prednisone.

Intriguingly, the use of systemic steroids may delay the time to subsequent exacerbation. Although initiation of inhaled steroids has no role at exacerbation, inhaled corticosteroids have an important role in exacerbation prevention, as discussed later.

Antibiotics

Anthonisen's seminal work on antibiotics at COPD exacerbation demonstrated benefit only when patients had an increase in at least two of three symptoms: breathlessness, sputum volume, and sputum purulence. Sputum purulence reliably indicates the presence of bacteria at exacerbation. More recently, a meta-analysis has confirmed a small but statistically significant benefit in favor of antibiotics. Local resistance patterns and antibiotic policies will dictate the choice of drug, but coverage should include the common pathogens *Haemophilus influenzae*, *Moraxella (Branhamella) catarrhalis,* and *Streptococcus pneumoniae*. An oral aminopenicillin, macrolide, or tetracycline is therefore an appropriate empirical choice. Comparative data across drug classes are sparse. Intravenous antibiotics are rarely required. Data on the optimal duration of therapy are minimal. Antibiotic use at exacerbation may also prolong the time to subsequent exacerbations, perhaps by modulating airway bacterial load.

OXYGEN THERAPY

Oxygen is indicated to correct the hypoxemic respiratory failure that may result at COPD exacerbation (and is not a treatment for breathlessness). *Hypoxemia* is caused by a combination of increased ventilation-perfusion (V/Q) mismatch and alveolar hypoventilation. Oxygen should be administered in a controlled manner with monitoring of ABG tensions to avoid carbon dioxide (CO_2) retention and development of hypercapnic respiratory failure that may occur in a proportion of patients (those classically said to rely on hypoxic respiratory drive). Studies have shown little risk of hypercapnia if oxygen is titrated to a maximum saturation of 90% to 92%. Failure to correct hypoxemia to over 90% (with fraction of inspired oxygen [FIO_2] >40%) suggests the presence of additional

Box 43-2 Indications and Relative Contraindications for Noninvasive Ventilation in Patients with COPD Exacerbation

Indications

Exacerbation with hypercapnic respiratory failure
- $PaCO_2 > 45$ mm Hg
- pH < 7.35 but > 7.25

Relative Contraindications

More severe acidemia
Life-threatening hypoxemia
Inability to protect airway
Hemodynamic instability
Inability to clear secretions
Undrained pneumothorax
Impaired consciousness or agitation

pathology, such as pulmonary embolus. Achieving adequate oxygenation only at the expense of rising partial pressure of CO_2 in arterial blood ($PaCO_2$) or falling pH is an indication for ventilatory support. Venturi masks provide a more reliable FIO_2 than nasal cannulas, but cannulas may be better tolerated.

NONINVASIVE VENTILATION

Noninvasive ventilation (NIV) refers to the provision of ventilatory support using a nasal or full-face mask and the patient's own upper airway, in the absence of an endotracheal tube. Evidence now supports the use of NIV for patients with hypercapnic respiratory failure caused by exacerbation of COPD. The benefit in mortality with additional reduction in hospital stay and complications may largely be attributed to the reduced need for sedation, intubation, and invasive ventilation. In addition, and in contrast to invasive ventilation, NIV may be used earlier and intermittently, which facilitates communication, nutrition, and physiotherapy. NIV is usually administered as pressure-cycled bilevel positive airway pressure in which the inspiratory and expiratory pressures may be independently varied.

However, NIV is not a substitute for invasive ventilation when required. Therefore, the management plan should consider suitability for invasive ventilation should NIV fail, and some patients may have relative contraindications to NIV or can have respiratory failure of such severity that they should be immediately assessed for invasive ventilation (Box 43-2). Most patients suitable for NIV are able to tolerate the treatment (Figure 43-5).

INVASIVE VENTILATION

The primary indications for invasive ventilation at exacerbation of COPD are severe hypoxia and acidemia (pH <7.26) in a patient unsuitable or failing NIV. However, although data suggest that patients with COPD have similar outcomes after invasive ventilation as patients with respiratory failure from other causes, the decision to institute invasive ventilation should consider the patient's prior functional status, severity of the current and underlying illness, degree of reversibility of the present deterioration, and presence and severity of comorbidities.

Mortality following invasive ventilation is about 20%, and weaning from the ventilator can be challenging. This is another setting in which NIV may be valuable. The aim of ventilation is to support gas exchange and respiratory muscle function until other therapies have had sufficient time to be effective. In such circumstances, parenteral corticosteroids and antibiotics are usually given, and bronchodilators may be added to the ventilator circuit from an inhaler and spacer.

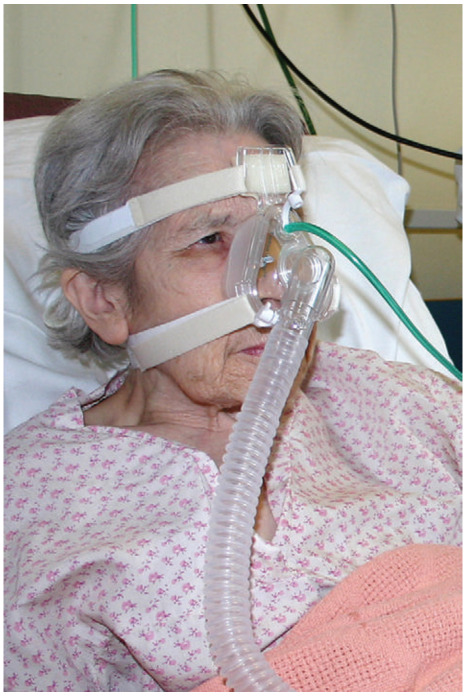


Figure 43-5 Application of noninvasive ventilation by nasal mask in patient with exacerbation of COPD. Note the addition of entrained oxygen.

OTHER THERAPIES

Methylxanthine drugs such as theophylline have a variety of potentially beneficial effects on respiratory and cardiac function, but a meta-analysis failed to show any benefit in lung function or symptoms with methylxanthines during COPD exacerbations. Despite this and well-recognized problems with drug interactions, side effects, and a narrow therapeutic range necessitating the monitoring of drug levels, theophyllines are still sometimes used in patients who are not demonstrating sufficient progress on otherwise maximal therapy. One action of theophyllines is as phosphodiesterase (PDE) inhibitors, and newer, selective PDE_4 inhibitors are currently undergoing trials (see Chapter 42).

No data support the use of intravenous albuterol (salbutamol) at exacerbation of COPD. Side effects are more common than with the inhaled route, and routine use is not recommended.

Although exacerbations are often associated with an increased volume or tenacity of sputum, no firm evidence currently supports the use of mucolytic drugs at exacerbation of COPD. Also, no evidence supports strategies to facilitate expectoration, such as physiotherapy or saline nebulization, although this largely reflects an absence of *evidence* rather than evidence supporting the absence of benefit. Cough suppressants are contraindicated.

Central respiratory stimulants such as intravenous *doxapram* have now been largely superseded by NIV, a therapy clearly superior in the management of hypercapnic respiratory failure. There remains a limited role for doxapram if NIV is not appropriate, as a bridge to NIV, or (with specialist advice) in conjunction with NIV. The use of doxapram is often limited by side-effects, especially agitation, and any potential benefits do not appear to persist beyond 48 hours.

Although intravenous magnesium may be an effective bronchodilator in exacerbations of asthma, no convincing data are available in COPD, and routine use is not recommended. *Heliox* (helium and oxygen) has a lower viscosity than air and may therefore reduce the work of breathing. However, there remains no evidence of benefit at exacerbation of COPD.

Other supportive measures that should be instituted include appropriate attention to fluid balance and consideration of prophylaxis against venous thromboembolism. For COPD patients not responding to maximal therapy, or for those in whom escalation of therapy is inappropriate, a range of palliative approaches to achieve symptom control should be considered.

CLINICAL COURSE AND PREVENTION

Using analysis of symptoms and lung function changes, the median length of an exacerbation in the COPD patient is 7 to 10 days, although there is wide variability and a proportion of exacerbations take considerably longer. Some patients never seem to recover their preexacerbation lung function. Patients admitted have an in-hospital mortality of about 10%, and for patients with hypercapnic respiratory failure, mortality approaches 50% at 2 years. Some patients may be suitable for early supported discharge, associated with similar outcomes but apparently no more cost-effective than standard care.

Given the importance of exacerbations and having managed the acute event, it is important to consider instituting a range of preventative measures to reduce the risk of further exacerbations in the COPD patient. Mounting evidence suggests that a number of drug classes are able to reduce exacerbation rates, including the long-acting β_2-agonists (LABAs), long acting anticholinergics, and inhaled corticosteroids (ICS), at least for those with moderately severe underlying disease. Combination therapy with LABAs and ICS appears superior to the use of either alone. Oral corticosteroids are ineffective at preventing exacerbations and have no effect on other outcomes measures, so these also are not indicated in stable COPD. Mucolytics may reduce exacerbation frequency in those with milder disease not taking ICS.

Ongoing trials are reexamining the role of antibiotics in reducing exacerbation frequency. Some evidence indicates antibiotic may be effective, but many trials included patients with simple chronic bronchitis; also, the drugs used were older, and any benefit must be balanced against the possibility of promoting drug resistance. Macrolides hold particular promise given their recognized antiinflammatory action.

Vaccination against influenza and pneumococcus *(S. pneumoniae)* is recommended.

Underprescription of long-term oxygen therapy in those requiring such treatment is associated with hospital readmission. Home NIV therapy may reduce admissions in those with chronic hypercapnic respiratory failure, although a specific effect on reducing exacerbations has not been demonstrated. Pulmonary rehabilitation has also been shown to reduce hospitalization in patients with COPD. Furthermore, early treatment that might be included in a patient education program can reduce exacerbation length.

The finding that exacerbation susceptibility varies among COPD patients means it is particularly important to target exacerbation reduction interventions at those most likely to develop these events. The simplest way is to ask patients how many courses of systemic (antibiotic and corticosteroid) therapy they received for exacerbations over the past 12 months. Patients receiving two or more such courses (“frequent exacerbators”) are likely to remain frequent exacerbators in the future and should be offered all appropriate exacerbation reduction interventions (see Figure 43-1).

Therefore, a variety of measures may be instituted to reduce the number and consequences of exacerbations, and COPD patients most in need can be identified by asking about prior exacerbation history. For this reason, and for further assessment of patients who present in respiratory failure, it is usually appropriate to review patients in an ambulatory care setting after admission with an acute exacerbation.

CONCLUSION

Research into exacerbations of COPD is moving rapidly. Not many years ago, these events were considered nothing more than “troublesome” deteriorations in symptoms without long-term consequence. We now know this is not true, but many unanswered questions remain. We still understand little about how bacterial and viral pathogens interact. More effective anti-inflammatory agents are required, and the optimal role of antibiotics in preventing exacerbations remains to be defined. We currently have no effective interventions targeting viral pathogens, especially rhinovirus. Understanding why some patients appear more susceptible to exacerbations could lead to the development of new therapeutic approaches. Also, it is now recognized that COPD is associated with systemic inflammation that may cause considerable cardiovascular comorbidity, and ways to assess and manage this may reduce the number and impact of exacerbations in patients with chronic obstructive pulmonary disease.

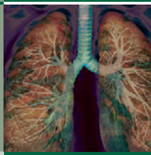
AIRWAY DISEASES



Chapter 44

Cystic Fibrosis

Felix Ratjen • Elizabeth Tullis

Cystic fibrosis (CF) is a common, fatal, autosomal recessive disorder. Its frequency varies among populations, with approximately 1 in 3300 live births in Caucasians, 1 in 15,000 in African Americans, and 1 in 32,000 in Asians. Although reports of CF exist from medieval times, it was first described and recognized as a genetic disease by Anderson in 1938. Although the increase in sweat chloride and sodium concentrations was observed by Saint Agnese in the 1950s, it was not until 1983 that Paul Quinton described the defective chloride transport in sweat glands and respiratory epithelium as the underlying abnormality. The discovery of the causative, mutated gene encoding a defective chloride channel in epithelial cells in 1989 elucidated the pathophysiology of CF and opened up new avenues of treatment. Despite these major advances, however, it is still unclear how mutations in the cystic fibrosis transmembrane regulator *(CFTR)* gene precisely cause the multifaceted manifestations of CF disease.

GENETICS

Cystic fibrosis is caused by mutations in a gene on chromosome 7 encoding the protein subsequently termed the *CFTR* gene. More than 1800 mutations have been reported to the Cystic Fibrosis Genetic Analysis Consortium. Most of these mutations are rare, and only four mutations occur in a frequency of more than 1%. *CFTR* mutations can be grouped into five classes: *CFTR* is not synthesized (I), is inadequately processed (II), is not regulated (III), shows abnormal conductance (IV), or has partially defective production or processing (V). Class I, II, and III mutations are more common and associated with pancreatic insufficiency, whereas patients with the less common class IV and V mutations often are "pancreatic sufficient" (Figure 44-1).

The most common mutation worldwide, found in approximately 66% of patients with CF, is a class II mutation caused by a deletion of *phenylalanine* in position 508 (F508del) of *CFTR*. F508del *CFTR* is misfolded and trapped in the endoplasmic reticulum (ER) and subsequently proteolytically degraded. However, small amounts of F508del *CFTR* reach the plasma membrane of epithelial cells and have some functional activity. These findings suggest that F508del *CFTR* rescue from ER degradation may be a potential therapeutic intervention.

The *CFTR* gene belongs to a family of transmembrane proteins called adenosine triphosphate (ATP)–binding cassette (ABC) transporters and functions as a chloride (Cl^-) channel in apical membranes. However, *CFTR* possesses other functions in addition to being a chloride channel. *CFTR* has been described as a regulator of other membrane channels, including the *epithelial sodium channel* (eNaC) and the *outwardly rectifying chloride channel* (ORCC). *CFTR* also transports or regulates bicarbonate (HCO_3^-) transport through epithelial cell membranes and may act as a transporter for other proteins, such as glutathione.

A relationship exists between *CFTR* genotype and clinical phenotype in CF. Patients who carry two "severe" mutations (classes I, II, and III) that cause loss of function in *CFTR* have *classic* CF, characterized by pancreatic insufficiency, early age of diagnosis, and elevated sweat chloride. In contrast, patients who have at least one "mild" mutation with partial function in *CFTR* are typically diagnosed at an older age, have sweat chloride values closer to normal, and are pancreatic sufficient.

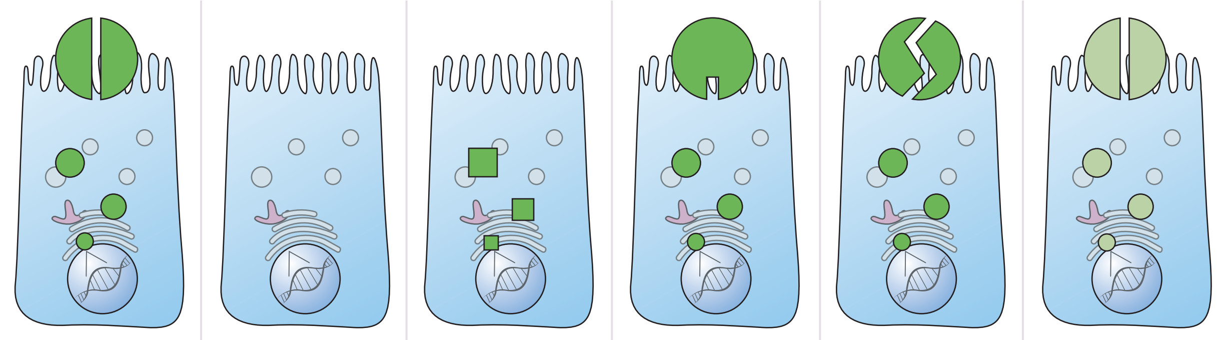
Whereas classes IV and V *CFTR* mutations are linked with pancreatic sufficiency, attempts to link specific mutations to the severity of lung disease have shown large phenotypic variability. This is best documented for patients homozygous for the F508del mutation who exhibit a wide spectrum in lung disease severity. This wide phenotypic variation suggests that environmental factors and genes other than *CFTR* influence the development, progression, and disease severity of CF (Figure 44-2).

PATHOPHYSIOLOGY

Although there is ongoing debate on how *CFTR* mutations cause disease, some of the fundamental questions have been clarified in recent years. *CFTR* is expressed in higher quantities in tissues clinically affected by CF, such as sinuses, lungs, pancreas, liver, gastrointestinal (GI) tract, and reproductive tract, although low levels also occur elsewhere. Because lung disease is the most pertinent clinical feature of CF, the focus here is on its pathophysiology in the respiratory tract.

Airway epithelial cells secrete chloride and absorb sodium chloride (NaCl), the balance of which is regulated through apical channels, including *CFTR* (Figure 44-3). Ion secretion and absorption affect water transport, and a balance between secretion and absorption is thought to be important to maintain an adequate layer of *airway surface liquid* (ASL). The ASL supports the thin mucous layer on top of epithelial cells, which is constantly transported out of the lungs through ciliary movement. Lack or dysfunction of *CFTR* leads to reduced chloride secretion and NaCl hyperabsorption with depletion of ASL. In the absence of adequate ASL, respiratory cilia collapse, leading to breakdown of mucociliary transport. Mucus accumulates in the lower airways, and inhaled bacteria are trapped in this viscous mucous layer on top of respiratory epithelial cells.

The spectrum of bacteria that are relevant for CF lung disease is relatively limited. Overall, *Pseudomonas aeruginosa* is the most common isolate, followed by *Staphylococcus aureus* and *Haemophilus influenzae*. Later in the course of disease, multiresistant organisms such as *Stenotrophomonas maltophilia*,



Class	Normal	I	II	III	IV	V

Achromobacter (Alcaligenes) xylosoxidans, and *Burkholderia cepacia* complex may be isolated. As in other chronic pulmonary diseases, nontuberculous mycobacteria (usually *Mycobacterium avium-intracellulare* or *M. abscessus*) may be isolated. It is challenging to prove whether these organisms are causing ongoing disease requiring treatment, or if they are colonizing only the damaged lung. For a more detailed discussion of nontuberculous mycobacteria (NTM) infections, see Chapter 31.

Stenotrophomonas maltophilia, *Alcaligenes xylosoxidans*, and *Burkholderia cepacia* complex are isolated in less than 10% of patients with CF. *B. cepacia* complex is an unusual organism that is found in the environment (soil and water) and causes chronic infection in only CF and chronic granulomatous disease. It is inherently multiresistant and difficult to treat and in CF is associated with a significantly worse prognosis. There is evidence for person-to-person spread in patients with CF. Approximately 15% to 20% of patients with CF who are infected with *B. cepacia* complex will have rapidly progressive deterioration, so-called cepacia syndrome, with necrotizing pneumonia, greatly elevated white blood cell (WBC) counts, bacteremia, and almost 100% mortality.

The mucus in CF lacks oxygen, leading to anaerobic growth conditions for bacteria. Anaerobic bacteria exist in high numbers in CF airways, but their clinical significance is uncertain. The anaerobic growth conditions trigger a switch of *S. aureus* and *P. aeruginosa* from nonmucoid to mucoid cell types, the predominant phenotype in CF lungs. These mucoid strains form biofilms in CF airways that are resistant to killing by the host defense system, resulting in chronic infection. Inflammatory products (e.g., elastase) released by neutrophils stimulate mucus secretion, perpetuating the cycle of mucus retention, infection, and inflammation.

Evidence indicates that inflammation is dysregulated in CF airways. Neutrophilic airway inflammation has been detected in infants with CF in the first months of life, as well as in CF fetal lung tissue. Whether or not inflammation is directly related to the *CFTR* defect is still disputed. However, an exaggerated, sustained, and prolonged inflammatory response to bacterial and viral pathogens is an accepted feature of CF lung disease. The persistent endobronchial inflammation is deleterious for the course of lung disease (Figure 44-4).

Exocrine pancreatic insufficiency is present in approximately 85% to 90% of patients with CF, generally in those patients who carry two copies of the class I, II, or III *CFTR* mutations. The exocrine pancreas has great functional reserve, and 98% to 99% of its function must be lost before malabsorption will occur. Patients who are pancreatic sufficient do not have normal pancreatic exocrine function but have sufficient function to prevent fat malabsorption. Pancreatic disease begins in utero and is thought to result from decreased volume of pancreatic secretions with decreased concentrations of HCO_3^-. Without sufficient fluid and HCO_3^-, digestive proenzymes are retained within small pancreatic ducts and are prematurely activated, ultimately leading to tissue destruction, fibrosis, and fatty replacement. The resulting malabsorption contributes to the failure to meet the increased energy demands because of the hypermetabolic state associated with endobronchial

infection. Lung infections may lead to anorexia and vomiting, promoting malnutrition. These factors may exacerbate lung infection, leading to a vicious cycle of malnutrition and infection.

CLINICAL FEATURES

Typical signs and symptoms for CF are listed in Box 44-1. Symptoms of CF may vary, with monosymptomatic cases often diagnosed late. It is therefore important to be aware of the spectrum of symptoms that may arise and to initiate adequate diagnostic steps.

Although the classic presentation of CF is the combination of chronic productive cough, steatorrhea, and failure to thrive, 10% to 15% of patients do not have pancreatic insufficiency clinically. Because the lungs of patients with CF are normal at birth, pulmonary symptoms may not be obvious. Between 10% and 15% of newborn infants with CF may fail to pass meconium, leading to *meconium ileus*, which is linked to pancreatic insufficiency but not directly associated with more severe clinical disease.

Less common presentations of CF, such as prolonged jaundice in the newborn and rectal prolapse in infants and young children, should trigger diagnostic tests. Occasionally, an infant may have severe malnutrition with anemia, hypoalbuminemia, and edema in the first 4 months of life.

Infertility can be a presenting symptom in adult patients with CF with limited pulmonary symptoms; 98% of males with CF are infertile, with *azoospermia* secondary to atretic or absent vas deferens. Spermatogenesis and sexual potency are normal. Female reproductive function is normal, although a lower rate of fertility has been postulated because of dehydrated cervical mucus.

Initially, pulmonary symptoms of cough will occur only at times of exacerbations, but eventually there is progression to a chronic daily cough productive of sputum. The sputum is initially white, but as infection continues, the mucus becomes thicker and purulent. Minor hemoptysis often occurs at exacerbation. Some patients have an "asthmatic" component to their disease, with wheezing, chest tightness, paroxysmal dry cough, and a degree of reversibility in airflow obstruction with bronchodilators. Over time, as pulmonary function declines, there is increasing dyspnea. Hypoxemia is not usually seen until forced expiratory volume in 1 second (FEV_1) is less than 35% of predicted value, and hypercarbia usually occurs when the FEV_1 is less than 25% or 30% predicted. Cor pulmonale occurs late in the illness.

Pansinusitis is found on sinus radiographs in most patients, although not all will have symptoms of recurrent sinusitis, headache, and postnasal drip. Nasal polyps are seen in approximately 20% of patients and tend to recur even after surgical removal.

Box 44-1 Symptoms and Signs of Cystic Fibrosis (CF)

Chronic Airway Disease
- Chronic productive cough
- Airway colonization with CF pathogens (*Staphylococcus aureus*, mucoid *Pseudomonas aeruginosa*)
- Persistent chest radiograph abnormalities
- Airway obstruction
- Digital clubbing
- Pansinusitis
- Nasal polyps

Gastrointestinal Disease
- Meconium ileus
- Distal intestinal obstruction syndrome
- Rectal prolapse
- Pancreatic insufficiency, pancreatitis
- Biliary cirrhosis
- Failure to thrive
- Edema with hypoproteinemia
- Deficiency of fat-soluble vitamins

Other
- Salt wasting with metabolic alkalosis
- Infertility caused by obstructive azoospermia

DIAGNOSTIC APPROACH

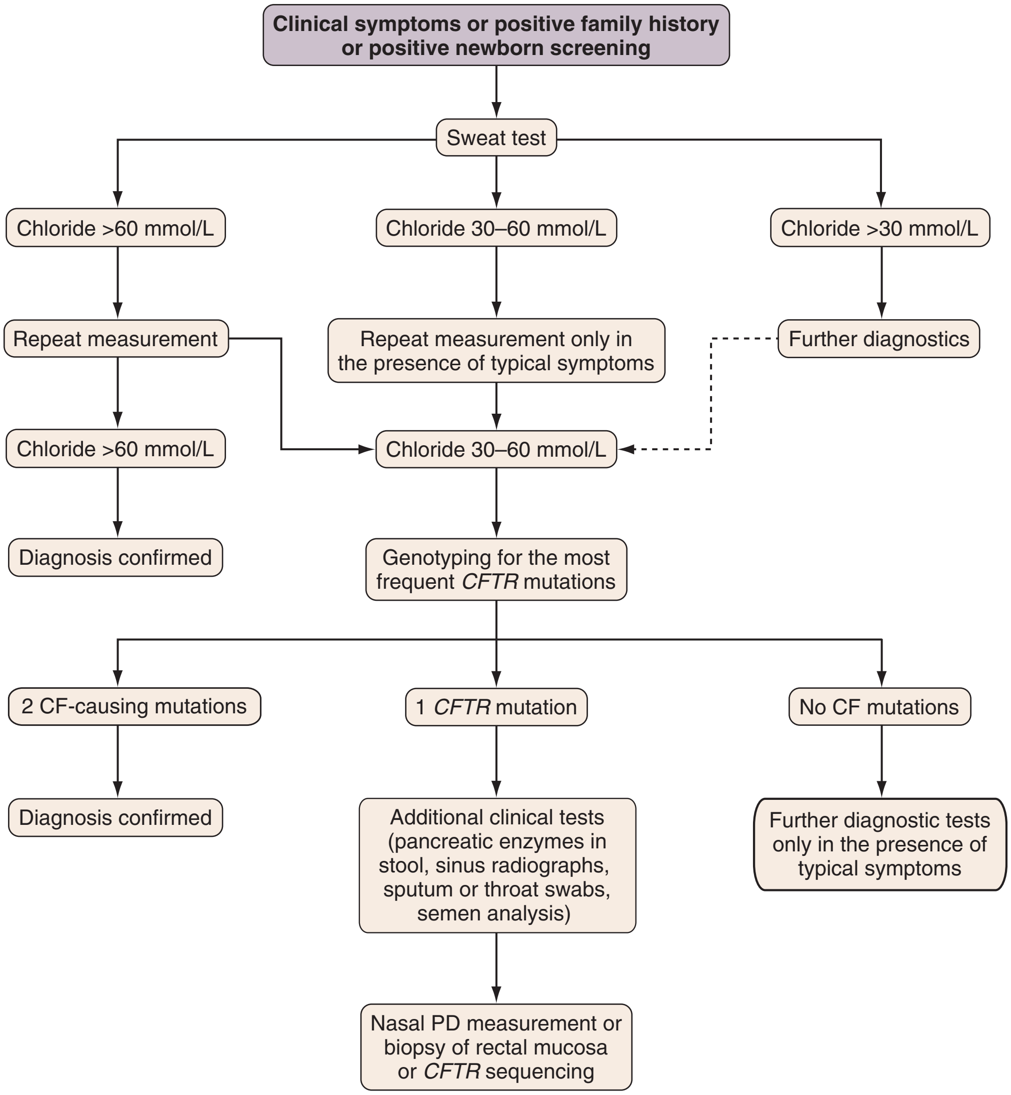
The diagnosis of cystic fibrosis is established by clinical manifestations (see Box 44-1), a history of CF in a sibling, or a positive newborn screening result, in conjunction with laboratory evidence of *CFTR* dysfunction. *CFTR* dysfunction is documented by elevated sweat chloride or characteristic abnormalities in nasal potential difference or by CF-causing mutations in the *CFTR* gene.

A diagnostic algorithm is presented in Figure 44-5. Abnormal ion transport is reflected in high sweat NaCl levels, and measurement of chloride concentration in sweat after iontophoresis of pilocarpine is used for diagnosis. Sweat testing must be done using standardized methods, by qualified staff in an experienced laboratory. A sweat chloride concentration greater than 60 mmol/L on repeated analysis is diagnostic for CF; 30 to 60 mmol/L is considered a "borderline" result but may be seen in patients with CF.

Diagnosis can be confirmed by genotyping of the most common *CFTR* mutations, which vary by ethnic origin of the population tested. More than 1800 mutations in *CFTR* have been reported to the *CFTR* database. Most commercial screening panels test for less than 50 mutations and will identify 85% to 90% of CF alleles. Although *CFTR* mutation testing has had no clinical implications in the past, this may change with the introduction of mutation-specific therapy (see later discussion).

The diagnosis of CF requires the presence of two CF-causing mutations. To be considered CF-causing, the mutation must (1) cause a change in the amino acid sequence that severely affects *CFTR* synthesis or function, (2) introduce a premature termination signal (insertion, deletion, or nonsense mutations), (3) alter the "invariant" nucleotides of intron splice sites (first or last two nucleotides), *or* (4) cause a novel amino acid sequence that does not occur in the normal *CFTR* genes from at least 100 carriers of CF mutations from the patient's ethnic group. Of the more than 1800 *CFTR* mutations reported, only approximately 25 are considered disease-causing to date.

If *CFTR* genotyping or sweat test is not diagnostic, a second test of *CFTR* function such as *nasal potential difference* (NPD) measurement can be performed. The transport of Na^+ and Cl^- ions across the nasal mucosa creates a transepithelial electrical potential difference. Changes in NPD in response to stimulation or inhibition of ion channels by nasal perfusion can be measured, and a typical normal or CF response exists. The NPD test is technically difficult, requiring a skilled operator, and therefore is not available in all CF centers. Standard operating procedures and reference values have recently been determined. Other techniques to examine *CFTR* function include analysis of rectal mucosal biopsies in an Ussing chamber.



Clinical symptoms or positive family history or positive newborn screening
Sweat test
Chloride >60 mmol/L
Chloride 30–60 mmol/L
Chloride >30 mmol/L
Repeat measurement
Repeat measurement only in the presence of typical symptoms
Further diagnostics
Chloride >60 mmol/L
Chloride 30–60 mmol/L
Diagnosis confirmed
Genotyping for the most frequent CFTR mutations
2 CF-causing mutations
1 CFTR mutation
No CF mutations
Diagnosis confirmed
Additional clinical tests (pancreatic enzymes in stool, sinus radiographs, sputum or throat swabs, semen analysis)
Further diagnostic tests only in the presence of typical symptoms
Nasal PD measurement or biopsy of rectal mucosa or CFTR sequencing

Figure 44-5 Diagnostic algorithm for cystic fibrosis *(CF). PD,* potential difference.

Clinical tests not directly assessing the *CFTR* defect can also aid in the diagnostic process. Most patients with CF are pancreatic insufficient, and a decreased concentration of chymotrypsin or pancreas-specific elastase in feces or 72-hour stool collection with fecal fat analysis can confirm this. Most patients with CF have total opacification of paranasal sinuses, and sinus radiography may be helpful. Bacterial pathogens typical for CF (e.g., mucoid *Pseudomonas, S. aureus*) can be detected in sputum or throat swabs and suggest a CF diagnosis. Obstructive azoospermia is found in 98% of men with CF and is a result of *congenital bilateral absence of the vas deferens* (CBAVD). The finding of azoospermia, or lack of vas deferens on careful urologic examination or transrectal ultrasound, suggests CF.

In the past, about 50% of patients with CF in North America were diagnosed by age 6 months and 90% by 8 years. Neonatal screening has been proposed as early diagnosis, and therefore earlier initiation of treatment may improve outcome. A randomized screening program in Wisconsin state found that weight gain and early growth were better in patients diagnosed by neonatal screening. Because good nutrition is linked to a better prognosis, these data would favor the introduction of population-wide neonatal screening. Neonatal screening programs have now been introduced in many countries, most often based on a two-step approach, with immunoreactive trypsinogen (IRT) in dried blood spots and confirmation by DNA analysis in positive cases. Blood trypsinogen is elevated in pancreatic-insufficient patients in the first weeks of life, but the rate of false-positive results of a single IRT test is high, which can be reduced substantially by inclusions of a second step, including genetic testing for the most common *CFTR* mutations.

DIAGNOSTIC CHALLENGES

In 5% to 10% of patients, the diagnosis of CF is not made until adulthood. Increased awareness continues to result in more adults being diagnosed with CF. Most will not have typical features of CF but rather single-organ disease (CBAVD, recurrent acute pancreatitis, or bronchiectasis) or symptoms that develop later in life. Most patients diagnosed as adults are pancreatic sufficient, have "borderline" sweat chloride tests, and have mutations in the *CFTR* gene that are not considered CF-causing. Commercial genetic screening panels may have diagnostic limitations for patients seen in adulthood by including the more common CF-causing mutations usually seen in childhood diagnosis. Adults are more likely to have less common *CFTR* mutations that are not part of the panel. Complete sequencing of the *CFTR* gene has now become feasible and may offer additional information to assist in the diagnosis of CF, especially for patients with equivocal sweat test results. NPD measurement may be especially helpful in establishing a diagnosis of CF in these patients. Interpretation of these results should be done by an experienced CF physician, who is aware of the limitations of these tests.

Obstructive azoospermia is highly related to mutations in *CFTR*, and the finding of CBAVD should trigger genetic testing for CF, especially because assisted reproductive techniques allow these men to father children. Up to 80% of men with CBAVD may have one or two *CFTR* mutations but no other phenotypic features of CF. A diagnosis of CF should not be made in these cases unless diagnostic criteria are met (sweat test >60 mmol/L or 2 CF-causing mutations). The long-term prognosis for these men is still not certain, including whether typical CF lung disease may develop over time, and thus they should receive appropriate clinical follow-up. The relationship between *CFTR* mutations and recurrent acute pancreatitis, bronchiectasis, or other sinopulmonary disease is not as strong as that seen with CBAVD. However, a higher-than-expected prevalence of *CFTR* mutations is found in these populations.

Despite all these tests, a small number of patients remain in whom a definite diagnosis cannot be made. Typical CF bronchiectasis may be seen in patients who have *CFTR* mutations that are not considered disease-causing and who have a normal or borderline sweat chloride test. Thus, it seems that CF lung disease may occur even with lesser degrees of dysfunction of *CFTR*. The important message is that presence of *CFTR* mutations may put patients at risk for significant CF disease developing later in life, and close follow-up is advised.

This dilemma is further complicated by lack of a common and standardized terminology for patients who have evidence of *CFTR* dysfunction without a definite diagnosis of CF. These patients are being referred to as *atypical* CF, *mild* CF, *nonclassic* CF, or CFTR*opathy*, or if *CFTR* mutations exist in the absence of lung or GI disease, *pre*-CF. The current preferred term for patients with a CF clinical phenotype and evidence of *CFTR* dysfunction but do not meet diagnostic criteria for CF is CFTR-*related disorder*.

CLINICAL COURSE OF LUNG DISEASE AND PRINCIPLES OF THERAPY

The lungs of newborns with CF are normal at birth. Pathologic studies show that the first abnormalities are usually detected in the small airways reflected by mucous plugs and dilation distal to the obstructed airways. These early abnormalities are often focal and do not necessarily produce clinically apparent symptoms. The disconnect between pathologic abnormalities and pulmonary symptoms is now recognized and has important implications for treatment. Studies that use bronchoalveolar lavage fluid show that ongoing airway inflammation is present in patients with mild disease and can be observed early in infancy. The lack of impressive symptoms does not mean that these patients do not have ongoing progressive disease requiring continuous treatment.

Although the traditional approach was to wait for symptoms, a more aggressive strategy is used today. This aggressive approach translates into continuous lifelong treatment, which is time-consuming and labor-intensive for patients and their families. Although the burden for individuals is considerable, it has changed the natural history of disease progression in patients with CF. The classic course of CF was characterized by chronic productive cough and a gradual, but steady, decline in pulmonary function Now most patients with CF maintain their pulmonary function over years, reflected in an annual rate of decline in FEV_1 of less than 2% predicted per year, and many do not regularly expectorate sputum until adulthood. However, it is important to be vigilant about periods of deterioration that present as episodes of pulmonary exacerbations and, unless treated rapidly and aggressively, may lead to an irreversible loss in pulmonary function.

Pulmonary exacerbations in patients with CF are often triggered by viral infections but require prompt treatment with antibiotics directed against pathogens present in respiratory cultures. It is important to recognize the signs of a pulmonary exacerbation early to avoid permanent damage to the lung (Box 44-2). In general, any increase in symptoms lasting more than a few days, associated with a decline in FEV_1, requires antibiotic therapy. Because most CF patients are chronically infected with bacteria, suppression rather than eradication of organisms is the primary goal of therapy. Duration of therapy is not guided by changes in sputum bacteriology but rather by improvement in symptoms and pulmonary function.

Because many patients have normal lung function and the annual rate of decline in pulmonary function is minimal, it has become difficult to assess lung disease by lung function alone. Despite this, FEV_1 remains the best predictor of outcome in patients with CF and is therefore used to follow the course of lung disease and to guide treatment. Chest radiographs are performed annually in most centers but have limited sensitivity to detect early abnormalities. High-resolution computed tomography can detect abnormalities not detected by conventional radiography, but CT is associated with a higher cumulative radiation dose and thus not considered part of routine care at present. There is considerable interest in developing more sensitive outcome parameters assessing function, structure,

Box 44-2 Symptoms and Signs of Pulmonary Exacerbation in Cystic Fibrosis Patients

Symptoms

Increased frequency, duration, and intensity of cough
Increased or new-onset sputum production
Change in sputum appearance
New-onset or increased hemoptysis
Increased shortness of breath; decreased exercise tolerance
Decrease in overall well-being: increased fatigue, weakness, fever, poor appetite

Physical Signs

Increased work of breathing: intercostal retractions and use of accessory muscles
Increased respiratory rate
New-onset or increased crackles on chest examination
Increased air trapping
Fever
Weight loss

Laboratory Findings

Decrease in FEV_1 of 10% or greater compared with best value in previous 6 months
Increased air trapping and/or new infiltrate on chest radiograph
Leukocytosis
Decreased oxygen saturation (SaO_2)

Data from Gibson RL, Burns JL, Ramsey BW: *Am J Respir Crit Care Med* 168:918–951, 2003.
FEV_1, forced expiratory volume in 1 second.

infection, and inflammation to help guide treatment, but currently these tests have a limited role outside of research studies.

Treating bacterial infections and avoiding lung function decline are key to management of CF patients, with regular assessment of clinical status, lung function, and sputum microbiology. Quarterly clinic visits are considered standard in CF care, but some patients require more frequent follow-up.

TREATMENT

GENE REPLACEMENT THERAPY AND PHARMACOTHERAPY

Cystic fibrosis is caused by deficient or absent *CFTR*, and thus gene replacement therapy is a form of curative treatment. Trials so far have targeted the respiratory tract directly. A number of vector systems have been tested in human trials, but adenoviruses and cationic lipids are the two most common vectors. Even though some transient effect on *CFTR* expression and function has been achieved, no study could demonstrate a long-lasting effect. Viral vectors seem to be more efficient than cationic lipids but have the disadvantage of being immunogenic. Although attempts are ongoing to overcome these shortcomings, gene therapy is currently not a therapeutic option for patients with CF.

Another approach to treat the underlying defect is *CFTR* pharmacotherapy aiming to improve trafficking, expression, or function of *CFTR*. For patients carrying class I *stop* mutations, which lead to premature termination codons in the messenger RNA and therefore truncated protein production, treatment with aminoglycosides or its derivative ataluren has been shown to increase *CFTR* expression. Uncontrolled studies also show improved chloride channel function in the nasal epithelium as well as positive trends in lung function. A larger placebo-controlled trial now underway will further clarify clinical benefits of this therapy.

Because most patients do not carry stop mutations, this approach addresses only a small fraction of the CF population. A potentiator of *CFTR* function, VX770, has been tested in patients with the G551D mutation, in which *CFTR* is present on the cell surface but channel function is reduced. Recent studies demonstrate that treatment not only improved lung function, but also reduced sweat chloride concentrations below the threshold clearly diagnostic for CF. A subsequent longer study confirmed these results, and VX770 has become the first *CFTR* modulator to be licensed for clinical use.

For the most common mutation, F508del, misfolded *CFTR* is degraded in the ER before reaching the cell membrane. Because this misfolded *CFTR* does have Cl^--conducting function, compounds that affect intracellular trafficking, called *chaperones*, may provide clinical benefit. Some studies have provided proof of concept, and one compound derived from high-throughput screening programs, VX809, is currently tested in clinical trials. Safety has been confirmed in early trials. Because the *CFTR* potentiator VX770 greatly enhanced the effect of *CFTR* corrector therapy in vitro, combination therapy with VX809 is also being tested to enhance therapeutic efficacy.

An alternative to *CFTR* pharmacotherapy is to activate other Cl^- channels present in the apical surface of epithelial cells or to inhibit Na^+ hyperabsorption. This concept seems useful because CF mice lacking *CFTR* do not develop lung disease, which may be caused by better function of alternative Cl^- channels. Whether activation of alternative Cl^- channels or inhibition of Na^+ hyperabsorption is a valid treatment option is currently unclear. Denufosol, an activator of alternative chloride secretion, has undergone a full development program and showed promise in improving lung function in both Phase II studies and a 6-month placebo-controlled Phase III trial. However, the second Phase III trial failed to confirm these findings.

SYMPTOMATIC THERAPY

In the absence of a proven curative regimen, symptomatic treatment is still the mainstay of CF therapy. Most of the treatment approaches are directed at interrupting the cycle of mucus retention, infection, and inflammation. Early initiation of therapy is important to avoid permanent damage to the lung.

Airway Clearance

Chest physiotherapy remains the mainstay of airway clearance and is recommended for all patients. Short-term benefits have been demonstrated for many techniques, but long-term efficacy data are limited. The most common techniques are manual percussion, positive expiratory pressure (PEP) mask therapy, and autogenic drainage. In addition, techniques that provide vibration to the airways actively or passively are being used. Debate is ongoing as to which technique provides the best efficacy for patients with CF. Physical activity and exercise are considered important adjuncts to physiotherapy, because impairments in exercise tolerance have been linked to poorer prognosis in CF patients.

Airway secretions in CF patients are highly viscous, indicating the use of drugs that reduce the viscoelasticity of sputum. Classic *mucolytics* such as *N*-acetylcysteine have little effect on lung disease in CF, although they are being revisited because of their potential benefit as antioxidants. Their ineffectiveness as a mucolytic may be because CF mucus contains little mucin and is mainly composed of pus. *Recombinant human deoxyribonuclease* (rhDNase) administered by inhalation reduced sputum viscosity, improved pulmonary function, and reduced the number of pulmonary exacerbations in patients with moderate and with mild lung disease. Data also suggest that rhDNase reduces inflammation in the airways. *Hypertonic saline* has been assessed as another potential drug to improve airway clearance, and recent studies suggest that it may also increase airway surface liquid. The effect on lung function seems to be smaller than that of rhDNase, but these therapies have different mechanisms of action and thus cannot be viewed as virtually exclusive. Hypertonic saline also reduces the frequency of pulmonary exacerbations, an important outcome because these are associated with decreased lung function.

Treatment of Airway Infection

Aggressive treatment of airway infection is a main reason for the increased life expectancy of patients with CF achieved over recent decades. As mentioned, bacterial pathogens in patients with CF are usually limited to a relatively small spectrum, with *S. aureus* or *H. influenzae* the most prominent in younger patients and *P. aeruginosa* in older patients. Most patients go through phases of clinical stability with intermittent pulmonary exacerbations. A set of criteria is used to diagnose pulmonary exacerbations (see Box 44-2), but the threshold for initiating targeted antibiotic therapy should be rather low. Genotyping has shown that the organisms present at exacerbation are the same as when the patient is clinically stable, but with higher bacterial density. Thus, choice of antimicrobial therapy on the basis of the most recent sputum cultures is indicated.

Pulmonary exacerbations are usually treated with intravenous (IV) antibiotic therapy, although oral therapy is used for exacerbations associated with minimal or no drop in lung function. Antistaphylococcal antibiotics are usually administered for 2 to 4 weeks. Patients with CF have differences in drug clearance and require dosages approximately 50% higher than individuals without CF. For patients with *Pseudomonas* infection, combination therapy with a semisynthetic penicillin (e.g., piperacillin), a third-generation cephalosporin (e.g., ceftazidime), or a carbapenem (imipenem or meropenem) with an aminoglycoside (most frequently tobramycin) is administered for 2 to 3 weeks. Oral ciprofloxacin is used for less severe exacerbations.

Treatment of the less common gram-negative organisms such as *B. cepacia* complex, *A. xylosoxidans*, and *S. maltophilia*, can be challenging. These organisms are inherently multiresistant. Although infection with *B. cepacia* complex is clearly associated with a worse prognosis, the relevance of the other gram-negative bacteria is less clear, and currently it is not established whether they are responsible for causing disease. For patients chronically infected with *B. cepacia* complex, trimethoprim-sulfamethoxazole (TMP-SMX) or doxycycline is effective for minor exacerbations. For more severe infections, the best in vitro antibiotics consist of meropenem, and high-dose inhaled tobramycin in combination with either ceftazidime, chloramphenicol, or TMP-SMX. Treatment of exacerbations with *B. cepacia* complex may require prolonged antibiotic therapy (weeks to months) before a clinical response is seen. Use of pulmonary function, WBC count, and markers of inflammation (CRP or ESR) may be helpful to guide therapy. *S. maltophilia* can be treated with TMP-SMX or doxycycline. Because *S. maltophilia* isolates can develop resistance during treatment, TMP-SMX is often combined with a second antibiotic, such as ticarcillin-clavulanate or levofloxacin. *A. xylosoxidans* can be challenging to treat, but options include imipenem and piperacillin. Inhaled colistin may also be effective, because in vitro studies found that high concentrations of colistin inhibit most strains of *A. xylosoxidans*.

Many CF physicians try to eradicate bacteria from CF airways with courses of oral antibiotics even in the absence of symptoms. Prophylactic antistaphylococcal therapy with flucloxacillin initiated at diagnosis is also used in some centers. Although one small study has reported a lower rate of cough and hospital admissions during the first 2 years of life, continuous antistaphylococcal therapy was associated with a higher rate of *P. aeruginosa* acquisition in two other studies, in which mainly cephalosporins were used. *P. aeruginosa* infection increases pulmonary inflammation and has a negative effect on lung function when this pathogen persists. At present, there is insufficient evidence to support the use of prophylactic antistaphylococcal therapy in patients with CF.

Overall, *Pseudomonas aeruginosa* is the major pathogen in CF lung disease. Its prevalence increases with age, and most adult patients are chronically infected with this organism. After an initial transient colonization period with nonmucoid strains, untreated patients generally become chronically infected with mucoid strains of *P. aeruginosa*. Antibiotic therapy usually fails to eradicate mucoid *P. aeruginosa* from the airways. High bacterial counts, low metabolic rate of pathogens in biofilms, poor penetration of antibiotics into airway secretions, and anaerobic conditions in sputum are considered responsible for this finding. Chronic infection with mucoid strains has a negative impact on the subsequent course of lung disease. Although eradication is virtually impossible in chronic infection, treatment can be effective in the early phase of *P. aeruginosa* infection; a major improvement in patients with CF is early antibiotic therapy. Both inhaled antibiotic therapy with tobramycin alone and combined inhaled antibiotics and oral ciprofloxacin have been used, but more recent evidence suggests that adding ciprofloxacin does not increase therapeutic success. Although the optimal treatment regimen for early *P. aeruginosa* infection has yet to be determined, inhaled tobramycin successfully reduces the incidence of chronic airway infection with *P. aeruginosa* in patients with CF (Table 44-1).

To avoid adverse effects and to obtain high drug concentrations in airways, inhaled antibiotic therapy is the treatment of choice for maintenance therapy in patients with *P. aeruginosa* infection. The best evidence currently available is for inhaled *tobramycin*, which has been shown to improve lung function and reduce pulmonary exacerbations in chronically infected patients. In addition, *colistin* is being used "off label" for inhalation. Although colistin has the advantage of low prevalence of resistant strains, its short-term efficacy is inferior to inhaled tobramycin. Inhaled *aztreonam* has been recently licensed as an alternative option to tobramycin based on two controlled clinical trials demonstrating its efficacy. A comparison to inhaled tobramycin also found similar efficacy with aztreonam and suggested superior lung function benefits during therapy; however, most of the patients were previously treated with inhaled tobramycin, which may favor the response to

Table 44-1 Options for Oral and Inhaled Antibiotic Therapy

Antibiotic: Choose One	Pediatric Dose	Adult Dose
Staphylococcus aureus		
Dicloxacillin	6.25-12.5 mg/kg four times daily	250-500 mg four times daily
Cephalexin	12.5-25 mg/kg four times daily	500 mg four times daily
Amoxicillin/clavulanate	12.5-22.5 mg/kg amoxicillin*	400-875 mg amoxicillin*
Haemophilus influenzae		
Amoxicillin	25-50 mg/kg twice daily	500-875 mg twice daily
Amoxicillin/clavulanate	12.5-22.5 mg/kg amoxicillin*	400-875 mg of amoxicillin*
Cefuroxime axetil	15-20 mg/kg twice daily	250-500 mg twice daily
Pseudomonas aeruginosa		
Ciprofloxacin	10-15 mg/kg twice daily	750 mg twice daily
Tobramycin†	300 mg by nebulizer, twice daily	300 mg by nebulizer, twice daily
Colistin†	150 mg by nebulizer, twice daily	150 mg by nebulizer, twice daily

Modified from Gibson RL, Burns JL, Ramsey BW: *Am J Respir Crit Care Med* 168:918-951, 2003.

*Component twice daily.

†By inhalation.

aztreonam. Both tobramycin and aztreonam have been studied in cycles of 28 days on and 28 days off, so many clinicians have also started to use both treatments in alternate months to avoid deterioration during the off periods.

Some centers treat chronically infected CF patients with routine IV antibiotic therapy every 3 months, regardless of respiratory symptoms, but this approach has not yet been supported by sufficient evidence.

In addition to inhaled antibiotics, *azithromycin* can improve pulmonary function and reduce pulmonary exacerbations in patients with *P. aeruginosa*–positive disease and more recently has been shown to reduce exacerbations in *P. aeruginosa*–negative patients as well. Although macrolides have no efficacy against *P. aeruginosa* when tested in routine cultures, some evidence suggests macrolides may affect *P. aeruginosa* growing in biofilms. Whether this explains their efficacy or whether this is caused by antiinflammatory properties of macrolides is still unclear (Table 44-1).

Patient-to-patient transmission of bacterial pathogens does occur. Thus, separation regimens have been implemented to prevent cross-infection in patients with CF. This is particularly important with *B. cepacia* complex because person-to-person transmission has been proved, and chronic infection is associated with a worse clinical outcome. Vaccines are being developed against *P. aeruginosa*, but their efficacy is currently unproven.

Inflammation

Cystic fibrosis is characterized by an intense, neutrophil-dominated airway inflammation. Early trials of antiinflammatory treatment have been performed with corticosteroids. Oral prednisone (1-2 mg/kg every other day) was found to reduce lung function decline in *P. aeruginosa*–positive patients, but serious side effects such as glucose intolerance, growth retardation, and cataracts were found in prednisone-treated patients. Inhaled steroids, although widely used in patients with CF, have not been shown to improve lung function and airway inflammation. Therefore, treatment is not indicated unless patients have demonstrated airway hyperreactivity, present in 25% to 40% of patients with CF. High-dose ibuprofen slowed lung function decline in patients with CF in a single-center trial, but its use is still controversial. Even though other drugs targeting specific elements of CF airway inflammation have been studied, none has proved both efficacious and safe.

LUNG TRANSPLANTATION

Double-lung or heart-lung transplantation is a therapeutic option for patients with CF with end-stage lung disease. Determining the timing for transplant remains challenging; many attempts have been made to develop prediction models to facilitate assessment. A patient must be ill enough that there would be a survival benefit from transplant, but not so sick that the patient would die on the waiting list. FEV_1 less than 30% predicted in a patient receiving maximal medical treatment has been found to be the best indicator, because generally it predicts a median survival of 2 years. However, the length of the waiting list for the transplant center must also be considered. Generally, survival is better for adults than children, although a survival benefit through lung transplantation has also been reported in children. Survival is significantly worse for patients infected with *B. cepacia* complex, particularly *B. cenocepacia*, and most centers consider *B. cenocepacia* infection a contraindication for transplantation. However, the Toronto group has shown that, even in these high-risk patients, transplantation improves survival. Currently, worldwide transplant experience (ISHLT data) has shown a 1-year survival after transplantation of 80%, 5-year survival of 55%, and 10-year survival of 35%.

PANCREATIC INSUFFICIENCY AND MALNUTRITION

Patients with CF with poor nutrition status are more prone to chest infections, and poor nutrition status is linked to worse prognosis. An aggressive approach to maintain normal weight in patients with CF is therefore warranted, by ensuring a high-fat, high-calorie diet with adequate replacement of pancreatic enzymes. If this cannot be achieved through oral intake, enteral feeding by nasogastric or gastrostomy tube is used to maintain adequate nutritional status and normal growth. Malabsorption often is incompletely corrected with pancreatic enzyme replacement and is caused by multiple factors, including incomplete dissolution of the pH-sensitive enteric coating in the proximal small bowel because of lack of neutralization of gastric acid by pancreatic bicarbonate. Use of medications to reduce gastric acidity may improve the effectiveness of enzymes in some patients.

INFERTILITY AND PREGNANCY

Although 98% of men with CF are infertile, with azoospermia secondary to absent vas deferens, spermatogenesis and sexual potency are normal. Men with CF can become fathers with assisted reproductive techniques such as microscopic epididymal sperm aspiration in conjunction with in vitro fertilization.

Female reproductive function is normal, although a lower rate of fertility has been postulated because of dehydrated cervical mucus. In general, women with CF tolerate pregnancy well, and many studies show pregnancy has no negative impact on survival. If women have reasonable lung function (FEV_1 >50% predicted), a stable clinical condition, and adequate nutrition status (BMI >19), the fetal and maternal outcomes are good. It is important to monitor maternal weight gain during pregnancy and check for gestational diabetes each trimester. Genetic testing for CF mutations in the partner is recommended for both men and women with CF who plan to have children.

COMPLICATIONS

PULMONARY COMPLICATIONS

Pneumothorax

Pneumothorax occurs in CF patients with more severe lung disease and lower lung function, usually older children and adults. Treatment is challenging because it may be difficult to expand the fibrotic and infected lung. Pneumothoraces are often recurrent. Chest tube drainage is usually required, and a small-gauge tube is preferred to minimize pain. Good analgesia is necessary to allow chest physiotherapy to continue and prevent worsening pulmonary infection. Chemical pleurodesis with doxycycline, talc, or thoracoscopic surgery may be required to treat recurrent pneumothoraces, although this may not be effective in all cases. If there is an ongoing air leak despite these interventions, surgical pleurodesis may be necessary. Pleurodesis was considered a contraindication to lung transplantation because of problems with removal of the lung at transplant and bleeding complications, but now most centers will perform lung transplant in patients who have had medical or surgical manipulation of the pleural space.

Hemoptysis

Chronic pulmonary infection leads to enlargement of the bronchial artery circulation supplying the lung. Hemoptysis can occur even in patients with mild lung disease and usually indicates infection. Vitamin K deficiency caused by pancreatic insufficiency can contribute to the problem. *Massive* hemoptysis (>250 mL of blood in 24 hours) is less common but occasionally can be life-threatening (see Chapter 20). Hemoptysis is usually treated with antibiotic therapy. Vitamin K and tranexamic acid may also be used. Ongoing massive hemoptysis requires bronchial artery embolization. Angiography is used to locate the abnormal bronchial artery vessels. These vessels are aberrant, and arteries arising from one side may supply contralateral segments of the lung. Because location of the bleeding does not always correlate with origin of abnormal bronchial arteries, bronchoscopy to locate source of bleeding is not helpful. However, bronchoscopy may be necessary to manage the airway in life-threatening hemoptysis. Embolization should be performed by experienced interventional radiologists because of potential complications of bronchial artery embolization, including infarction of the esophagus, lung parenchyma, or chest wall (causing dysphagia or severe chest pain), and transverse myelitis caused by accidental embolization of the spinal arteries.

Allergic Bronchopulmonary Aspergillosis

Although *Aspergillus* is frequently detected in sputum cultures, most of these patients do not have symptoms that can be attributed to the presence of the fungus. About 5% of patients with CF have symptoms caused by hypersensitivity. This entity is called allergic bronchopulmonary aspergillosis (ABPA) and should be suspected in patients who have respiratory deterioration but do not respond well to antibiotic therapy. In addition to symptoms of chronic productive cough, ABPA is usually accompanied by asthmatic features (wheezing), and patients may expectorate gritty brown sputum ("sandy" sputum). Some features of ABPA are difficult to assess in CF, because bronchiectasis, wheezing, productive cough, and presence of *Aspergillus* in the sputum are common features of CF lung disease. Diagnosis is supported by elevated IgE (usually >1000 IU/mL), a positive skin test, and serum precipitins against *Aspergillus* (see aspergilloma, Chapter 53). Treatment of symptoms and decline in lung function requires corticosteroids; high doses (1-2 mg/kg) may be required initially before the dose can be tapered. Adjunctive antifungal therapy with itraconazole may be efficacious in patients without CF who have ABPA, but its efficacy in patients with CF remains unproven. Duration of ABPA therapy is tailored to clinical response, improvement of FEV_1, and normalization of serum IgE levels.

GASTROINTESTINAL COMPLICATIONS

Pancreas

Pancreatic insufficiency is present in most patients from birth, or shortly thereafter, and occurs when more than 98% of the pancreas has been destroyed. Malabsorption of fat leads to malnutrition and deficiency of fat-soluble vitamins (A, D, E, and K). From 10% to 15% of patients have adequate pancreatic function, or pancreatic sufficiency (PS), and thus require no enzyme replacement. Acute pancreatitis develops in 20% of patients with PS and may be recurrent, and some patients have ongoing destruction of the pancreas and become pancreatic insufficient (PI).

Distal Intestinal Obstruction Syndrome

Undigested fat, mucus from the GI tract, swallowed sputum, and reduced water in the small bowel result in thick, sticky bowel contents. Partial bowel obstruction, usually at the ileocecal junction, can cause recurrent right lower quadrant (RLQ) pain and occasionally altered bowel habit. This condition occurs in 15% to 20% of patients and is called distal intestinal obstruction syndrome (DIOS). The diagnosis is made clinically from the history and palpation of a tender mass in the RLQ along with evidence of fecal collection in the RLQ on abdominal imaging. DIOS rarely causes complete bowel obstruction, elevated WBC count, or fever; if these features are present, other causes of abdominal pain should be considered, such as intussusception, appendicitis or appendiceal abscess, and *Clostridium difficile* colitis. Treatment requires large volumes of intestinal lavage solution (GoLytely, Peglyte) to clear the bowel. Occasionally, enemas with water-soluble osmotic agents such as Gastrografin or Hypaque (diatrizoate sodium) are needed. Prevention of recurrent DIOS should focus on adequate pancreatic enzyme replacement and use of mineral oil or polyethylene glycol.

Intussusception can occur in 1% to 2% of children and young adults with CF and may mimic DIOS. The location of the intussusception is usually ileo-ileo but may be ileo-colic. Intussusception may be recurrent and asymptomatic but can cause small bowel obstruction. It also may be associated with intermittent severe colicky abdominal pain, a palpable mass, and vomiting.

CYSTIC FIBROSIS LIVER DISEASE

Infants may have cholestasis from abnormally concentrated and sticky bile. Fatty infiltration of the liver may be seen, but its significance is uncertain. *CFTR* is expressed in cells of the biliary tract, and plugging of the small intralobular ducts, periductal inflammation, and fibrosis can occur. *Focal biliary cirrhosis* is the most common feature of CF liver disease but is difficult to detect. Autopsy studies suggest that cirrhosis is present in up to 70% of adults with CF. Approximately one third of patients have abnormal liver function tests, but the presence of abnormality does not correlate well with the presence or extent of liver disease. Hepatocellular function is generally preserved. Focal biliary cirrhosis progresses to multinodular cirrhosis and portal hypertension in 5% of patients.

Liver disease is a life-limiting factor in only a few patients, and liver transplantation is rarely indicated, because hepatocellular failure is rare. A small, poorly functioning "microgallbladder" is typically found, and cholesterol gallstones develop in up to 10% of patients with CF. Choledocholithiasis is less common. Ursodeoxycholic acid can normalize elevated liver enzyme levels, but its long-term effect on the evolution of liver disease remains largely unproved.

CYSTIC FIBROSIS–RELATED DIABETES

Langerhans cell function is initially retained, and diabetes mellitus is rare in the first decade of life in patients with CF. The prevalence of glucose intolerance and diabetes mellitus rises continuously with increasing age, and 25% to 30% of adults with CF and PI will have diabetes requiring insulin therapy. CF-related diabetes (CFRD) shares features of both type 1 and

2 diabetes, with a combination of decreased and delayed insulin secretion, as well as insulin resistance. Glucose intolerance can persist for many years before frank diabetes occurs. Control of diabetes is important to prevent protein catabolism and weight loss. Poorly controlled diabetes may increase pulmonary infections. Most patients will require treatment with insulin. During pulmonary exacerbations, increased insulin resistance can temporarily raise insulin needs three-fold to four-fold. Patients with CFRD with poor blood glucose control develop *micro*vascular complications but rarely show *macro*vascular complications.

MALIGNANCY

A review of CF clinics in North America and Europe found an increased prevalence of GI malignancies in patients with CF. The proposed etiology is the chronic injury and inflammation of the GI tract. The increased risk starts in the third decade of life, and the malignancies are found in all parts of the GI tract (colon, esophagus, small bowel, pancreas, liver, biliary tree). The odds ratio for the risk of digestive tract malignancies in patients with CF is 6.5. Screening is difficult because of the widespread nature of the cancers and overall low prevalence but may be indicated in patients referred for lung transplantation, those with a family history of GI cancers, and those with gastroesophageal reflux disease. (GERD) New GI symptoms should trigger appropriate diagnostic tests.

CYSTIC FIBROSIS–RELATED BONE DISEASE

Adults with CF have evidence of decreased bone density, including osteopenia and osteoporosis, as measured by bone dual-energy x-ray absorptiometry (DEXA). Prevalence of low bone density in adults with CF ranges from 40% to 70%, and up to 50% of adults with severe lung disease who are awaiting transplantation will have osteoporosis. The etiology of the decreased bone density is multifactorial, and both failure of normal bone formation and excessive bone loss occur. Malnutrition, vitamin D and K deficiency, hypogonadism, increased bone loss because of elevated inflammatory cytokines from chronic pulmonary infection, and use of corticosteroids all may play a role in the development of low bone density. It is not completely clear whether DEXA scans predict fracture risk in patients with CF. A consensus report suggests treatment with calcium and vitamin D supplementation, treatment of hypogonadism if present, promotion of exercise, treatment of pulmonary infection, and use of bisphosphonates in patients with osteoporosis, in those receiving corticosteroids, and in those on the transplant list.

Hypertrophic pulmonary osteoarthropathy (HPOA) is a chronic proliferative periostitis associated with digital clubbing. It can cause severe bony pain and swelling, especially in knees, ankles, and wrists. It frequently flares at times of pulmonary exacerbations, improving with treatment of the lung infection. Radiography confirms the typical periosteal new bone formation at the distal ends of long bones.

Episodic arthropathy occurs in 5% to 10% of CF patients and presents as transient episodes of acute swelling and joint pain involving single or multiple, large or small joints. These episodes do not necessarily correlate with pulmonary exacerbations. This is a nonerosive arthropathy and responds to nonsteroidal anti-inflammatory drugs or corticosteroids.

About 1% to 2% of patients with CF develop a cutaneous vasculitis, which on biopsy is a *leukocytoclastic vasculitis.* Systemic involvement is rare. It is usually seen on the lower extremities, and the rash consists of usually painless purpura. This typically resolves spontaneously, and specific treatment is not required.

PROGNOSIS

When CF was first described, the median survival was less than 2 years of age. With improvements in therapy, institution of a high-calorie, high-fat diet to optimize growth and nutrition, and establishment of multidisciplinary CF care centers, survival has steadily improved, with national median survival rates of about 36 to 46 years. CF should no longer be thought of as a pediatric disease; in Canada, for example, greater than 50% of patients with CF are now adults.

A number of factors have been shown to influence prognosis in patients with CF. For many decades a gender gap was noted, with males having better survival. Although this gender-related difference in survival is decreasing, it still exists. The etiology is unclear and does not seem to be related to pulmonary function or nutrition status. Other factors influencing survival in CF include socioeconomic status and presence of chronic infection with *P. aeruginosa* or *B. cepacia* complex.

CONTROVERSIES AND PITFALLS

The advances in treatment options for patients with cystic fibrosis over the past 20 years has been welcome and associated with marked improvements in life expectancy, but also leading to new challenges. Better patient outcomes with slower decline in lung function and better survival have made the outcome measures of previous studies difficult to use. The treatment burden for patients has increased, and lifelong therapy with multiple drugs is now the norm. Testing efficacy of new therapies will be difficult because placebo-controlled trials of one therapy alone are no longer possible. Creative study methodologies will be needed to determine which drugs to use in the day-to-day care of patients with CF at different stages of the disease. It will not be acceptable just to keep adding new therapies, because of both the time burden and the financial cost.

With drugs now becoming available to treat the basic defect, investigators need to determine how much correction of *CFTR* function is needed to prevent the progressive lung disease. Long-term follow-up of patients and use of national registries will help address these questions and will require collaboration between countries to obtain the sample sizes needed.

CONCLUSION

Overall, CF treatment has been one of medicine's success stories, because the increase in life expectancy achieved over the recent decades has been impressive. Although the understanding of the disease process has greatly advanced with the definition of the underlying abnormality, treatment is still largely targeted at the "downstream" consequences of the *CFTR* defect: mucus retention, infection, and inflammation. There is considerable promise that in the near future, therapies will become available that will lead to partial or complete correction of *CFTR* function, as well as more efficient symptomatic therapies. Even if these therapies fail in completely correcting the underlying defect, they may be sufficiently efficacious to prevent clinical deterioration. Thus, cystic fibrosis may continue to be a chronic disease requiring long-term treatment but may cease to be life-shortening.

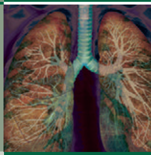
Section 7
AIRWAY DISEASES



Chapter 45
Bronchiectasis

Deborah Whitters • Robert Stockley

Bronchiectasis was first described by Laënnec in 1819 as irreversible dilation and destruction of airways associated with chronic bacterial infection. It is characterized by inflamed and dilated thick-walled bronchi. The clinical features of bronchiectasis include chronic production of often mucopurulent or purulent sputum, persistent bacterial colonization, and recurrent lower respiratory tract infection.

EPIDEMIOLOGY

It is generally believed that the incidence of bronchiectasis has declined since the 1950s, when prevalence in the United Kingdom (UK) was estimated at 100 per 100,000 population, based on mass chest x-ray findings. There are no recent studies in the UK to confirm this belief, and the overall incidence remains unknown. Evidence from other European countries, however, shows a reduction in hospital admissions and new diagnoses of bronchiectasis since the 1970s, attributed to reduced incidence of tuberculosis and more effective treatment of pulmonary infections.

Bronchiectasis remains a significant cause of childhood morbidity in developing countries. Prevalence of non–cystic fibrosis (CF) bronchiectasis in indigenous communities in New Zealand and Australia is reported to be among the highest worldwide, along with Inuit populations of the Northern Hemisphere. Poverty, barriers to medical care (e.g., antibiotic therapy, vaccination), and poor education are contributing factors. Mortality from respiratory disease, including bronchiectasis, is also higher in rural versus urban areas in China; epidemiologic studies are lacking, however, and these populations likely face similar barriers to medical care and therefore antibiotic availability. There are no studies to illustrate the effect of antibiotic therapy or immunization programs on the incidence in countries where it has only recently become available.

PATHOLOGY

The most comprehensive description of bronchiectasis pathology remains that of Whitwell, who examined 200 consecutive resected surgical specimens in 1952. The findings revealed dilated, thickened bronchi, often containing pus with distortion of the bronchial lumen. The inflammatory reaction, visible macroscopically, was shown often to cause complete occlusion of the smaller bronchioles. These findings may be widespread or localized depending on the cause. Microscopically, examination of the bronchial epithelium showed ulceration with granulation tissue in areas where healing had begun. Other specimens had evidence of infiltration of inflammatory cells in the subepithelial tissues and hyperplasia of mucous glands. Supporting connective "elastic" tissues may also be damaged to varying degrees. These features may all be present in varying degrees, in keeping with the varying clinical symptomatology and severity of the disease.

Whitwell classified bronchiectasis into three groups based on pathologic findings—saccular, atelectatic, and follicular—and although these terms may have changed, the descriptions remain the same. *Cylindrical* bronchiectasis is characterized by bronchi showing a regular outline, with dilated airways only and usually ending abruptly. *Varicose* bronchiectasis has similarities to the appearance of varicose veins, with dilation that is deformed by areas of relative constriction. These bronchi also have a distorted and bulbous end. *Cystic* (saccular) bronchiectasis is considered the most severe form of bronchiectasis; its most prominent feature is progressively increasing dilation as the bronchi progress toward the lung periphery and airways, ending in cystlike clusters. These three basic forms of bronchiectasis are demonstrated in **Figure 45-1** by high-resolution computed tomography (HRCT) scanning.

PATHOGENESIS

The cause of non-CF bronchiectasis may only be identifiable in up to 50% of patients. However, a number of recognized conditions and factors are associated with bronchiectasis, and an underlying cause should be assessed in all patients (**Box 45-1**).

The genetic influence on the development of non-CF bronchiectasis is the subject of ongoing research, often on the role of the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene. The most common mutation of this gene, ΔF508 (F508del), is associated with severe CF (see Chapter 44). Numerous other mutations have been identified and associated with a milder clinical phenotype. As a consequence, late first presentation of CF has been described in patients who would otherwise have been considered to have *idiopathic* non-CF bronchiectasis. It is now recognized that mutations of the *CFTR* gene are more frequently observed in patients with bronchiectasis and a normal sweat chloride test than in the general population. Studies show that the spectrum of *CFTR* genotypes is associated with a continuum of *CFTR* dysfunction in the airways. Phenotypes range from patients with bronchiectasis, normal sweat test, and no other features suggestive of CF to those with classic CF. Also, some evidence suggests the *CFTR* mutations are associated with non-CF bronchiectasis and rheumatoid arthritis. Therefore, *CFTR* dysfunction can be identified as a cause of bronchiectasis in patients previously diagnosed with idiopathic non-CF bronchiectasis, but without fulfilling the diagnostic criteria for CF. How this affects patient management is currently unknown.

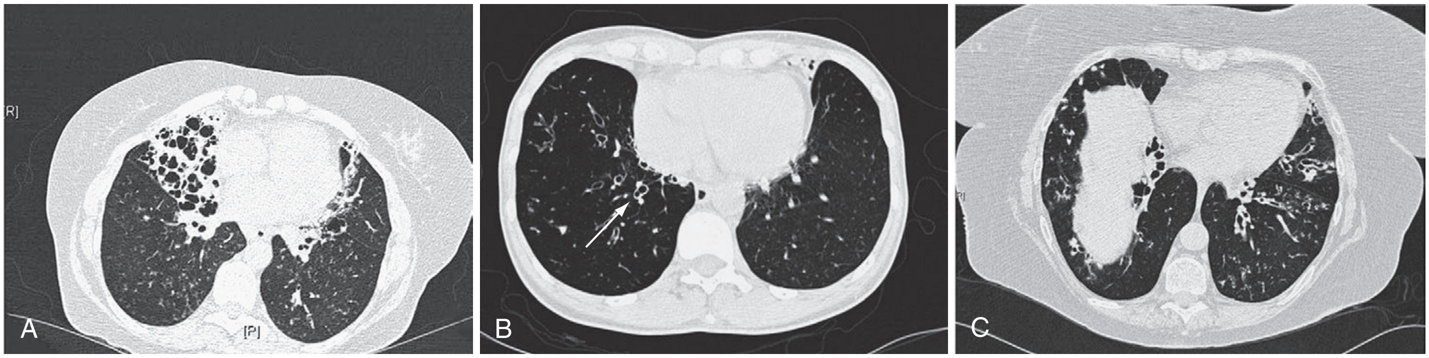


Figure 45-1 **A,** Bilateral *cystic* bronchiectasis. **B,** Moderate *cylindrical* bronchiectasis in right middle lobe, as demonstrated by classic signet ring sign *(arrow)*. **C,** Bilateral severe *varicose* bronchiectasis, more marked on the left side, with associated bronchial wall thickening.

Box 45-1 Underlying Causes of Bronchiectasis

Postinfective Causes
Viral infection (adenovirus, measles, human immunodeficiency virus)
Bacterial infection *(Pneumococcus)*
Mycobacterium tuberculosis
Pertussis (whooping cough)
Allergic bronchopulmonary aspergillosis

Host Immune Defects
Humoral immune deficiency (IgA, IgG, IgM)
Selective IgG subclass deficiency
Specific antibody deficiency
Complement deficiency
Chronic granulomatous disease

Mucociliary Clearance Defects
Primary ciliary dyskinesia
Kartagener's syndrome
Young's syndrome

Other Inflammatory Disease
Rheumatoid arthritis
Inflammatory bowel disease
Chronic obstructive pulmonary disease (COPD)

Miscellaneous
Foreign body inhalation
Middle lobe syndrome
Alpha$_1$-antitrypsin deficiency
Toxic inhalation
Gastroesophageal reflux disease (GERD)
Yellow nail syndrome

Establishing a cause for bronchiectasis depends on an accurate recollection of events by patients, making it difficult to establish a direct cause and effect in most patients. Nonetheless, an infective insult undoubtedly plays a role in establishing and maintaining the pathologic changes seen in bronchiectasis. This is demonstrated by the falling incidence since the widespread use of antibiotic therapy and immunizations in childhood. The role of infection is further emphasized by the association between the immune defects, and therefore increased susceptibility to infection, and the development of bronchiectasis.

The "vicious cycle" hypothesis of bronchiectasis suggests an initial failure or overwhelmed host defenses, leading to a host-mediated chronic inflammatory response, which in turn causes new or further impairment of mucociliary clearance and defenses, amplifying the problem. This interaction between chronic infection and excessive inflammation, which is predominantly neutrophilic, ensures ongoing damage to the airways and the development and maintenance of the features seen in bronchiectasis. Inflammatory mediators such as the neutrophil chemoattractant interleukin-8 (IL-8) and tumor necrosis factor alpha (TNF-α) are found in bronchial mucosal biopsies and secretions from bronchiectatic airways, in addition to tissue neutrophilia. This initiation of the inflammatory reaction results in the recruitment of phagocytes, dendritic cells, and lymphocytes, which contribute to the adaptive response (Figure 45-2).

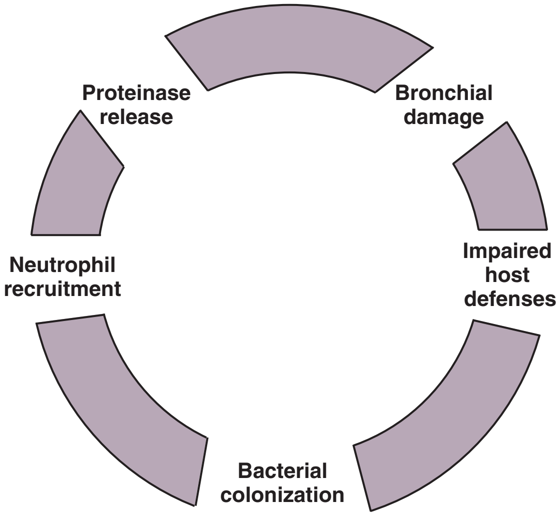

Figure 45-2 Infectious inflammatory cycle of bronchiectasis. Damage to airway results in impaired mucociliary clearance, leading to bacterial colonization, which stimulates neutrophilic inflammation. This not only damages the tissues further, but also disturbs the local immune status, resulting in establishment and maintenance of colonization. Neutrophilic proteinases damage immunoglobulins, reduce antibacterial properties, reduce ciliary beat frequency, and damage airway epithelium, all leading to increased bacterial adherence and retention.

CLINICAL FEATURES

The severity of clinicopathologic events varies widely in patients with bronchiectasis. At the milder end of the spectrum, patients may have occasional exacerbations, with little or no intervening sputum production. Others have frequent exacerbations with chronic production of purulent sputum, even in the stable state. Symptoms can include *hemoptysis,* especially during exacerbations, and *breathlessness,* characterized by mild to moderate airflow obstruction, lethargy, and reduced health status. Hemoptysis may be only a minor problem, although erosion of mucosal neovascular arterioles during an acute exacerbation can result in massive hemoptysis. Quantitative analysis of HRCT scanning in bronchiectasis shows that the airflow obstruction is primarily linked to disease of small and medium-sized airways and not to bronchiectatic abnormalities in large airways, emphysema, or retained endobronchial secretions. Nonspecific chest pain varying in severity is also reported with increased frequency in bronchiectatic patients.

CLINICAL SIGNS

Finger (digital) clubbing has long been recognized as a sign of chronic suppurative lung disease. Despite previous reports of being frequently encountered in bronchiectasis, clubbing is much less common in more recent studies, perhaps because of a lower threshold for diagnosis of bronchiectasis. Studies report that the prevalence of clubbing is 1% to 2%, both in patients who develop symptoms as adults or in childhood and in adult patients. Overall, this suggests that finger clubbing is now seen only in a minority of patients with non-CF bronchiectasis.

The characteristic clinical finding in bronchiectasis is *coarse crackles* heard on auscultation, consistently reported in up to 73% of patients in more recent studies. Interestingly, an in-depth study of the phenotypes of bronchiectasis found the frequency of crackles to be much less in patients with adult onset of the symptom of chronic productive cough than in those with childhood onset of symptoms (20% vs. 64%). This difference was also associated with a greater amount of sputum production in the childhood-onset group. The crackles typically heard in bronchiectasis occur in the early and middle phases of inspiration, fading by the end of inspiration. Crackles also are usually present at expiration, which differentiates these from the finer crackles in alveolitis or chronic obstructive pulmonary disease (COPD). Although crackles are profuse, this may be reduced with coughing and expectoration. The location and extent of the crackles on physical examination, however, does not necessarily relate to the extent or area of distribution of bronchiectasis on the CT scan.

DIAGNOSIS AND PATIENT ASSESSMENT

RADIOLOGY

Chest radiography is often the first imaging modality used to investigate patients with suspected bronchiectasis. However, radiographs are insensitive as a diagnostic tool for bronchiectasis and suggest the diagnosis in less than 50% of cases in some studies. There is also little evidence for the use of chest radiographs in monitoring patients with bronchiectasis with no change in symptoms.

HRCT is the radiologic modality of choice for establishing the diagnosis of bronchiectasis, although its reported sensitivity and specificity vary. It is difficult to assess fully the accuracy of HRCT in diagnosing all patients with bronchiectasis, but it is believed to be highly specific for the diagnosis of moderate or severe disease. However, the features of early bronchiectasis with bronchial wall thickening are also seen in other conditions (e.g., COPD, asthma), suggesting its specificity is less for frank bronchiectasis. Furthermore, a comparison of thin-section CT with bronchography demonstrated that although bronchial wall thickening is often seen, bronchography shows this is not always bronchiectatic in origin. The increasing use of multidetector CT scanners, which allow for greater variance in section thickness compared to standard HRCT (sections obtained only at 10-mm intervals), may lead to improved detection of bronchiectasis, although this has yet to be assessed for early disease. However, this must be weighed against an increased radiation burden, and at present, standard HRCT remains the recommended investigation for the diagnosis of bronchiectasis.

Box 45-2 Diagnostic Testing in Patients with Bronchiectasis

Investigation
Nonspecific inflammatory markers (WBC count, ESR, neutrophils, CRP)
Serum immunoglobulins
Serum electrophoresis
Functional antibodies
Total IgE, specific IgG to *Aspergillus*

In Some Patients
IgG subclasses
Rheumatoid factor
Alpha$_1$-antitrypsin levels
Cystic fibrosis screening

CRP, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *IgE*, immunoglobulin E; *IgG*, immunoglobulin G; *WBC*, white blood cell.

BLOOD TESTS

Inflammatory markers include white blood cell (WBC) count, neutrophil count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) and can be used as nonspecific tests of disease activity and exacerbation severity. These tests can also be used to guide the need for and response to antibiotics in the absence of changes in clinical state or symptomatology of bronchiectatic patients (Box 45-2).

IMMUNOGLOBULINS

Immunoglobulins (IgA, IgG, and IgM) are often elevated in a significant proportion of patients with bronchiectasis, which reflects chronic bronchial infection. *Hypogammaglobulinemia* as a recognized cause of bronchiectasis and antibody deficiency or an inadequate antibody response has been reported in 8% of patients in a large study into causative factors in bronchiectasis. This supports the need for antibody levels (IgA, IgG, IgM) to be checked in patients because they may influence treatment. The role of IgG subclasses is less clear because normal ranges for each subclass have been difficult to establish, and absence or deficiency of a subclass can be found in otherwise healthy individuals, as can IgA deficiency. The inability to produce a response to immunization with a polysaccharide antigen despite normal levels of serum immunoglobulin also suggests a causative but specific immunodeficiency.

Current guidelines recommend that evaluation of antibody deficiency in bronchiectasis should include a universal or targeted assessment of a specific baseline antibody response to peptide and polysaccharide antigens. Routinely, tetanus toxoid, *Streptococcus pneumoniae* and *Haemophilus influenzae* type B are used. If these are low, immunization should occur with the appropriate antigen and levels should be remeasured approximately 21 days later. Whether a response affects the subsequent clinical course remains unknown, and in some cases seems illogical, especially as the *H. influenzae* lung infections are nontypeable *H. influenzae*, not type B.

Allergic bronchopulmonary aspergillosis (ABPA) has been recognized as a cause of bronchiectasis, usually affecting atopic patients and caused by an allergy to *Aspergillus* species. The proximal bronchiectasis, usually affecting the upper lobes, associated with *Aspergillus* is IgG and type 3 immune reaction–related. When ABPA is clinically suspected, elevated total blood eosinophils and IgE suggest an allergic response. Specific IgE in addition to precipitating IgG to *Aspergillus* should be checked.

Rheumatoid factor (RF) is also found to be elevated in some patients in isolation and is a nonspecific finding. However, high RF values can be important in some patients, related to a true arthritic etiology and small airways disease. Nonspecific arthralgia can also be a feature of the exuberant inflammatory reaction related to airway colonization. Treatment of the arthritis or bacterial load can lead to improvement in the related feature.

Alpha$_1$-antitrypsin levels should be guided by clinical suspicion of bronchiectasis, as should genetic testing for CF or its variants (Box 45-2).

MUCOCILIARY FUNCTION

Mucociliary function is assessed in adult patients with suspected *primary ciliary dyskinesia* (PCD). This needs consideration in patients with a history of chronic rhinitis, sinusitis, otitis media, neonatal respiratory symptoms, or situs inversus viscerum (a feature of only 50% of patients with PCD). Male infertility and subfertility in females are also features. PCD is best assessed using the saccharin method or nasal nitric oxide measurements as first-line investigations. Cilia can be obtained for direct examination in patients who require further investigation when these initial investigations are abnormal, although secondary abnormalities can be found in the nasal and bronchial tissues, especially in the patient with chronic infection in the region tested.

NEUTROPHIL FUNCTION

Neutrophil-dominant inflammation is a central feature in bronchiectasis. Neutrophils aggregate quickly at the site of infection. Phagocytosis occurs when the neutrophil moves in response to chemotactic stimuli to the site of bacterial colonization or infection. In particular, leukotriene B$_4$ (LTB$_4$) and IL-8 are major chemoattractants identified, with IL-8 playing a crucial role during acute exacerbations.

The granule proteins of the neutrophil release antibacterial proteins and cytolytic enzymes on activation. Excessive degranulation and activity of cytolytic enzymes such as myeloperoxidase and elastase have been implicated most in host tissue damage and thus may be central to the establishment or amplification of the vicious cycle. The neutrophils also produce reactive oxygen species (ROS) directed at bacterial killing. The release of uncontrolled ROS by neutrophils, however, may also lead to damage to the surrounding tissues, again exacerbating the lung-destructive process. With the genetic defect of chronic granulomatous disease, patients develop a variety of inflammatory complications, including bronchiectasis, as a result of an exaggerated inflammatory response; are unable to produce ROS; and manifest recurrent life-threatening bacterial infections and granuloma formation.

Tests of neutrophil function are not routinely performed in patients with bronchiectasis. However, some studies of immune function have shown oxidative burst to be lower in patients with bronchiectasis. The significance of this abnormality remains to be identified.

Table 45-1 Organisms Isolated in Bronchiectasis

Organism	Frequency
Haemophilus influenzae	14%-35%
Pseudomonas aeruginosa	9%-31%
Staphylococcus aureus	0%-14%
Streptococcus pneumoniae	2%-13%
Moraxella (Branhamella) catarrhalis	0%-20%
Possibly “nonpathogenic organisms” *Corynebacterium* spp., *Neisseria* spp., coagulase-negative *Staphylococcus*, β-hemolytic *Streptococcus*	5%-60%

SPUTUM MICROBIOLOGY

An assessment of lower respiratory tract microbiology is imperative in the investigation and management of bronchiectasis. Table 45-1 summarizes the most common organisms isolated from the respiratory tract and their frequency in adults with bronchiectasis.

Bronchiectasis is associated with frequent bacterial colonization of the airway. As such, patients, even in the stable state, often produce sputum daily as part of the host defense response. Sputum may be mucopurulent to purulent in appearance, dependent on the neutrophil content. Development or increasing purulence of sputum is often indicative of a bacterial exacerbation. Purulent sputum color can be graded visually and is associated with activity of the underlying markers of bronchial inflammation, such as myeloperoxidase, IL-8, and leukocyte elastase. These factors are central in the ongoing neutrophil-derived inflammation, which, when overexuberant or ineffective, can impair even the competence of lung defenses. Patients with purulent sputum are more frequently found to be colonized than those with persistently mucoid sputum.

The role of quantitative bacterial culture has been important in establishing increased airway inflammation and exacerbation in patients with chronic sputum production. An increase in the bacterial load of more than 10^6 colony forming units (CFUs) is associated with increasing airway neutrophils and inflammation, with a reduction in bacterial load as the exacerbation resolves. Similarly, even in the presence of a background of 10^6 organisms, a further increase in the load may be confirmatory of a change in the bronchiectatic patient’s clinical status, requiring intervention even in the absence of other clinical or biochemical markers.

Therefore, identification of colonizing organism is important in patients with bronchiectasis, but quantitative microbiology remains a vital tool for identifying exacerbation status and is a surrogate marker of inflammation that correlates with degree of sputum purulence. Although clinically useful, this is not routinely employed and requires further study and validation.

EXACERBATIONS

ACUTE EXACERBATION

As discussed earlier with microbiologic identification of bronchiectasis exacerbation, presence of bacteria alone does not necessarily indicate an exacerbation requiring antibiotic therapy, in view of the prevalence of colonization in the stable clinical state. A worsening of symptoms from baseline and acute deterioration with a change in bacterial load, however, indicate the

Box 45-3 Features Suggestive of Exacerbation in Bronchiectasis

Change in sputum production (volume, viscosity, or color)
Increasing cough
Increasing dyspnea
Increasing wheeze
Malaise, fatigue
Decreased exercise tolerance
Fever
Decreased pulmonary function (10%)
Radiographic changes indicative of acute process
Change in chest sounds from baseline

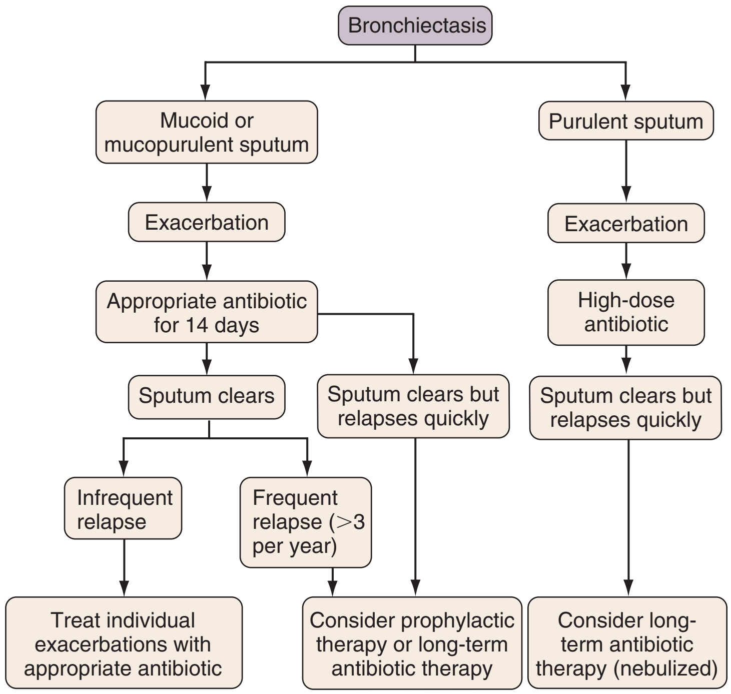
need to introduce or add further antibiotics. Box 45-3 lists other symptoms suggestive of an acute bacterial exacerbation.

A review of previous microbiology, and thus any change from the stable state, is essential before initiating antibiotic therapy, and ideally, sputum should be obtained for culture, preferably before antibiotic therapy, to guide antibiotic choice.

RECURRENT EXACERBATION

Patients with frequent exacerbations may require longer-term antibiotic therapy. The principle of treatment is to reduce the microbial load and thereby modulate the persistent inflammation characteristic of bronchiectasis, that is, an attempt to break the vicious cycle of bronchiectasis previously described. The aim is to improve the symptoms and subsequent poor health status and quality of life for these patients and reduce the number of exacerbations. The generally accepted cutoff for considering long-term antibiotic therapy is more than three exacerbations in 1 year. This particularly applies to patients colonized with *Pseudomonas aeruginosa*, which is associated with more hospital admissions, poorer quality of life, and more rapidly declining lung function.

Pseudomonas aeruginosa frequently persists in the airways of patients with bronchiectasis after its initial isolation. One feature of *P. aeruginosa* that enhances its ability to colonize the lungs is its ability to form biofilms. A *biofilm* is a community of bacterial cells irreversibly attached to a surface or each other and embedded in a matrix of extracellular polymeric substance (EPS). Existing in biofilms enhances the ability of bacteria to colonize and to evade antimicrobial therapies, thus making it difficult to eradicate these organisms from the lungs of chronically infected patients. The formation of biofilms is multifactorial, but one influential bacterial behavior is *quorum sensing*, a complex cell-to-cell signaling mechanism well characterized in *P. aeruginosa* that modulates bacterial functions, including metabolism, expression of virulence factors, and biofilm formation. This ability to regulate bacterial behavior also enhances the ability of *P. aeruginosa* to invade and colonize the host. Because this pathogen frequently colonizes the lungs of patients with bronchiectasis, its significance in this condition merits further investigation.



Bronchiectasis
Mucoid or mucopurulent sputum
Purulent sputum
Exacerbation
Exacerbation
Appropriate antibiotic for 14 days
High-dose antibiotic
Sputum clears
Sputum clears but relapses quickly
Sputum clears but relapses quickly
Infrequent relapse
Frequent relapse (>3 per year)
Treat individual exacerbations with appropriate antibiotic
Consider prophylactic therapy or long-term antibiotic therapy
Consider long-term antibiotic therapy (nebulized)

Figure 45-3 The degree of purulence of stable-state sputum must be considered when treating bronchiectasis exacerbation. Patients who relapse quickly or frequently (>3 times in 1 year) with mucoid or mucopurulent sputum are usually managed with short courses (10-14 days) of appropriate antibiotics but may need longer-term preventive therapy. Patients with chronic purulent sputum usually require higher-than-conventional doses of antibiotics and would have a lower threshold for consideration of long-term nebulized antibiotic therapy.

Furthermore, the clinical problems associated with *P. aeruginosa* may be further exacerbated by the development of antibodies that reduce bacterial killing. Studies in the 1970s and 1980s of CF patients colonized with *P. aeruginosa* identified a blocking factor in serum that inhibited killing of *Pseudomonas*, subsequently shown to be an IgG_2 subclass. Recent work supports the role of inhibitory antibodies in the ability of other bacteria to establish infection within the host. This may partly contribute to the failure of the host to control infection, and although the role of this mechanism has yet to be established in bronchiectasis, it is worthy of study. However, this ability of organisms to survive will establish ongoing inflammation as a frustrated attempt by the host to eradicate them, leading to proteolytic damage and perpetuation of the vicious cycle illustrated in Figure 45-2. For these reasons, patients should receive longer-term antibiotic therapy as appropriate, if the cycle can be broken (i.e., sputum purulence disappears).

ANTIBIOTIC THERAPY

Figure 45-3 provides a decision-making algorithm for antibiotic therapy of the patient with bronchiectasis.

PATIENT WITH ACUTE EXACERBATION

Prompt antimicrobial therapy is required once an acute exacerbation is identified, guided by the most up-to-date microbiology results and local guidelines. There are not randomized, placebo controlled trials evaluating the effectiveness of antibiotics in exacerbations in bronchiectasis, but in general high-dose, targeted antibiotics are required for effective treatment. The British Thoracic Society guidelines recommend that many patients with bronchiectasis should receive 14 days of antibiotics rather than the conventional dose. The antibiotics most often used for exacerbations have a broad spectrum of activity. Amoxicillin remains the initial choice for many organisms, especially in the UK, but patterns of resistance need to be recognized and management adapted appropriately. *H. influenzae* is usually sensitive to amoxicillin, but the production of

Table 45-2 Antibiotic Guidelines for Bronchiectasis Exacerbation

Organism	Antiobiotic/Dose
Streptococcus pneumoniae β-lactamase –ve *Haemophilus influenzae*	Amoxicillin 500 mg three times daily orally (higher doses may be required in some patients)
β-lactamase +ve organisms *Moraxella catarrhalis* *H. influenzae*	Co-amoxiclav (amoxicillin-clavulanate), 625 mg three times daily orally
Staphylococcus aureus	
Methicillin sensitive	Flucloxacillin, 500 mg three times daily orally
Methicillin resistant	Trimethoprim, 200 mg twice daily orally + Rifampicin (based on weight) orally
Pseudomonas aeruginosa	Ciprofloxacin, 500 mg twice daily orally (750 mg twice daily in severe cases) Patient may require intravenous (IV) therapy. Ceftazidime Piperacillin + tazobactam Aztreonam Meropenem *May be combined with:* Gentamicin Tobramycin Colistin

β-lactamase or changes in penicillin-binding proteins increase resistance, and the presence of resistant strains varies from country to country. *Moraxella (Branhamella) catarrhalis* also produces β-lactamase. Antibiotic choices based on current UK guidelines are shown in Table 45-2, but local guidelines should be considered.

The decision to give high-dose antibiotics instead of conventional doses is based on clinical judgment and the patient's usual stable state. Those who usually produce purulent sputum in the stable state will often require a higher dose to elicit a clinical response. Furthermore, patients who fail to respond to a conventional dose of antibiotic with an apparently fully sensitive organism may respond only to a higher dose. The failure of sputum to clear (become mucoid) or the occurrence of rapid relapses (within days) indicates a need to consider longer-term therapy. However, the antibiotic regimen should be reviewed early (within 7 days) in patients receiving antibiotics who appear to be failing to respond and in whom sputum remains purulent.

LONG-TERM THERAPY

Long-term antibiotic therapy, either oral or nebulized (inhalational), are considered in patients who exacerbate frequently or have considerable morbidity as a result of their condition. A systematic review of long-term oral antibiotics failed to demonstrate an effect on lung function or exacerbation frequency, although symptoms were improved. Oral antibiotic therapy after detailed assessment of microbiology results most often uses amoxicillin, amoxicillin-clavulanate (co-amoxiclav), and flucloxacillin. These are used at lower than the standard dose for an acute exacerbation and only with caution. Long-term quinolones alone are not used because of the high risk of resistance in patients colonized with *P. aeruginosa*.

Long-term inhalational (nebulized) antibiotics are used more often because of the low risk of systemic side effects, most frequently in patients chronically colonized with *P. aeruginosa*. Bacterial sensitivities should be assessed before initiation of long-term therapy. Nebulized colistin is often used in patients with *P. aeruginosa* colonization and has been associated with increased quality of life and slower decline in forced expiratory volume in 1 second (FEV_1). However, there remains a paucity of specifically designed studies of colistin in patients with bronchiectasis. Gentamicin and tobramycin are associated with reduced microbial load, and in some cases, tobramycin has been shown to eradicate *P. aeruginosa*. In other patients, however, tobramycin has been associated with significant side effects, precluding its continued use.

PROPHYLACTIC THERAPY

Some antibiotics are used for their potential immunomodulatory properties and ability to mediate the host inflammatory response. *Macrolides* are the most common of these antimicrobials used in clinical practice, although their benefits require further study. Azithromycin, twice weekly for 6 months, has shown positive results, with reduced 24-hour sputum volume and reduced number of exacerbations. Earlier results with erythromycin showed similar effects. However, significant side effects are associated with macrolides, and therefore their long-term use also requires further assessment. Their beneficial effect is thought to result from both their immunomodulatory effect and their inhibitory actions on biofilm formation.

VACCINATION

In keeping with most accepted guidelines, patients with bronchiectasis are routinely vaccinated against influenza. However, no trials provide evidence for or against this intervention or for its role in decreasing the severity or frequency of respiratory exacerbations or decline in lung function. Similarly, evidence is minimal regarding the pneumococcal vaccine, although limited data do support the use of 23-valent pneumococcal vaccine as routine management in adults with bronchiectasis.

ALTERNATIVE THERAPY

As discussed, the role of the neutrophil in bronchiectasis is central to maintaining the inflammation and continued destructive processes of bronchiectasis. Therefore, therapies targeting the actions of the neutrophil provide a potential alternative to conventional therapies. Chemoattractants are required to enable migration of the neutrophil in the airways, and IL-8 is particularly important during exacerbations. The increased activity of IL-8 is associated with increasingly purulent sputum, suggesting cause and effect. With antibiotic therapy, the chemotactic activity decreases as the purulence resolves. However, although targeting this process may be a potential therapeutic option in reducing neutrophilic lung damage, neutrophil recruitment clearly is also necessary as a component of the normal response to infection.

Therefore, modulating this process requires further careful investigation, as would abrogation of the other chemoattractants (e.g., LTB_4). Neutrophil-derived proteinase activity, particularly that of neutrophil elastase, is also crucial in maintenance of inflammation in chronic lung disease and the ongoing destructive process. This is normally counteracted by the actions of antiproteinases (SLPI, α_1-antitrypsin), but overwhelming this central mechanism leads to the ongoing lung destruction. Sputum elastase activity appears to correlate with disease activity, severity, and other inflammatory markers, even in stable-state bronchiectasis. Antielastase therapy may therefore also provide a theoretic disease-modifying therapy for this condition. Indeed, studies of such an approach in CF patients show potential beneficial effects (see Chapter 44).

PHYSIOTHERAPY

It is generally accepted that patients with bronchiectasis should be referred for chest physiotherapy and instruction in chest clearance techniques. Despite minimal evidence to define which patients will benefit or the efficacy of many current interventions, an airway clearance regimen is important in the clinical management of patients with sputum production in the stable state, although no data are available on exacerbations. Further research is required into establishing any true benefits of airway clearance techniques.

MANAGEMENT

SURGERY

With the advent of the antibiotic era, surgery with the aim of symptomatic relief or cure of bronchiectasis is rare. Current indicators for surgery include severe symptoms unrelieved by usual medical management, lung abscess, or major hemoptysis (see Complications). Removal of a segment or lobe would be considered, especially if a proximal obstruction is leading to distal disease. In principle, however, the bronchiectasis should be localized rather than diffuse, and because many patients tend to have multiple segments of the lung affected, “cure” is not possible by limited resection. Perioperative mortality is reported to be low.

TRANSPLANTATION

Lung transplantation has become an option for end-stage lung disease, but data are sparse regarding non-CF bronchiectasis. In general, the guidelines that apply to CF patients are used in patients with non-CF bronchiectasis. General guidelines suggest considering transplantation in patients with FEV_1 of less than 30% predicted, or respiratory deterioration despite maximal medical intervention. Factors such as massive hemoptysis, severe pulmonary hypertension, recurrent admissions, and respiratory failure are all indicators to consider a transplant option.

COMPLICATIONS

HEMOPTYSIS

Hemoptysis occurs in bronchiectasis as a result of erosion of neovascular arterioles and is reported frequently, especially during exacerbations. The definition of massive hemoptysis remains unclear and is thus a subjective term. Many studies use a definition of greater than 200 mL of blood-tinged sputum in 24 hours, which is associated with hemodynamic instability of the patient, or a significant fall in hematocrit during the episode. However, hemoptysis is associated with mortality greater than 50% and requires prompt and appropriate management. Following stabilization of the patient, percutaneous bronchial artery embolization has been shown to be a safe and effective treatment at controlling hemoptysis in non-CF bronchiectasis. In the event that this is not possible, consideration of surgical intervention is recommended.

Patients with bronchiectasis experience frequent exacerbations and thus are more often subject to the complications associated with respiratory infection, such as pneumonia, empyema, and lung abscess.

RESPIRATORY FAILURE

Respiratory failure and cor pulmonale still occur in severe bronchiectasis. These patients should be treated conventionally, including long-term oxygen therapy (LTOT) and diuretics, in accordance with guidelines.

There is little information on the use of noninvasive ventilation (NIV) either in the acute setting or in the longer term for bronchiectatic patients in respiratory failure. A study of survival in 48 patients admitted to the intensive care unit included those receiving NIV (13) and those who required intubation (26). There was a 19% mortality associated with the first episode of respiratory failure in patients with bilateral bronchiectasis, with mortality of 40% at 1 year, similar to that with COPD. The population studied was at an advanced stage of bronchiectasis, with severe impairment of lung function, frequent use of LTOT, and a high rate of colonization with *P. aeruginosa*, although this alone was not associated with reduced survival. There is a possible overlap with COPD in this group, and although intubation may have been associated with a reduced survival, this likely represented a more severely affected group, making interpretation of the success of NIV in the acute setting less clear. Age and LTOT were also associated with decreased survival.

Comparison of LTOT alone versus that with home nasal mask ventilation in patients with diffuse bronchiectasis and chronic respiratory failure failed to demonstrate an additional benefit on arterial blood gases and survival, although it did reduce hospitalization and improve functional status. Other studies, however, have failed to demonstrate this decrease in hospitalization.

PROGNOSIS

The overall prognosis for patients with bronchiectasis is good, even with a significant risk of mortality at the severe end of the disease spectrum. However, most of the information regarding the prognosis of bronchiectasis is based on a 1990s study in Finland. The prognosis for bronchiectatic patients treated in the hospital was better than that for age-matched and gender-matched COPD patients, but poorer than matched asthmatic patients. Bronchiectasis was the primary cause of death in 13% of bronchiectatic patients.

For patients admitted to the hospital with an acute exacerbation of bronchiectasis, factors associated with an increased mortality risk include male gender, increased creatinine, decreased FEV_1, need for mechanical ventilation, history of smoking, and need for systemic steroids during hospitalization. A U.S. review of mortality in patients admitted with acute exacerbation of bronchiectasis found 9% mortality during admission and 30% at 1 year, with median survival of 46.6 months.

CONTROVERSIES AND PITFALLS

The increasing frequency of HRCT scanning has made it apparent that radiologic changes associated with bronchiectasis are present in a large proportion of patients with COPD. Whether this represents the same pathophysiologic process as in patients with classic non–cystic fibrosis bronchiectasis remains to be determined and will subsequently guide the appropriate treatment for these patients. Furthermore, the experience of successful CF therapies failing (or being detrimental) in patients with non-CF bronchiectasis means that evidence for their use cannot simply be extrapolated. The role of quantitative microbiology, long-term antibiotics, immunization strategies, and mechanical therapies remains based largely on expert opinion rather than evidence. Further studies and clinical trials in patients with non-CF bronchiectasis need to be undertaken.

CONCLUSION

Bronchiectasis is a chronic disease characterized by chronic sputum production and bacterial colonization, regardless of the underlying cause, which should be identified. Conventional management as well as alternative therapies are used to break the vicious cycle that underlies bronchiectatic pathophysiology. Increased understanding of the mechanisms that enhance the ability of bacteria to colonize the lungs of patients with bronchiectasis will also help elucidate the many factors that initiate and perpetuate the damage to the lungs and subsequently to the host defenses.

Section 8
PARENCHYMAL LUNG DISEASES

Chapter 46
Approach to Diagnosis of Diffuse Lung Disease
Athol Wells

The term *diffuse lung disease* (DLD) includes infiltrative lung processes that involve the alveolar spaces or lung interstitium. This definition is fundamentally unsatisfactory because it groups together a variety of diverse disorders, some of which, such as cryptogenic organizing pneumonia, are not actually "diffuse," but rather patchy and sometimes limited in extent. Furthermore, many secondary infiltrative abnormalities, including bacterial infection and malignancy, are excluded, whereas others, such as pulmonary involvement in *connective tissue disease* (CTD), are retained in most DLD classifications. The DLDs are grouped for historical reasons; in early series, DLDs presented most frequently with widespread clinical and chest radiographic abnormalities. However, with increasing clinician awareness of possible DLD, the diagnosis is often made when chest radiographic findings are limited, or disease is apparent only on high-resolution computed tomography (HRCT).

The diagnostic difficulties resulting from the multiple disorders within the DLDs are exacerbated by semantic confusion. Synonymous terms abound for some of the more frequently encountered DLDs, such as the following:

- Cryptogenic organizing pneumonia (bronchiolitis obliterans organizing pneumonia, proliferative bronchiolitis)
- Idiopathic pulmonary fibrosis (cryptogenic fibrosing alveolitis)
- Hypersensitivity pneumonitis (extrinsic allergic alveolitis)

This problem has been partially addressed by the reclassification of the *idiopathic interstitial pneumonias* by a joint American Thoracic Society/European Respiratory Society (ATS/ERS) international consensus committee, discussed in detail in Chapter 47. However, the term *cryptogenic fibrosing alveolitis* (CFA) continues to cause difficulties. As defined in the ATS/ERS reclassification, CFA is strictly synonymous with *idiopathic pulmonary fibrosis* (IPF). The diagnosis of IPF/CFA now requires the presence of usual interstitial pneumonia (UIP) at surgical biopsy or typical appearances on HRCT, in association with a compatible clinical picture. This represents a radical change; in historical series, various disorders presenting with a clinical picture of IPF were grouped together as IPF/CFA. The entity of "clinical CFA syndrome" is still necessary for epidemiologic studies but should not be viewed as a final diagnosis in clinical practice.

In routine practice, a simplified pragmatic approach to diagnosis of DLD is essential; consideration of a checklist of the more common diseases is often useful. The classification of DLD by their disease burden was addressed most definitively in a study from Bernalillo County, New Mexico, in which the incidence and prevalence of individual DLDs was quantified using a variety of methods (Table 46-1). New cases were estimated to occur in 32 : 100,000 years in males and 26 : 100,000 years in females; thus, although less common than lung infection, malignant disease or obstructive airways disease, the DLDs are responsible for a considerable disease burden. More recent evidence shows an increase in the prevalence of DLD, especially IPF, which inevitably means that the burden of disease has increased further in the previous one to two decades. Moreover, the workload for the respiratory medicine physician is disproportionate because the diagnosis of individual DLDs is often uncertain, despite more intensive investigation than is generally required in obstructive airways disease, malignancy, or chronic lung suppuration.

A consideration of the differential diagnosis of DLD, based on prevalence alone, is merely a starting point, for two reasons. First, clinical information at initial evaluation profoundly alters diagnostic probabilities; therefore a longer checklist of the DLDs, based on the possible underlying cause, is indispensable. Second, the length to which a specific diagnosis is pursued, with particular reference to surgical biopsy, is critically dependent on the importance of discriminating between *likely* differential diagnoses in individual cases. This crucial point is discussed in detail in the concluding section of this chapter.

INITIAL CLINICAL EVALUATION

Even before chest radiography and HRCT findings are considered, a wealth of diagnostic information can be obtained from initial evaluation. A possible underlying cause is often apparent, although environmental and drug exposures occurring many years earlier and apparently limited exposures are often difficult to interpret in isolation. Much information can often be obtained on the longitudinal behavior of disease from the evolution of symptoms, serial chest radiographic data, and less frequently, serial spirometric volumes. Associated systemic disease and prominent airway-centered symptoms both provide useful diagnostic clues. Less frequently, physical examination may serve to broaden the differential diagnosis. In addition to chest radiography and HRCT, certain noninvasive ancillary tests should be performed in select patients, including autoimmune serology, measurement of precipitins, and echocardiography.

Table 46-1 Prevalence and Incidence of Interstitial Lung Diseases in Bernalillo County, New Mexico

Cause	Interstitial Lung Disease (ILD)	Prevalent Cases, *N* (%)	Incident Cases, *N* (%)
Occupational and environmental	Pneumoconiosis	8 (3.1)	—
	Anthracosis	3 (1.1)	—
	Asbestosis	17 (6.6)	15 (7.4)
	Silicosis	8 (3.1)	6 (3.0)
	Hypersensitivity pneumonitis	3 (1.5)	—
Drug/radiation	Drug-induced ILD	5 (1.9)	7 (3.5)
	Radiation fibrosis	1 (0.4)	3 (1.5)
Pulmonary hemorrhage syndromes	Goodpasture syndrome	1 (0.5)	—
	Vasculitis	—	1 (0.5)
	Hemosiderosis	2 (0.8)	—
	Wegener granulomatosis	2 (1.2)	6 (3.0)
Connective tissue disease	Mixed connective tissue disease	2 (0.8)	2 (1.0)
	Systemic lupus erythematosus	6 (2.3)	1 (0.5)
	Rheumatoid arthritis	14 (5.4)	10 (5.0)
	Scleroderma	9 (3.5)	3 (1.5)
	Sjögren syndrome	2 (0.8)	1 (0.5)
	Dermatomyositis, polymyositis	—	1 (0.5)
	Ankylosing spondylitis	—	—
Pulmonary fibrosis	Pulmonary (chronic) fibrosis/postinflammatory	43 (16.7)	28 (13.9)
	Idiopathic/interstitial fibrosis	58 (22.5)	63 (31.2)
	Interstitial pneumonitis	8 (3.1)	12 (5.9)
Sarcoidosis		30 (11.6)	16 (7.8)
Other	Alveolar proteinosis	1 (0.4)	—
	Amyloidosis	—	—

	Lymphocytic infiltrative lung disease	1 (0.4)	—
	ILD, not otherwise specified	29 (11.1)	20 (9.8)
TOTAL		258	202

CLINICAL HISTORY

The identification of an *underlying cause* is the single most important contribution made by clinical evaluation. Table 46-2 provides a checklist of the more important causes of DLD. A careful occupational history is essential and should include details of all previous occupations, including short-term employment. *Asbestos exposure* is often extensive in railway rolling-stock construction, shipyard workers, power station construction and maintenance workers, naval boilermen, garage workers (involved in brake lining), and other occupations in which asbestos exposure is overt; generally, workers in these occupations are well aware of their asbestos exposure. However, other workers, including joiners, electricians, carpenters, and construction workers, who handle asbestos in the form of roofing and insulation material, are often unaware of significant exposure. Other occupations associated with DLD include coal mining (coal worker's pneumoconiosis), metal polishing (hard metal disease), and sandblasting (silicosis).

A careful history will also disclose exposure to organic antigens known to cause *hypersensitivity pneumonitis.* The two most prevalent forms of hypersensitivity pneumonitis are farmer's (harvester's, thresher's) lung disease, in which the offending antigen, thermophilic actinomycetes *(Thermoactinomyces vulgaris)* is contained within moldy hay, and pigeon (bird) breeder's lung disease (bird fancier's lung), in which avian proteins are inhaled by those breeding birds, or more often, those who keep birds as domestic pets. However, a wide range of other exposures also cause hypersensitivity pneumonitis, and particular attention should be paid to molds (often arising in sites of

Table 46-2 Frequently Encountered Diffuse Lung Diseases with Identifiable Underlying Cause

Cause	Differential Diagnosis
Occupational-related or other inhalant-related	
Inorganic	Aluminum oxide fibrosis Asbestosis Baritosis (barium) Berylliosis Coal worker's pneumoconiosis Metal polisher's lung/hard metal fibrosis Siderosis (iron oxide) Silicosis Stannosis Talc pneumoconiosis
Organic	Bird breeder's (fancier's) lung Bagassosis (sugar cane) Coffee worker's lung Farmer's (harvester's) lung Fishmeal worker's lung Malt worker's lung Maple bark stripper's lung Pituitary snuff-taker's lung Mushroom worker's lung Tea grower's lung Tobacco grower's lung
Collagen vascular disease-related	Ankylosing spondylitis Behçet syndrome Dermatomyositis Goodpasture syndrome Mixed connective tissue disease Polymyositis Primary Sjögren syndrome Rheumatoid arthritis Scleroderma Systemic lupus erythematosus
Drug-related	Amiodarone Azathioprine Bleomycin Bromocryptine Busulfan Carmustine Cephalosporins Chlorambucil Cyclophosphamide Cytarabine Gold Lomustine Melphalan Methotrexate Mitomycin Nitrofurantoin Penicillamine Phenytoin Propranolol Sulfasalazine Tocainide
Physical agents/toxins	Cocaine inhalation High-concentration oxygen Intravenous drug use Paraquat toxicity Radiation/radiotherapy
Neoplastic disease	Bronchoalveolar cell carcinoma Lymphangitis carcinomatosis
Vasculitis-related	Churg-Strauss syndrome Giant cell arteritis Wegener granulomatosis
Disorders of circulation	Pulmonary edema Pulmonary venoocclusive disease
Chronic infection	Aspergillosis Histoplasmosis Tuberculosis Parasites, viruses
Smoking-induced	Alveolar cell carcinoma Desquamative interstitial pneumonia Emphysema Langerhans cell histiocytosis Nonspecific interstitial pneumonia Respiratory bronchiolitis (alone and with interstitial lung disease)

water damage); bathroom molds (as in "basement shower syndrome" and "hot-tub lung" are easily overlooked. Hobbies should also be considered (e.g., cheese-maker's lung, winemaker's lung). There are now more than 100 known causes of hypersensitivity pneumonitis, and an up-to-date list (e.g., see Bertorelli et al.) of the 50 more frequent causes of hypersensitivity pneumonitis is highly useful.

A detailed drug history is also essential. The drugs most frequently causing DLD are probably amiodarone, methotrexate (at doses used in CTD), and antineoplastic agents, especially bleomycin. However, a wide variety of other agents (>200 at present) cause DLD, although often in only a small number of patients, and the list increases yearly. Fortunately, an international website is now devoted to drug-induced lung disease (www.pneumotox.com), through which all medications should be routinely checked in patients with DLD.

Other therapeutic modalities causing DLD include radiotherapy and exposure to high concentrations of oxygen (especially in those previously receiving bleomycin). Paraquat ingestion (causing acute or delayed proliferative bronchiolitis), inhalation of crack cocaine or heroin (causing eosinophilic pneumonia, diffuse alveolar hemorrhage, organizing pneumonia or pulmonary edema), and intravenous drug use (causing venoocclusive disease) are also relevant.

Smoking-related DLD is increasingly diagnosed; diseases other than chronic obstructive pulmonary disease caused by smoking include Langerhans cell histiocytosis, *respiratory bronchiolitis associated with interstitial lung disease* (RBILD), desquamative interstitial pneumonia, and nonspecific interstitial pneumonia. Recently, HRCT evaluation has shown that all these processes may coexist in the same patient. Further, both sarcoidosis and hypersensitivity pneumonitis are rare in current smokers. Because RBILD and hypersensitivity pneumonitis often have overlapping clinical and HRCT features, the smoking history is an important discriminator between these two disorders.

Information on likely longitudinal behavior often helps distinguish between acute and chronic disease, because acute infection, heart failure, and disseminated malignancy may all simulate DLD clinically and radiologically. The duration of dyspnea and cough, pattern of symptomatic progression, and previous responsiveness (or nonresponsiveness) to corticosteroid therapy may provide valuable diagnostic clues. Variable dyspnea and cough over several years, responding to steroid therapy, is compatible with hypersensitivity pneumonitis or sarcoidosis, whereas inexorably progressive dyspnea for 2 to 3 years, not responding to steroid therapy, is typical of IPF. Previous chest radiographs may be useful, with unchanging appearances over many years a frequent finding in sarcoidosis, but not in IPF. Previous full pulmonary function tests are seldom available, but serial spirometry may be performed in general practice, because asthma is often suspected when the first symptoms of DLD occur. Thus, useful conclusions may be drawn from the rapidity of decline, or conversely the duration of stability, of spirometric volumes.

Relevant systemic diseases associated with DLD include malignancy (lymphangitis carcinomatosis or multiple metastases) and CTDs complicated by DLD, especially rheumatoid arthritis, systemic sclerosis, systemic lupus erythematosus (SLE), polymyositis or dermatomyositis, and Sjögren syndrome. Lung disease may precede systemic manifestations in all the CTDs (most frequently in polymyositis/dermatomyositis) or may develop concurrently with systemic manifestations. Thus, a full history should include details of arthritis/arthralgia, myositis, skin disorders, Raynaud's phenomenon, and dryness of the eyes or mouth. A subgroup of patients with autoimmune disease who fail to meet formal criteria for an individual disorder are considered to have "undifferentiated connective tissue disease" but may nonetheless develop DLD.

Airway-centered symptoms may help to refine the differential diagnosis. Cough occurs frequently in IPF, but prominent wheeze is more suggestive of hypersensitivity pneumonitis or, less frequently, sarcoidosis. Wheezing is also an important feature of some of the pulmonary vasculitides, especially Churg-Strauss syndrome and occasionally Wegener granulomatosis. Hemoptysis is the most frequent pulmonary symptom at presentation in Goodpasture syndrome; however, the volume is not a good guide to disease severity, because hemoptysis may be trivial or even absent, despite considerable alveolar hemorrhage.

CLINICAL EXAMINATION

Physical examination tends to be less fruitful than the history and HRCT findings in refining the differential diagnosis of DLD. Bilateral predominantly basal crackles on auscultation are a defining feature of IPF and are also common in other forms of idiopathic interstitial pneumonia and asbestosis, but seldom present in sarcoidosis. Digital clubbing is a useful sign strongly indicating IPF or asbestosis; clubbing is rare in sarcoidosis, hypersensitivity pneumonitis, or pulmonary fibrosis associated with connective tissue (except possibly rheumatoid arthritis). However, no diagnostic conclusions can be drawn from the absence of clubbing. Mid- to late-inspiratory "squawks," an underrecognized sign, are strongly indicative of an underlying bronchiolitic disorder, including hypersensitivity pneumonitis, in which the bronchiolitic component may be prominent. Central cyanosis, tachypnea, and pulmonary hypertension are nonspecific findings in end-stage DLD. When pulmonary hypertension is associated with limited DLD, underlying CTD, especially systemic sclerosis and SLE, should be suspected.

DIAGNOSTIC PROCEDURES

BLOOD TESTS

In most cases, specific diagnostic tests for DLD are confined to autoimmune serology and precipitins against organic antigens. Serologic evidence of rheumatoid arthritis and the other major CTDs should be sought in any patient with apparently idiopathic DLD in whom the diagnosis is uncertain. This is particularly important when the diagnosis appears to be cryptogenic organizing pneumonia, because underlying connective disease is common; when present, prognosis is not always good, and prolonged treatment may be required. In the antisynthetase syndrome, characterized by Jo1 antibody positivity, polymyositis or dermatomyositis, and progressive pulmonary fibrosis, lung disease often precedes systemic manifestations. However, although antibodies to extractable nuclear antigens tend to be disease specific, levels of antinuclear antibodies and rheumatoid factor are often moderately increased in idiopathic pulmonary fibrosis and are less useful diagnostically unless titers are greatly elevated.

The presence of *precipitins to organic antigens* increases the likelihood of hypersensitivity pneumonitis but should never be considered diagnostic in isolation. Positive precipitins denote exposure to an antigen, with immune recognition, but alone are not indicative of clinically significant DLD; pigeon and other bird breeders often have avian precipitin positivity without overt lung disease. Moreover, in many patients with convincing exposure histories and a histologic diagnosis of hypersensitivity pneumonitis, the appropriate precipitins are not present; avian antigens, for example, vary between bird species and even between individual birds.

PULMONARY FUNCTION TESTS

Most DLDs are characterized by a restrictive ventilatory defect, a reduction in gas transfer, and variable hypoxia at rest or on exercise. A purely obstructive defect is often present in Langerhans cell histiocytosis and lymphangioleiomyomatosis and is sometimes a feature of fibrotic pulmonary sarcoidosis. A mixed ventilatory defect, which usually denotes an airway-centered component, is often present in hypersensitivity pneumonitis, sarcoidosis, and CTD (in which bronchiolitis or bronchiectasis may coexist with pulmonary fibrosis). Paradoxically, normal lung volumes in association with severe reduction in gas transfer levels are the hallmark of the combination of emphysema and pulmonary fibrosis. The often-cited phenomenon of a marked increase in gas transfer (measured using single-breath techniques) caused by diffuse alveolar hemorrhage is rarely clinically useful because this abnormality persists for only 36 hours after hemorrhage.

The most diagnostically useful pulmonary function pattern is *preservation of gas transfer* in association with *irreversible airflow obstruction*, a combination that points strongly toward intrinsic airways disease (i.e. bronchiolitis) rather than emphysema. However, the pattern of pulmonary function impairment seldom makes a major diagnostic contribution.

CHEST RADIOGRAPHY

With recent attention focused on the diagnostic value of HRCT, it is often forgotten that the plain chest x-ray film provides invaluable information in diffuse lung disease. The chest radiograph points strongly toward a specific diagnosis in some patients. *Sarcoidosis*, the most prevalent DLD encountered in clinical practice, can be diagnosed with confidence from the clinical and chest radiographic features at presentation in many patients. HRCT seldom adds useful diagnostic information in this context.

Several radiographic features have useful positive predictive values (PPVs). The presence of *hilar lymphadenopathy* on chest radiography is particularly strongly predictive of sarcoidosis in the correct clinical context, although the radiographic differential diagnosis includes tuberculosis and malignancy, especially when hilar lymphadenopathy is asymmetric. *Pleural effusions* are an occasional feature of CTD, lymphangioleiomyomatosis, and asbestos-related disease, as well as disease processes that sometimes mimic DLD, including heart failure, infection, and malignancy. The distribution of disease on chest radiography is also diagnostically useful; granulomatous diseases (tuberculosis, sarcoidosis, hypersensitivity pneumonitis) tend to be more prominent in the middle to upper zones, whereas fibrotic diseases (IPF, fibrotic nonspecific interstitial pneumonia, asbestosis) have a predominantly lower-zone distribution.

However, apart from a large subgroup of patients with sarcoidosis, diagnoses based on chest radiography are seldom confident. Chest radiography is sometimes insensitive; in one often-quoted series (Epler et al.), 10% of patients with biopsy-proven DLD had normal chest radiographic appearances. The superior diagnostic accuracy of HRCT over chest radiography has been documented in numerous series, and the increased confidence associated with an HRCT diagnosis is a considerable aid to management. The classification of chest radiographic abnormalities as "nodular, reticulonodular, or reticular" provides relatively little diagnostic information. Predominantly basal *honeycombing* on chest radiography (invariably associated with honeycombing on HRCT) may be diagnostically useful in increasing the likelihood of IPF but is radiographically overt in surprisingly few IPF patients. It is now generally accepted that, except in patients with obvious sarcoidosis, routine HRCT is almost always warranted in DLD, although occasional exceptions exist, including elderly patients with obvious lower-zone honeycombing on chest radiography, indicative of IPF, and patients with long-standing pulmonary fibrosis on serial chest radiography and an obvious underlying cause, such as coal mining.

Two chest radiographic appearances pose particular diagnostic difficulties. *Persistent unexplained multifocal consolidation* has usually been treated unsuccessfully as for community-acquired pneumonia and has a wide differential diagnosis. Serial chest radiography tends to be more useful than HRCT in refining investigation, because the crucial diagnostic distinction lies between *fixed* infiltrates (nonbacterial infection, including tuberculosis, alveolar cell carcinoma, and other malignant processes) and *changing* infiltrates, in which these diagnoses are effectively excluded. However, immunologically mediated diseases, including eosinophilic pneumonia, cryptogenic organizing pneumonia, and vasculitic disorders, may give rise to either fixed or evanescent radiographic abnormalities, and a histologic diagnosis is often warranted. *Diffuse alveolar filling processes* giving rise to widespread air-space consolidation are generally indicative of life-threatening disease. Although this picture may represent DLD (e.g., acute interstitial pneumonitis, acute eosinophilic syndromes, drug-induced pulmonary infiltration), it is essential to broaden the differential diagnosis beyond DLD to include diffuse pulmonary infection, toxic inhalation, severe aspiration, opportunistic infection (especially *Pneumocystis* pneumonia), diffuse alveolar hemorrhage syndromes, mitral stenosis, and most importantly, heart failure. In both these radiographic presentations, successful management often depends on consideration of a wide differential diagnosis from the outset.

HIGH-RESOLUTION COMPUTED TOMOGRAPHY

High-resolution CT has been the most important diagnostic advance in DLD in the last two decades. Numerous studies have confirmed the overall diagnostic accuracy of HRCT against findings at surgical biopsy, with a striking increase in sensitivity and specificity for individual diseases, compared with chest radiography. However, academic series understate the impact of HRCT, because the most important benefit has been to increase clinician confidence in noninvasive diagnosis, with a corresponding reduction in the numbers of patients needing to undergo surgical biopsy. Before HRCT, diagnoses based on clinical data and chest radiographic findings were seldom confident, and management was necessarily tentative in many cases. The combination of clinical and HRCT information now provides a confident first-choice diagnosis in the majority of patients, and in many other cases, the realistic differential diagnosis is shortened to two or three disorders. This allows surgical biopsy to be reserved for patients in whom the distinction between a small group of possible disorders has important management implications and for occasional patients in whom HRCT appearances are not suggestive of any single disorder. Thus, routine surgical biopsy, as a diagnostic "gold standard," can no longer be justified in the HRCT era.

Histospecific diagnosis aside, HRCT sometimes plays an important role in detecting DLD. The superior sensitivity of HRCT over chest radiography has been an invariable finding in studies of a wide range of disorders. This feature of HRCT is particularly useful when symptoms or lung function impairment are associated with normal chest radiographic appearances. In CTD, pulmonary involvement is now the leading cause of death, and early treatment of progressive lung disease is desirable. By identifying limited pulmonary fibrosis, HRCT allows clinicians to select patients requiring more intensive monitoring, even when immediate treatment is not warranted. In workers previously exposed to asbestos, HRCT often discloses pulmonary fibrosis, which is obscured on chest radiography by concurrent pleural disease. However, it should be stressed that the sensitivity of HRCT occasionally creates its own difficulties. When interstitial abnormalities are limited, their clinical significance is sometimes difficult to rationalize; disease evident only on HRCT should not be extrapolated, in terms of natural history and management, to the more extensive disease described in historical clinical series. It is essential that HRCT findings are integrated with other clinical and investigative features and not interpreted in isolation.

The distinction between predominantly inflammatory and predominantly fibrotic disease can generally be made with reasonable confidence from HRCT. Anatomic distortion and reticular abnormalities are strongly indicative of irreversible fibrotic disease, and this is invariably true of honeycomb change (Figure 46-1). Consolidation is usually reversible, although it may occasionally represent dense fibrosis, especially in sarcoidosis. *Ground-glass attenuation* is often more difficult to interpret. In early work, this HRCT sign was shown to identify a substantial increase in the likelihood of significant inflammation, especially in the absence of concurrent reticular abnormalities. However, it is now clear that ground-glass attenuation denotes fine fibrosis in many cases, especially in sarcoidosis and nonspecific

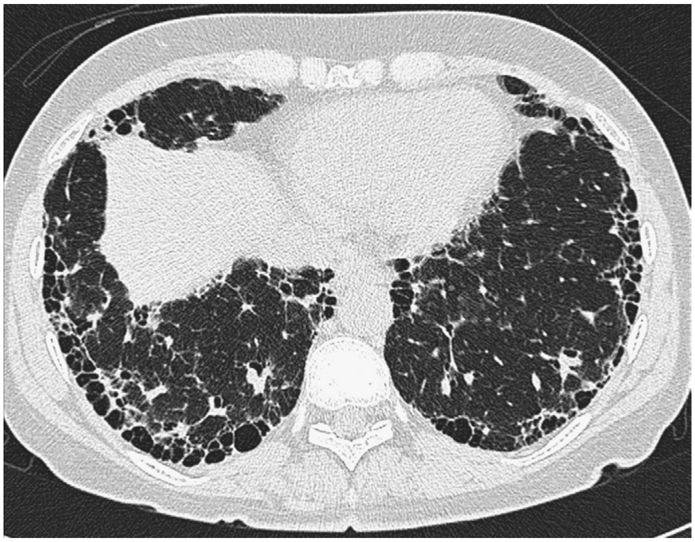

Figure 46-1 High-resolution computed tomography (HRCT) scan in patient with idiopathic pulmonary fibrosis (IPF). There is prominent subpleural honeycombing with no ground-glass attenuation. In the correct clinical context, this image is virtually pathognomonic of IPF.

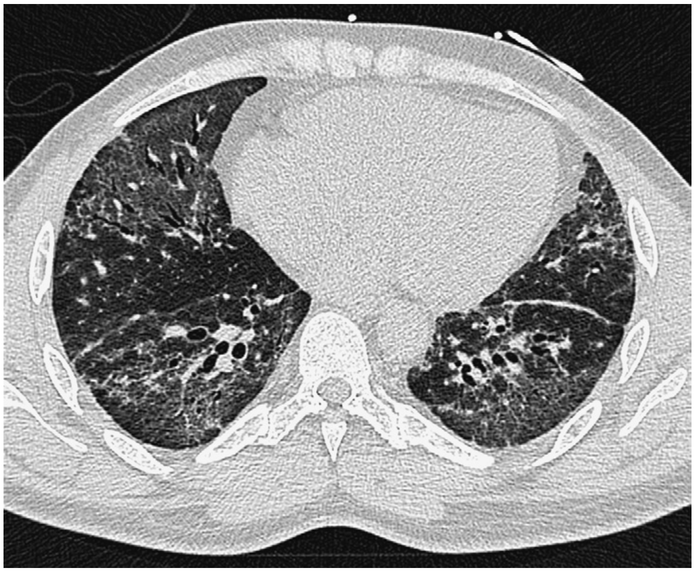

Figure 46-2 HRCT scan in patient with nonspecific interstitial pneumonia. Predominant abnormalities are ground-glass attenuation, with variable admixed fine reticular abnormalities, and traction bronchiectasis. Notably, there is no honeycomb change.

Box 46-1 High-Resolution Computed Tomography (HRCT) Features of Select Diffuse Lung Diseases (DLDs)

Idiopathic pulmonary fibrosis: Lower zone, subpleural predominance, maximal posterobasally, predominantly reticular pattern with associated honeycombing.

Nonspecific interstitial pneumonia: Two typical appearances:

1. Variant that overlaps with idiopathic pulmonary fibrosis in disease distribution: ground-glass attenuation predominates, with a variable fine reticular component and traction bronchiectasis, but no honeycombing.
2. Variant that overlaps with cryptogenic organizing pneumonia: consolidation with surrounding ground-glass attenuation and a variable, fine reticular pattern.

Desquamative interstitial pneumonia: Ground-glass attenuation, sometimes diffuse, sometimes basal and peripheral–centered, frequent associated fibrotic cysts with anatomic distortion and traction bronchiectasis.

Acute interstitial pneumonia: Widespread ground-glass attenuation admixed with features of fibrosis, usually with air space consolidation and occasionally with emphysema.

Respiratory bronchiolitis interstitial lung disease: Patchy ground-glass attenuation, poorly defined centrilobular nodules, occasional mosaic attenuation, prominent bronchial wall thickening.

Sarcoidosis: Highly variable; nodules distributed along bronchovascular bundles, interlobular septae, and subpleurally, including the fissure; ground-glass attenuation that may represent either inflammation or fine fibrosis; reticular abnormalities representing fibrosis; distortion most often in upper zones with posterior displacement of upper lobe bronchus; air trapping; associated hilar and mediastinal lymphadenopathy.

Subacute hypersensitivity pneumonitis: Widespread ground-glass attenuation, often containing poorly defined centrilobular nodules, admixed with areas of “black lung” (mosaic attenuation), representing air trapping and enhanced on expiratory HRCT.

Cryptogenic organizing pneumonia: Bilateral patchy consolidation, subpleural and predominantly basal in most cases; occasional peribronchial distribution; associated, often-sparse nodules up to 1 cm in diameter.

Constrictive bronchiolitis: Patchy areas of hyperlucency enhanced on expiration, which may not change in cross-sectional diameter on full expiration; associated bronchiectasis and bronchial wall thickening.

Langerhans cell histiocytosis: Bizarre cyst shapes and associated nodules throughout the lung fields but sparing costophrenic angles and tips of lingula and middle lobes; associated emphysema often seen.

Pulmonary lymphangioleiomyomatosis: Homogeneously distributed, thin-walled parenchymal cysts, varying from a few millimeters to several centimeters in diameter; associated with retrocrural adenopathy, pleural effusion, thoracic duct dilation, pericardial effusion, and pneumothorax.

interstitial pneumonia, in which ground-glass attenuation is the cardinal HRCT feature (Figure 46-2). *Traction bronchiectasis* is a key HRCT discriminator because it invariably indicates underlying fibrosis. Thus, reversible inflammatory disease is likely only when ground-glass attenuation is not associated with traction bronchiectasis or admixed with reticular abnormalities.

A wide range of HRCT profiles encompassing the distribution and pattern of DLD strongly suggests individual diseases. Box 46-1 summarizes the cardinal findings in common DLDs. As with its other applications, it is essential that HRCT findings be integrated with the pretest diagnostic probability, distilled from the history, clinical signs, previous natural history, or treatment course and the investigative findings, especially chest radiography, pulmonary function tests, and serology for autoimmune disease and environmental antigens. The role of HRCT in diagnosis is critically dependent on the presence or absence of a likely cause. In patients with appropriate environmental antigen or drug exposures (hypersensitivity pneumonitis, pneumoconioses, drug-induced lung disease), malignant disease (lymphangitis carcinomatosis), clinical or serologic evidence of CTD, or a heavy smoking history (Langerhans cell histiocytosis, RBILD), the diagnostic weighting required from HRCT can be reduced. In these contexts, HRCT appearances that are merely compatible (and not classic) often allow a sufficiently confident diagnosis to obviate diagnostic surgical biopsy.

By contrast, as discussed, the diagnostic role of HRCT is much greater in idiopathic disease, but unless the pretest diagnostic probability is high, confident diagnosis requires the presence of typical HRCT appearances. The optimal diagnostic use of HRCT in apparently idiopathic DLD can be distilled in a simple pragmatic algorithm, as follows:

1. The first step is to determine whether HRCT abnormalities are predominantly *fibrotic,* based on the presence of honeycombing, reticular abnormalities, anatomic distortion, or in patients with prominent ground-glass attenuation, the presence of traction bronchiectasis.
2. If disease is fibrotic, as in a large majority of cases, the next important question is whether HRCT findings are typical of *idiopathic pulmonary fibrosis.* As stated in the 2011 American Thoracic Society/European Respiratory Society (ATS/ERS) recommendations, IPF can be diagnosed confidently on HRCT when there is honeycombing with minimal ground-glass attenuation in a predominantly basal and subpleural distribution. It is logical to focus on IPF because it is the most prevalent idiopathic fibrotic disease among patients in whom the diagnosis is not obvious from clinical and chest radiographic findings (most cases of sarcoidosis are diagnosed without recourse to HRCT) (**Figure 46-3**). Further, IPF has a much worse prognosis than other fibrosing processes and therefore is the most important diagnosis to confirm or exclude from the outset. It is now known that HRCT appearances considered typical of IPF by experienced thoracic radiologists have a PPV greater than 95%.
3. If appearances are not typical of IPF, the five most important differential diagnoses (based on prevalence in routine practice) are (a) IPF with atypical HRCT appearances, (b) sarcoidosis, (c) nonspecific interstitial pneumonia, (d) hypersensitivity pneumonitis (with the antigen unknown), and (e) the fibrotic sequelae of cryptogenic organizing pneumonia. Among these, IPF with atypical HRCT appearances is the most prevalent disorder in most populations; up to 30% of IPF patients have atypical HRCT features. Atypical IPF is especially likely when HRCT appearances are not typical of any of the other four disorders (b-e).

The weighting given to HRCT in the diagnosis of DLD varies from case to case but can usefully be considered in three categories. In some patients, HRCT appearances are virtually *pathognomonic;* this includes many cases of IPF, Langerhans cell histiocytosis, sarcoidosis, and lymphangitis carcinomatosis. Often, HRCT findings are *diagnostic* when combined with clinical information. A good example is the combination of widespread ground-glass attenuation (often with poorly defined centrilobular nodules) in combination with mosaic attenuation, which may be strongly indicative of hypersensitivity pneumonitis in nonsmokers with a compatible exposure history but may also represent RBILD in smokers (**Figure 46-4**). Third, even when not conclusive alone, HRCT may be invaluable when considered with *diagnostic surgical biopsy*. The histologic entity of *nonspecific interstitial pneumonia* (NSIP) is found in a variety of clinicoradiologic contexts, including entities overlapping clinically with IPF, fibrosing organizing pneumonia, and hypersensitivity pneumonitis; HRCT evaluation is key to distinguishing among these variants.

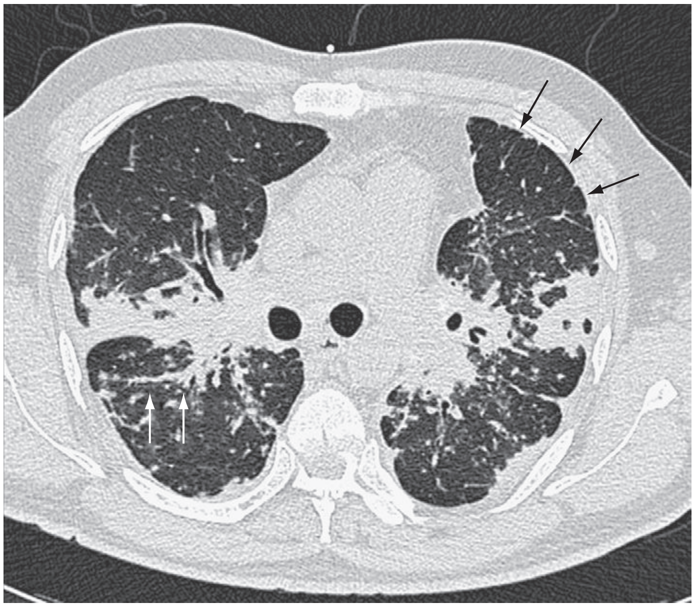

Figure 46-3 HRCT scan in patient with sarcoidosis. Abnormalities suggesting the diagnosis include multiple, well-defined nodules, surrounding bronchovascular beading *(white arrows)*, micronodules (especially in left anterior lung, *black arrows*), septal thickening (by granulomatous infiltration), and areas of dense consolidation, which may be reversible (coalescence of granulomas) or irreversible (fibrosis). This combination of abnormalities is virtually pathognomonic of sarcoidosis.

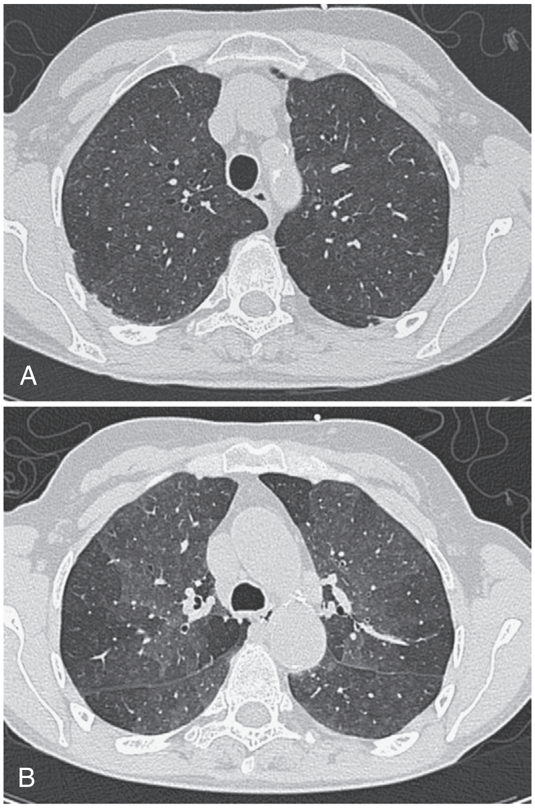

Figure 46-4 HRCT scans in patient with hypersensitivity pneumonitis. **A,** Abnormalities on inspiratory scan show widespread ground-glass attenuation, often with poorly formed centrilobular nodules, and are often extremely subtle; appearances may be virtually normal. **B,** On expiratory scan, striking regional variation in lung attenuation is often apparent, with areas of darker lung representing gas trapping (from bronchiolitic component of disease).

BRONCHOSCOPIC PROCEDURES

Although endobronchial and transbronchial biopsies are straightforward and relatively noninvasive procedures, the volume of tissue taken is small, with only bronchial and peribronchial tissue sampled. Thus, both procedures have a high yield in diseases with peribronchial distribution, especially sarcoidosis and lymphangitis carcinomatosis. Occasionally, transbronchial biopsy findings can help confirm a diagnosis of hypersensitivity pneumonitis, although bronchoalveolar lavage fluid tends to be more rewarding in this regard. Bronchoscopic biopsy procedures have little or no diagnostic value in the idiopathic interstitial pneumonias.

Hemorrhage and pneumothorax (with transbronchial biopsy) are the important risks associated with bronchoscopic procedures. Major hemorrhage is rare, but pneumothoraces complicate transbronchial biopsies in 1% to 2% of procedures, although intercostal tube drainage is not always required.

In the 1980s, many regarded bronchoalveolar lavage (BAL) as an important part of the diagnostic algorithm in DLD. The distinction between a BAL neutrophilia (suggestive of IPF) and a BAL lymphocytosis (as in sarcoidosis or hypersensitivity pneumonitis) was held to be particularly useful. With experience, however, it became apparent that diagnostic distinctions based on BAL fluid in large groups of patients were insufficiently reliable in individual patients. The advent of HRCT also limited the role of BAL, which had been more influential in the pre-HRCT era, when most noninvasive diagnoses were tentative. There are currently no published evaluations of the diagnostic value added by BAL, once HRCT findings are taken into account.

In recent years, however, use of BAL has increased in some centers. In the 2002 ATS/ERS recommendations, compatible BAL findings (i.e., no lymphocytosis) are a requirement for the noninvasive diagnosis of IPF. Although not formally retained in the 2011 recommendations, this criterion reflects the diagnostic value of BAL findings when HRCT appearances are suggestive of IPF but not definitive. However, a BAL lymphocytosis has an even greater diagnostic impact in some patients with sarcoidosis or hypersensitivity pneumonitis. When significant fibrosis supervenes in these disorders, HRCT appearances often become atypical, and IPF is frequently the preferred diagnosis, before performance of BAL. A BAL lymphocytosis in the setting of fibrotic DLD may be an important justification for diagnostic surgical biopsy. Thus, BAL continues to play a useful diagnostic role in a significant subset of patients, when clinical and HRCT features are inconclusive, although adding little to diagnosis in the majority of DLD patients.

SURGICAL BIOPSY

Surgical biopsy, formerly performed as an open procedure but now widely obtained using video-assisted thoracoscopic surgery (VATS), was once regarded as the diagnostic reference standard and, until recently, was advocated as a routine diagnostic procedure by some authorities. However, routine surgical biopsy is impractical outside referral centers, and in the 1980s, even before HRCT had a significant diagnostic impact, it was performed in less than 15% of patients with IPF in the United Kingdom. Even in referral centers, number of diagnostic surgical biopsies has been radically reduced with the application of HRCT. In one UK referral center, the Royal Brompton Hospital, biopsy was performed in more than 50% of IPF patients in the 1980s but in less than 25% in the mid-1990s. Moreover, it is increasingly clear that open or VATS biopsy is not a true diagnostic gold standard. Variation between 10 thoracic pathologists in assigning a histologic diagnosis in DLD was recently found to be considerable, with agreement only moderate (kappa coefficient of agreement of 0.38). In more than 20% of biopsies, the first-choice diagnosis was assigned with low confidence.

Thus, although biopsy procedures add invaluable information in select patients, and a pattern of usual interstitial pneumonia is usually diagnostically definitive, a histologic diagnosis alone should no longer be viewed as a diagnostic gold standard.

Sometimes, the histologic diagnosis is at odds with clinical and HRCT information and must be integrated with other information. In some patients with fibrotic hypersensitivity pneumonitis, a histologic pattern of *usual interstitial pneumonia* (which is normally indicative of IPF) is disclosed at biopsy, despite clinical, HRCT, and BAL features of hypersensitivity pneumonitis and an indolent course during follow-up. Similarly, in a cohort of more than 100 patients with IPF or fibrotic NSIP (Flaherty et al., 2003), a combination of histologic and HRCT findings provided more accurate prognostic information than either modality alone. Thus, surgical biopsy is now best viewed, as with HRCT, as a diagnostic "silver standard" that can often be avoided when HRCT and clinical features are typical of an individual DLD.

The morbidity and mortality associated with surgical biopsy in DLD are low in patients with an adequate pulmonary reserve but increase significantly in those with severe disease. In one series (Utz et al.), patients with advanced IPF (mean gas transfer <35% predicted) had a mortality ascribable to biopsy of 15%. Although this figure is generally regarded as an overstatement of the risk of the procedure, based on other series and widespread anecdotal experience, a surgical biopsy should not be performed unless central to management if the gas transfer is less than 30% of predicted. Moreover, in advanced idiopathic fibrotic disease, the prognostic value of a histospecific diagnosis diminishes. In another series (Latsi et al.), mortality was identical in IPF and fibrotic NSIP when the gas transfer was less than 35%, despite major differences in survival in less severe disease.

Thus, in younger patients (<60) presenting with a typical clinical picture of severe IPF and HRCT features suggestive of fibrotic NSIP, immediate referral for consideration of lung transplantation is warranted, without a histologic diagnosis. The exception is the patient presenting with overwhelmingly severe acute DLD, in which the diagnosis is unclear, and realistic differential diagnoses include acute interstitial pneumonia, severe infection (e.g., opportunistic infection), and malignancy. BAL fluid may be required to exclude infection, and occasionally a histologic diagnosis is required to plan management. Both procedures can be performed in ventilated patients, and if disease is slightly less severe, elective mechanical ventilation may be warranted to investigate appropriately.

INTEGRATED DIAGNOSIS IN DIFFUSE LUNG DISEASE

The central diagnostic challenge for the clinician is to integrate the clinical and diagnostic information into a final diagnosis, without overemphasizing any single clinical or investigative feature. Indeed, only the clinician is able to play this latter role, because both histologic and HRCT diagnoses made without reference to other information are seriously flawed in a significant proportion of patients. The most difficult dilemma, when noninvasive evaluation discloses two or more realistic diagnoses, is whether to accept diagnostic uncertainty, without investigating further, or to resort to invasive (surgical biopsy) or semi-invasive (BAL fluid, transbronchial biopsy) procedures.

This decision should be made pragmatically and not by protocol. The value of a specific diagnosis in diffuse idiopathic lung disease is that the clinician is informed of the probable natural history and the likelihood that treatment will play a useful role. From these considerations, the optimal approach to monitoring disease during follow-up usually becomes apparent. Thus, the essential purpose of pursuing a diagnosis is to identify *probable* disease behavior with and without treatment. Broadly, with occasional exceptions, *longitudinal* disease behavior in DLD can be subdivided into five patterns (Table 46-3). When a patient can be subclassified confidently into one of these groups, invasive investigation will often add little to short-term and long-term management. Three strands of information are of particular value in making these distinctions: the underlying cause (if any), a morphologic assessment using HRCT (and histologic evaluation in select patients), and observed longitudinal disease behavior.

The identification of an underlying cause is vital because considered with HRCT appearances, it may allow disease to be classified confidently as *self-limited inflammation* (e.g., acute drug-induced lung disease, hypersensitivity pneumonitis, RBILD in smokers), with a good outcome, provided the offending agent is removed. In long-standing disease, knowledge of a cause often allows the clinician to classify fibrotic abnormalities on HRCT as *stable fibrotic disease* (e.g., fibrotic sequelae of nitrofurantoin lung, silicosis, other pneumoconioses); the confidence of this conclusion is increased by the documentation of stable longitudinal disease behavior, based on previous chest radiographs, symptoms, and occasionally pulmonary function tests. In both self-limited inflammation and stable fibrotic disease, invasive diagnostic investigations are seldom warranted, and potentially toxic treatments can usually be minimized.

A histologic diagnosis is required more frequently in apparently idiopathic disease, to draw two essential distinctions: between inherently stable and potentially progressive fibrotic disease, and between major inflammation (with high risk of evolution to fibrosis with undertreatment) and inexorably progressive fibrotic disease. In both scenarios, therapeutic intervention may be the key to a substantially better outcome. Knowledge of likely intrinsic disease behavior is invaluable because it allows decisive management and increases patient confidence considerably. A confident diagnosis of hypersensitivity pneumonitis, NSIP, or cryptogenic organizing pneumonia associated with significant fibrosis justifies aggressive intervention with a higher risk of drug toxicity, because the treated outcome is often good. By contrast, in IPF, in which the benefits of treatment may be marginal, a more cautious therapeutic approach is often warranted, and in younger patients, the timing in considering transplantation can be planned. As a general principle, BAL and surgical biopsy should always be pursued in patients fit for these procedures, as determined by age, disease severity, and comorbidity, if a confident management strategy based on disease behavior cannot be devised from noninvasive evaluation.

These principles apply especially to the most common presentation of nongranulomatous idiopathic DLD: the cryptogenic fibrosing alveolitis (CFA) clinical syndrome. In previous decades, underlying histologic appearances have tended to be lumped together, but the recent ATS/ERS reclassification of the idiopathic interstitial pneumonias has provided a framework for the separation of a number of disease entities with strikingly diverse natural histories and treated outcomes (Table 46-4). In evaluation of biopsy diagnoses in the 1980s of “cryptogenic fibrosing alveolitis” in patients presenting with the CFA clinical syndrome, an alternative histologic diagnosis associated with a much better observed outcome was evident on review in more

Table 46-3 Most Common Patterns of Longitudinal Disease Behavior in Diffuse Lung Disease (DLD) with Select Underlying Diagnoses*

Pattern	Select Diagnoses
Self-limited inflammation	Drug-induced lung disease (acute onset) Hypersensitivity pneumonitis (usually short-term exposure) Sarcoidosis (distinct subset with, usually, acute onset)
Stable fibrotic disease	Drug-induced lung disease (residual fibrosis after cessation) Hypersensitivity pneumonitis (after prolonged exposure) Nonprogressive pneumoconioses after exposure (e.g., silicosis) Sarcoidosis (residuum of burnt-out disease)
Major inflammation, risk of fibrotic progression	Drug-induced lung disease (unusually florid reactions) Hypersensitivity pneumonitis (usually continuing exposure) Sarcoidosis (prolonged severe inflammation)
Inexorably progressive fibrosis	Drug-induced lung disease (continuing exposure) Hypersensitivity pneumonitis (antigen usually unknown) Progressive pneumoconioses after exposure (e.g., asbestosis) Sarcoidosis (small subset of patients)
Explosive acute DLD	Drug-induced lung disease

*May appear in several categories; excluding idiopathic interstitial pneumonias (see Table 46-4).

Table 46-4 Idiopathic Interstitial Pneumonias*

Clinicopathologic Diagnosis	Likely Longitudinal Behavior
Idiopathic pulmonary fibrosis/ cryptogenic fibrosing alveolitis	Inexorably progressive fibrosis
Nonspecific interstitial pneumonia (NSIP)	Cellular NSIP: self-limited or major inflammation Fibrotic NSIP: stable or progressive fibrosis
Cryptogenic organizing pneumonia	Self-limited or major inflammation
Desquamative interstitial pneumonia	Self-limited or major inflammation
Respiratory bronchiolitis–associated interstitial lung disease	Self-limited inflammation
Lymphocytic interstitial pneumonia	Self-limited or major inflammation

*American Thoracic Society/European Respiratory Society (ATS/ERS) consensus classification, with most common patterns of longitudinal behavior associated with individual diagnoses.

than 50% of cases. The ATS/ERS classification system is logical and pragmatic because each entity tends to fall into a particular category of longitudinal disease behavior, although a degree of overlap is inevitable. Thus, when a confident noninvasive diagnosis is unattainable in patients with idiopathic interstitial pneumonia, surgical biopsy should always be considered.

In the influential 2004 study of Flaherty et al., in which the final diagnosis was multidisciplinary, two conclusions highly relevant to routine diagnosis were apparent. When a confident prebiopsy diagnosis of IPF was made by clinicians or radiologists, the diagnosis virtually never changed with the addition of *histologic* data. By contrast, in the remaining cases, diagnoses made by clinicians and radiologists changed in approximately 50% of cases when *biopsy* data were considered. However, it should also be stressed that the final diagnosis differed from the histologic diagnosis in 25% of cases. It is now widely accepted that a multidisciplinary diagnosis, negotiated among clinicians, radiologists, and in biopsied cases, pathologists, is the diagnostic reference standard in DLD.

TREATMENT

Key diagnostic distinctions include those that influence the management algorithm. Treatment regimens can be subdivided into those used in predominantly inflammatory disease, in which a treatment response can be expected, and those in which a response is not expected but the primary goal is to prevent or delay the progression of interstitial fibrosis. The broad pragmatic approaches to therapy can best be considered in relation to the broad patterns of disease behavior, as follows:

1. A policy of careful observation without immediate intervention is appropriate if the pattern of behavior is one of self-limited inflammation or stable fibrotic disease.
2. When inflammatory disease is viewed as intrinsically dangerous because of disease severity or is admixed with progressive fibrotic disease, high-dose initial therapy is necessary, with careful definition of the optimal treatment status, as determined by clinical features, imaging, and pulmonary function tests. In the longer term, after initial treatment, best management consists of establishing the minimum level of treatment that serves to preserve the initial gains. However, the specifics of any follow-up treatment protocol depend on the amplitude of the response and the severity of residual irreversible disease.
3. In purely fibrotic diseases, in which stabilization is a realistic long-term goal, initial high-dose corticosteroid or immunosuppressive therapy would not be expected to achieve regression of disease. The key to management lies in finding “civilized” long-term regimens, with toxicity levels acceptable to patients, which prevent further disease progression.
4. In inexorably progressive fibrotic disease, effectively equating with IPF or an IPF-like treatment course in other fibrosing disorders, a “civilized” nontoxic approach is paramount. Delaying disease progression is a realistic goal in some patients, but not at the cost of major toxicity. The importance of distinguishing between IPF and other fibrosing disorders is that in non-IPF diseases, it may be justifiable to take risks with treatment toxicity to attempt to stabilize disease.
5. A final diagnosis is not possible in many patients. The most likely scenario, based on disease prevalence, is probable IPF, but possible fibrotic NSIP or hypersensitivity pneumonitis. Guideline statements written for “definite IPF” do not address this frequent conundrum, and in many elderly patients with major comorbidity or severe lung disease, a surgical biopsy is not practical. In the absence of guideline statements, arguably the most frequent error is to miss an opportunity, and management should be determined by the most optimistic outcome scenario. If NSIP or hypersensitivity pneumonitis is a realistic possibility, a more aggressive approach, as indicated by those diagnoses, is appropriate, even when IPF is clearly the most probable diagnosis.

The optimal diagnostic approach to DLD, as discussed in this chapter, informs all these treatment considerations. In the end, best management consists of reconciling treatments to the predicted and observed patterns of disease behavior. Careful assessment of the many aspects of the DLDs at presentation and during follow-up is indispensable.

CONTROVERSIES AND PITFALLS

CLASSIFICATION OF DISEASE

Given the pivotal importance to management of identifying the likely or observed pattern of disease behavior, with a view to effective management, clinicians need a formalized disease behavior classification of DLDs, as discussed earlier. This approach (1) provides a better understanding of treatment principles by patients and non-DLD clinicians because this classification sidesteps the opaque terminology of DLD, (2) deals with the problem of diagnostic overlap (e.g., probable IPF, possible NSIP, possible hypersensitivity pneumonitis), and (3) provides a simple framework for rational treatment for the large subset of patients who cannot be classified using the current classification approach. An ATS/ERS committee is constructing a preliminary disease behavior classification along these lines.

To achieve a useful system, clinicians need to confront three uncertainties highly relevant to routine practice. First, this type of approach is not a replacement for the current *diagnostic* classification. Best diagnosis and management practice requires that the two classifications be viewed as complementary. A confident histospecific diagnosis establishes which patterns of disease behavior are possible. A diagnosis of IPF, for example, is essentially a statement that management should be as for inexorably progressive fibrosis. A diagnosis of hypersensitivity pneumonitis clarifies that all patterns of disease behavior are possible, and therefore best management should be strongly influenced by many other considerations, as discussed earlier.

A second problem is that in DLD, the current ethos is “definite classification at a single point in time.” An approach in which *disease behavior* is the basis for management is limited because such a system is tentative at presentation and becomes increasingly certain as short-term disease behavior, including change with initial therapy, is taken into account. This is actually an advantage because the use of a disease behavior classification perfectly mirrors the way in which experienced clinicians evaluate DLD, with reappraisal of initial impressions and therapies at follow-up. However, formalization of this approach undoubtedly requires a change in mindset.

Third, it is important to consider that although the inflammation/fibrosis dichotomy is the most therapeutically relevant treatment distinction, new antifibrotic agents may ultimately result in partial reversibility of some fibrotic disorders. It may now be timely to design a disease behavior classification around “reversible” versus “irreversible” disease, rather than inflammation and fibrosis. Such an approach would make a classification of disease behavior relevant to rare disorders, such as pulmonary alveolar proteinosis and Langerhans cell histiocytosis, and to clinicians who manage chronic lung and systemic diseases in general, who will appreciate the straightforward rationale of therapies applied to a framework of reversible/irreversible disease.

OPTIMAL DIAGNOSIS AND REGIONAL EXPERTISE

The major shift within DLD to multidisciplinary diagnosis and away from a histologic gold standard does create important practical difficulties outside referral centers. Robust multidisciplinary diagnosis is a process of debate, disagreement, and the reconciliation of divergent views, and this approach cannot work well if one of the three disciplines, whether clinical, radiologic, or histologic, is hegemonic. However, away from referral centers, it is highly unlikely that there will be equivalent expertise in all three disciplines; even within some referral centers, this ideal is not entirely achieved. The act of questioning in a public forum nonetheless undoubtedly leads to improved diagnostic practice, but the importance of maximizing expertise should not be overlooked.

DECISION TO PERFORM BIOPSY

No authoritative guidance on the indications for performing a diagnostic lung biopsy changes that the decision is often nuanced and difficult to make clinically, even before patient concerns are considered. Clinicians know what constitutes a high-risk biopsy and generally know what constitutes a low-risk biopsy. However, many biopsies fall somewhere in-between. Moreover, patients are involved in decisions, especially those associated with increased risk, although expecting a patient to decide whether to undergo a biopsy is unreasonable. One helpful approach is to outline for patients the following five conversations about biopsy and to inform them where they lie in this spectrum:

1. A biopsy is an absolute requirement if a logical management plan can be constructed only with this information, if disease is overtly dangerous, and if there is a real risk of worsening the situation with the wrong treatment approach. Clearly, it is the duty of the physician in this scenario to persuade the patient to undergo the lung biopsy.
2. A biopsy would make management somewhat more precise and might provide benefits in terms of diagnosis and management in the longer term. However, it would be possible to construct a rational, reasonably definitive treatment approach without this information, but without less confidence. The patient can then be informed that a biopsy is strongly recommended, but that the physician could, with some misgivings, construct a logical treatment plan without this information if the patient does not accept the recommendation.
3. The arguments for and against a biopsy are finely balanced ("50/50 call"). In this case, if the patient has strong views as to whether or not to undergo the procedure, the decision is no longer finely balanced.
4. On balance, a biopsy is not needed, and the physician can construct management without this information. However, a biopsy might provide earlier information on the likely outcome, and the patient needs to be informed that a biopsy might therefore reduce uncertainty, while not changing management. Severe anxiety caused by uncertainty is a valid indication for an invasive diagnostic procedure, and it is appropriate for the patient to choose to undergo the procedure for that reason alone.
5. A biopsy should *not* be performed because the diagnosis is already secure, based on noninvasive data, or because the risks of the procedure are unacceptably high.

The five conversations just summarized do allow a clear statement of the balance of benefit and risk and provide most patients with the information they need to participate in decision making. By contrast, an isolated discussion of the risks of a diagnostic surgical biopsy, although satisfying the demands of clinical governance, fails to make the discussion relevant to the key medical considerations or to engage the patient fully.

Section 8
PARENCHYMAL LUNG DISEASES

Chapter 47

Idiopathic Pulmonary Fibrosis and Other Interstitial Lung Diseases

Amen Sergew • Kevin K. Brown

Interstitial lung diseases (ILDs) are a large and diverse group of pulmonary disorders that affect the interstitium and air space of the lung and are histopathologically characterized by inflammation and/or fibrosis. Many ILDs are of known cause or association, although the most common remain idiopathic. In 2002 the American Thoracic Society/European Respiratory Society (ATS/ERS) International Multidisciplinary Consensus standardized the classification of the *idiopathic interstitial pneumonias* (IIPs) and categorized them into seven distinct disorders: (1) idiopathic pulmonary fibrosis (47%-64% of idiopathic ILDs), (2) nonspecific interstitial pneumonia (14%-36%), (3) cryptogenic organizing pneumonia (4%-12%; formerly bronchiolitis obliterans organizing pneumonia), (4) respiratory bronchiolitis interstitial lung disease, (5) desquamative interstitial pneumonia (10%-17%), (6) acute interstitial pneumonia (<2%), and (7) lymphoid interstitial pneumonia (<2%).

These ILDs differ based on epidemiology, onset of disease, chest imaging findings, histopathology, and most importantly, prognosis and response to treatment. Cryptogenic organizing pneumonia presents and is treated similarly to noncryptogenic presentations of organizing pneumonia, as discussed in Chapter 50. The remaining idiopathic ILDs are discussed in this chapter. **Table 47-1** compares various characteristics and **Figure 47-1** shows some distinct radiologic and histologic patterns of these idiopathic ILDs.

IDIOPATHIC PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis (IPF) is the prototypic chronic, progressive fibrosing interstitial lung disease. In 2011, new ATS/ERS guidelines on the diagnosis, prognosis, and therapy of IPF were published (Raghu et al.). Its prevalence in the United States approaches 100,000 cases with an incidence of 15,000 to 30,000 cases per year. The disease generally affects patients in their sixth decade of life or later, and in patients older than 75 the prevalence increases to 175 per 100,000. There is a slight male predominance.

The cause of IPF is unknown, although risk factors include tobacco use, environmental and occupational exposures, infectious agents such as Epstein-Barr virus (EBV) and hepatitis C virus (HCV), and gastroesophageal reflux disease (GERD). Symptoms are frequently insidious and include cough and shortness of breath, especially with exertion. Symptomatic progression typically occurs over years, although abrupt and otherwise unexplained declines in respiratory symptoms, physiology, and imaging studies (acute exacerbation of IPF) can occur. On examination, digital clubbing may be present. Chest auscultation reveals mid- to end-inspiratory crackles, most pronounced at the bases. During late stages, patients may show evidence of right-sided heart failure caused by the development of pulmonary artery hypertension.

The diagnostic utility of laboratory testing is limited because no biologic fluid-based biomarkers are currently useful in making a definitive diagnosis. Serum Krebs von den Lugen-6 (KL-6), serum surfactant A and D, serum CCL18, serum brain natriuretic peptide (BNP), plasma and bronchoalveolar lavage (BAL) fluid, and matrix metalloproteinases (MMPs) 1 and 7 are all potential biomarkers. Ongoing studies are evaluating the role of these and other potential biomarkers in diagnosis and disease progression. Laboratory testing is useful in defining the clinical context and excluding alternatives to explain the ILD. In particular, serologic testing for *connective tissue diseases* (CTDs) is recommended in all patients because the distinction between CTD and idiopathic ILD may have prognostic significance. Pulmonary functions tests (PFTs) reveal a restrictive ventilatory defect with a decreased diffusion capacity. BAL findings are nonspecific, and the procedure is not normally required in the diagnostic evaluation. If performed, a mild neutrophilia and mild (<20%) eosinophilia are frequently found. Lymphocytosis, especially greater than 40%, favors an alternate diagnosis.

When a surgical lung biopsy is performed, the histopathologic pattern seen is termed *usual interstitial pneumonia* (UIP). A definite UIP histopathologic pattern diagnosis requires all four of the following features:

1. Extensive fibrosis and architectural distortion, characterized by significant myofibroblasts and fibroblasts and dense collagen in the interstitium. This may be with or without honeycombing.
2. Heterogeneous involvement of the lung with areas of diseased lung, mostly in the subpleural/basilar regions, intermixed with areas of normal lung.
3. Fibroblast foci present.
4. Lack of features inconsistent with UIP:
    - Hyaline membranes
    - Organizing pneumonia
    - Granuloma
    - Extensive interstitial inflammation away from honeycombing
    - Primarily airway-centered
    - Other, atypical features suggestive of an alternate diagnosis

Table 47-1 **Comparison of the Idiopathic Interstitial Pneumonias**

Onset	Epidemiology	HRCT	Histopathology	Primary Differential	Prognosis
Idiopathic Pulmonary Fibrosis (IPF)					
Insidious over years	Sixth decade of life; male predominance	UIP pattern: peripheral/subpleural and lower lobe-predominant reticular abnormalities; volume loss and architectural distortion; honeycombing and traction bronchiectasis	UIP pattern: dense fibrosis, architectural distortion, fibroblastic foci, subpleural and basilar predominance, minimal inflammation, heterogeneous with areas of normal lung	Familial IPF, chronic HP, CTD-ILD, idiopathic fibrotic NSIP, asbestosis and other toxin exposures, chronic aspiration, Hermansky-Pudlak syndrome	Mortality: 85% in 10 years; mean survival: 4-5 years
Nonspecific Idiopathic Pneumonia (NSIP)					
Subacute to chronic onset over months to years	Fifth to sixth decade of life; slight female predominance	NSIP pattern: reticular abnormalities, ground-glass opacities, subpleural, bibasilar, symmetric	NSIP pattern: Cellular: homogeneous chronic inflammation and few areas of lymphoid granule; type II cell hyperplasia Fibrotic: uniform interstitial fibrosis; chronic interstitial inflammation	CTD-ILD, UIP, chronic HP, sarcoidosis, OP, eosinophilic pneumonia, LIP, DIP, AIP, drugs and toxin, resolving DAD, infection (mycobacteria, PCP, HIV, fungi)	35% (fibrotic predominant) to 100% (cellular predominant) 10-year survival
Respiratory Bronchiolitis Interstitial Lung Disease (RBILD)					
Subacute over weeks to months	Young patients, active smokers (>90%); slight male predominance	RBILD pattern: patchy ground-glass opacities, reticular marking, thickened airways, diffuse centrilobular nodules	RBILD pattern: bronchioles filled with pigmented macrophages; minimal fibrosis, limited to peribronchial areas	Follicular bronchiolitis, HP, infection, talc pneumonitis, chronic aspiration, DIP, NSIP	7-year survival: 75%-100%
Desquamative Interstitial Pneumonia (DIP)					
Subacute over weeks to months	Young patients, generally active smokers (>90%); male predominance	DIP pattern: ground-glass opacities without significant fibrosis; reticular markings; lower lobe and peripheral predominance; rare cysts	Homogeneous, uniform, and diffuse interstitial thickening; diffuse alveolar filling with macrophages	CTD-ILD, infection (e.g., hepatitis, PCP, HIV), PAP, pneumoconiosis, DAH, chronic eosinophilic pneumonia	Mortality: 20%-30%; mean survival: 12 years
Acute Interstitial Pneumonia (AIP)					
Acute onset over days to weeks	Wide age range, with mean of 50 years	DAD pattern: diffuse ground-glass opacification and consolidation; bilateral lobular sparing; late stages: possible traction bronchiectasis	DAD pattern: uniform distribution, hyaline membranes, septal thickening secondary to organizing fibrosis	Environmental, toxic, and drug exposures; infection; ARDS, DAH, hydrostatic edema, AEP, acute exacerbation of underlying ILD, COP, CID-ILD	6-month mortality: 87%-100%
Lymphoid Interstitial Pneumonia (LIP)					
Subacute to chronic over months to rarely years	Wide age range in adults	LIP pattern: basilar reticular opacities or centrilobular nodularity; fibrosis and ground-glass opacities; suggestive perivascular cysts	LIP pattern: interstitial inflammation in alveolar septae, predominantly with histiocytes, plasma cells, and lymphocytes; germinal centers with non-necrotizing granulomas; later stages honeycombing and cysts	HP, CTD-ILD CVID; infection, especially HIV, EBV, and HTLV-1; dysproteinemia; lymphoma	Median survival: 12 years

UIP, Usual interstitial pneumonia; *HP*, hypersensitivity pneumonitis; *CTD-ILD*, connective tissue disease-interstitial lung disease; *DAD*, diffuse alveolar damage; *OP*, organizing pneumonia; *PCP*, *Pneumocystis jirovecii (carinii)* pneumonia; *HIV*, human immunodeficiency virus; *PAP*, pulmonary alveolar proteinosis; *ARDS*, acute respiratory distress syndrome; *DAH*, diffuse alveolar hemorrhage; *AEP*, acute eosinophilic pneumonia; *COP*, cryptogenic pneumonia; *CVID*, common variable immunodeficiency; *EBV*, Epstein-Barr virus; *HTLV-1*, human T-lymphotropic virus type 1.

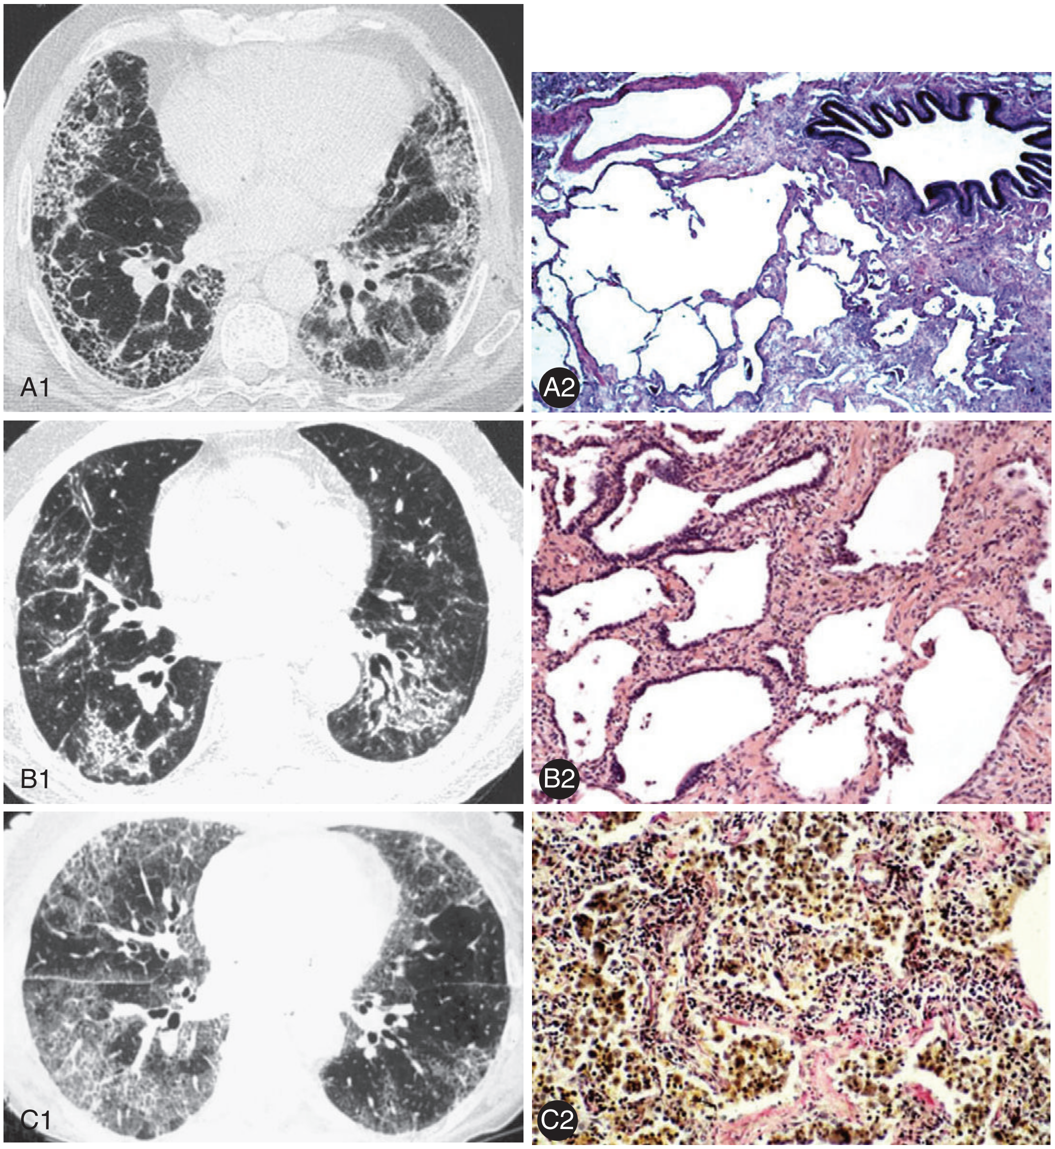

Figure 47-1 Representative high-resolution computed tomography (HRCT) and histopathologic images for common idiopathic interstitial lung diseases (ILDs). *A1*, Usual interstitial pneumonia (UIP) HRCT shows honeycombing, traction bronchiectasis, and fibrosis in subpleural and basilar distribution; *A2*, UIP histology shows heterogeneous findings with some areas of normal alveolar septae as well as areas of severe fibrosis with architectural distortion. *B1*, Nonspecific idiopathic pneumonia (NSIP) HRCT shows reticular abnormalities and ground-glass opacity; *B2*, NSIP histology shows diffuse and homogeneous interstitial inflammation and fibrosis. *C1*, Desquamative interstitial pneumonia (DIP) HRCT shows ground-glass opacities without significant fibrosis or honeycombing; *C2*, DIP histology shows uniform and diffuse interstitial thickening and diffuse alveolar filling with macrophages. *(Histology images courtesy Dr. Dirk Theegasten, Department of Pathology, Ruhr University, Bochum, Germany.)*

The chest imaging or radiologic pattern seen on high-resolution computed tomography (HRCT) scanning in about 50% of patients is also termed UIP. In the other 50% of patients, less well-characterized patterns are seen. When present, a UIP radiographic pattern has a positive predictive value of 90% to 100% for the presence of a UIP histopathologic pattern. Therefore, when this pattern is present, a surgical lung biopsy is rarely if ever needed. A definite HRCT radiologic pattern diagnosis of UIP can be made if all the following characteristics are present:

1. Subpleural/basal predominance
2. Honeycombing with or without traction bronchiectasis
3. Reticular abnormalities
4. Lack of features inconsistent with UIP:
    - Distribution that is not localized to subpleural or basilar region (peribronchial, upper lung or midlung predominance)
    - Extensive ground-glass opacities
    - Diffuse micronodules
    - Discrete cysts
    - Consolidation
    - Air trapping
    - Other, atypical features suggestive of an alternate diagnosis

In the clinical context of an idiopathic ILD, the identification of a UIP chest imaging pattern confirms the diagnosis of IPF. In patients with discordant findings in their clinicoradiologic appearances, or if they have atypical features on HRCT,

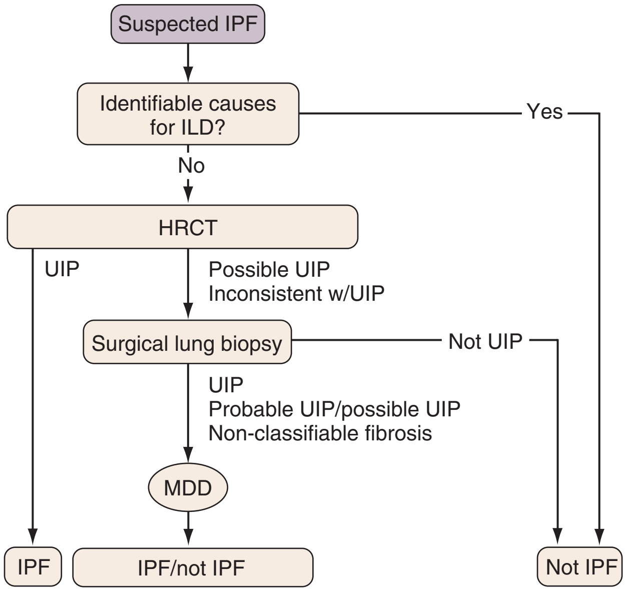

Figure 47-2 Algorithm for diagnosis of idiopathic pulmonary fibrosis *(IPF).* The initial evaluation of a patient with suspected IPF (typically a patient with cough and chronic progressing dyspnea who has radiographic changes consistent with ILD) rules out other causes of interstitial lung disease *(ILD).* If no other causes are identified, high-resolution computed tomography *(HRCT)* should be done. If HRCT shows usual interstitial pneumonia *(UIP)*, this is diagnostic. If HRCT is nondiagnostic, surgical biopsy is obtained, followed by multidisciplinary discussion *(MDD)* to make the diagnosis. *(Modified from Raghu G et al:* Am J Respir Crit Care Med *183:788–824, 2011.)*

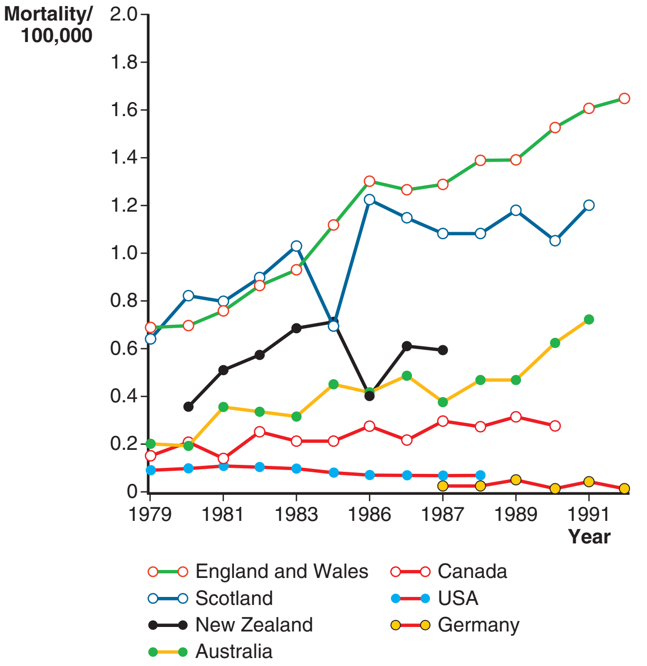

Figure 47-3 Mortality estimates for patients with idiopathic pulmonary fibrosis (IPF) in seven countries (1979–1991). *(Modified from Coultas DB et al:* Am J Respir Crit Care Med *150:967–972, 1994.)*

a surgical biopsy is recommended in those who need a definitive diagnosis and are suitable for surgery. Transbronchial biopsies are too small to be diagnostic; therefore when a definitive diagnosis is necessary, a surgical biopsy should be obtained, preferably using video-assisted thoracoscopy, with biopsies from more than one lobe. A UIP histopathologic pattern confirms the diagnosis.

In summary, the new guidelines allow the clinician to establish the diagnosis of IPF based on the following criteria:

1. The clinical context is that of an idiopathic ILD; other potential causes or associations, including infection, drug or environmental exposures, and systemic disorders (e.g., CTDs), have been excluded.
2. The chest imaging and histology show a UIP pattern.

Because the diagnosis of IPF requires combining clinical, radiologic, and often pathologic information, multidisciplinary discussions with chest imagers and pathologists are strongly recommended, especially since a definitive diagnosis cannot be made based on radiologic and histologic findings alone. Figure 47-2 outlines an algorithm for the diagnosis of IPF.

Patients have complications directly and indirectly related to their IPF. Although the natural history of IPF is generally slow symptomatic and physiologic progression, otherwise unexplained rapid deterioration can occur. *Acute exacerbations* of IPF are defined as the presence of an acute respiratory decompensation of unknown cause and occur in 5% to 10% of patients yearly. Patients tend to present with a viral prodrome and worsening baseline hypoxemia. Invasive mechanical ventilation is often required to maintain oxygenation, but its use is not generally recommended given the poor prognosis associated with acute exacerbations, although it may be appropriate in a minority of patients. Workup should include exclusion of pulmonary embolism, infection, congestive heart failure, volume overload, pneumothorax, and other causes of lung injury. Imaging studies may show new onset of bilateral diffuse ground-glass opacity or dense consolidation. Lung biopsies show a diffuse alveolar damage (DAD) pattern. Although strong evidence is lacking, treatment with high-dose steroids is provided to most patients, in addition to broad-spectrum antibiotics. The prognosis is poor, with mortality rates of up to 70% or more during the following year.

Pulmonary hypertension is a recognized complication affecting about 10% of IPF patients at diagnosis. Its presence correlates with increased early mortality. With progression of disease, a majority of patients may ultimately develop some clinical evidence of pulmonary hypertension. In patients with worsening symptoms without significant changes in lung imaging studies or in lung volumes or spirometry, pulmonary hypertension should be considered.

Other comorbidities associated with IPF include an increased risk of venous thromboembolic disease, lung cancer, emphysema, GERD, obesity, obstructive sleep apnea, and cardiovascular disease.

A study quantified the mortality rate associated with IPF in 2003 in the United States as 61.2 deaths per 1 million in men and 54.5 per 1 million in women, with 60% of deaths attributed to progressive lung disease. Increased rates are seen in older patients and in the winter months. Figure 47-3 compares mortality rates (per 100,000 population) from various countries. Although the median survival of symptomatic patients is generally accepted as 3 to 5 years, the survival of individual patients varies widely.

Figure 47-4 shows the natural history of IPF. Relatively stable lung function and slow (most common) or rapid disease progression can all occur. A patient's course is unpredictable, and risk factors for decompensation are poorly understood. No clear consensus exists on a valid staging system for IPF. However, the specific characteristics used at diagnosis to identity patients with risk factors for early mortality include severity of dyspnea, lower forced vital capacity (FVC) or diffusion capacity (D_{LCO}),

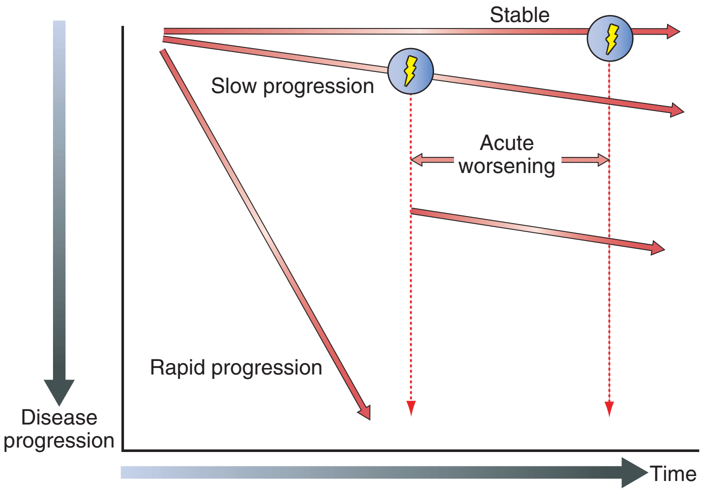

Figure 47-4 Most patients with idiopathic pulmonary fibrosis display a slowly progressive natural history. In a minority of patients, IPF can be stable or rapidly progressive. Some slowly progressive or stable patients may also have acute decompensation *(lightning bolt)*, from a known infection, other lung insult, or an unknown cause, generally with high mortality or resulting in worsened lung function. *(Modified from Raghu G et al:* Am J Respir Crit Care Med *183:788–824, 2011.)*

significant desaturation on 6-minute walking distance (6MWD) testing, and the extent of fibrosis on HRCT. Other suggested risk factors include a shorter 6MWD, presence of significant emphysema, and pulmonary hypertension. Important longitudinal factors associated with an increased risk of early mortality in IPF patients are worsening dyspnea, decline in FVC, decline in DLCO, and increasing extent of disease on HRCT.

Treatment The 2011 IPF guidelines also review evidence on treatment. To summarize, no medical therapy has proved to provide a survival, quality of life, or functional benefit in patients with IPF, and therefore no specific treatment approach was thought to be useful in the majority of patients. Given this, appropriate patients should be considered for early referral for lung transplantation, as well as referral to research centers to consider prospective therapeutic studies. Beyond this, oxygen therapy for hypoxia at rest, with activity, exercise, and sleep, is frequently used for symptom control. Pulmonary rehabilitation and routine vaccinations are also important to incorporate into disease management. For patients with asymptomatic GERD, therapy is recommended.

Despite inadequate information, many patients will desire medical therapy for IPF. Although convincing evidence of efficacy is lacking, conventional therapy has been considered to be a combination of azathioprine, prednisolone, and *N*-acetylcysteine (NAC). This regimen is has been tested in the prospective, multicenter, placebo-controlled Prednisolone, Azathioprine, and *N*-Acetylcysteine in People with Idiopathic Pulmonary Fibrosis (PANTHER-IPF) trial in the United States. The prednisone + azathioprine + NAC arm of the study was terminated early due to increased mortality and adverse effects when compared to the placebo arm. Thus this regimen is no longer recommended for patients with well-characterized IPF. While the remaining active NAC and placebo arms of the PANTHER-IPF study will hopefully provide a definitive answer, NAC alone is often considered in a minority of patients dosed at 1800 mg daily (split into twice or three times daily doses). *Pirfenidone* is a small-molecule drug thought to be an antifibrotic agent that is approved for use in IPF patients in Japan and Europe. The drug has been tested in multiple trials with conflicting results, and as a result, the statement does not suggest its use in the majority of patients. A large Phase III trial is now underway in the United States to provide clarity on pirfenidone's usefulness. The Sildenafil Trial of Exercise Performance in Idiopathic Pulmonary Fibrosis (STEP-IPF) studied the effects of *sildenafil* on IPF patients with physiologically severe disease and showed no significant improvement in 6MWD. However, there were some improvements in secondary outcomes such as arterial oxygenation, DLCO, and symptoms of dyspnea and quality of life in the sildenafil group. Further studies would be helpful to assess the risks and benefits of long-term use of sildenafil in IPF patients.

Despite the elevated risk of venous thromboembolic disease, no strong evidence favors prophylactic anticoagulation. Although a small study suggested a potential survival benefit to chronic anticoagulation, a more recent large-scale study of warfarin (Coumadin) in patients with IPF was stopped early for lack of efficacy.

NONSPECIFIC INTERSTITIAL PNEUMONIA

Historically, nonspecific interstitial pneumonia (NSIP) has been the catchall phrase for ILD that does not fit into other categories. In the mid-1990s, NSIP was defined as a specific histopathologic pattern that did not match histopathologic criteria for other idiopathic ILDs. Since then, NSIP has expanded from simply describing a histopathologic pattern to a specific form of an otherwise idiopathic ILD. Because the histopathologic NSIP pattern is not unique, a concerted effort should identify a potentially causative exposure or associated medical condition. When no alternative explanation is identified, the diagnosis of "idiopathic NSIP" can be made.

The epidemiology of NSIP is unknown. Significantly less common than IPF, estimates of the prevalence of idiopathic NSIP range from 1 to 9 per 100,000 population. NSIP presents in a younger population than IPF, with patients in their 40s to 50s and with a female predominance. Symptoms are nonspecific and include cough and dyspnea with a presentation that ranges from subacute (6-12 months) to chronic (up to 3 years); median duration is 18 to 31 months. History and physical examination should be used to evaluate for features suggestive of an alternative explanation for the presence of ILD. For example, the presence of Raynaud's phenomenon, arthritis, and myositis suggests an underlying CTD. Pulmonary examination typically reveals basilar crackles.

Laboratory testing offers limited information and cannot make a definitive diagnosis. However, testing helps define the clinical context and exclude alternative explanations for ILD. Similar to IPF, serologic testing for a CTD is recommended in all patients because the distinction between idiopathic NSIP and the histopathologic pattern of NSIP associated with a CTD may have prognostic significance. PFTs reveal a restrictive ventilatory defect with a decreased DLCO. A minority of patients may present with a mild airflow obstruction. In contrast to IPF, BAL fluid will show lymphocyte predominance in 50% of suspected NSIP patients, generally with a minor proportion of neutrophils and/or eosinophils.

The histopathologic pattern of NSIP is a homogeneously abnormal parenchyma with diffuse interstitial involvement. It can be subdivided based on the amounts of lung fibrosis and inflammation, with *cellular* NSIP consisting almost exclusively of cellular inflammation and *fibrotic* NSIP showing some component of acellular fibrosis. Cellular NSIP has mild to moderate chronic interstitial inflammation with associated type II

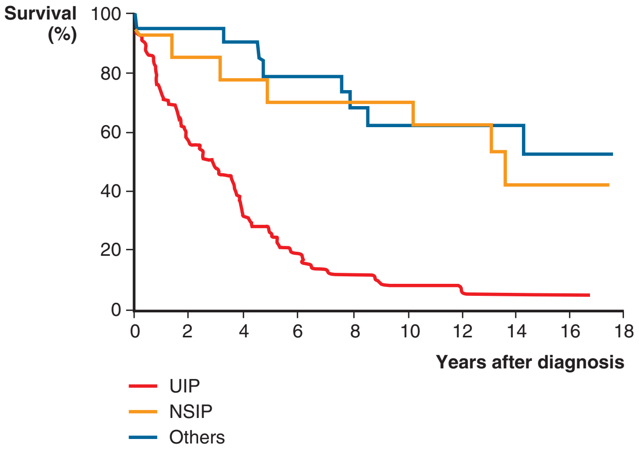

Figure 47-5 Survival curves based on histopathologic subgroups comparing usual interstitial pneumonia *(UIP)*, idiopathic pneumonia *(NSIP)*, and other idiopathic interstitial lung diseases. Patients with UIP pattern have worse prognosis than those with NSIP or other ILDs. *(Modified from Bjoraker JA et al:* Am J Respir Crit Care Med *157:199–203, 1998.)*

pneumocyte hyperplasia and few areas of lymphoid aggregates. Fibrotic NSIP results in uniform involvement with dense or loose interstitial fibrosis and a lack of honeycombing or fibroblast foci.

On imaging studies, cellular NSIP has diffuse areas of ground-glass infiltrate, whereas fibrotic NSIP is associated with reticular changes, volume loss, and traction bronchiectasis. The findings are typically symmetric, lower lung predominant, and often the subpleural zone is relatively free of fibrosis. Honeycombing and consolidation are rare findings. The sensitivity and specificity of imaging studies in NSIP are not to the level of being diagnostic. Therefore, when the diagnosis of NSIP is suspected, a surgical lung biopsy should be considered.

Treatment and Prognosis Prospective, controlled therapeutic trials are lacking in the treatment of patients with NSIP, and expert opinion provides the basis for most recommended regimens. Corticosteroids are typically initiated in these patients, with an anticipated transition to steroid-sparing agents such as azathioprine, mycophenolate mofetil, or cyclophosphamide. The prognosis of NSIP is variable, with a minority of patients with progressively fatal disease and others with nearly complete recovery. Patients with a predominantly fibrotic NSIP have a worse prognosis than those with predominantly cellular NSIP. The majority of patients will have relatively stable disease or some mild improvement with therapy. Overall, mortality is better than with UIP. Figure 47-5 compares the survival curves of patients with NSIP, UIP, and other idiopathic ILD.

RESPIRATORY BRONCHIOLITIS INTERSTITIAL LUNG DISEASE

The histopathologic pattern respiratory bronchiolitis (RB) is a common finding in current or former heavy smokers. However, the overwhelming majority of patients appear to have no related clinical sequelae and it exists as an incidental finding when a patient has lung pathology obtained for other reasons. In contrast, respiratory bronchiolitis interstitial lung disease (RBILD) occurs when a patient with clinical and physiologic evidence of interstitial lung disease has RB as the sole histopathologic finding to account for their ILD. Given the overlapping clinical context, imaging, and pathologic findings, RBILD appears to be on a spectrum of disease that includes desquamative interstitial pneumonia (DIP).

Patients with RBILD present in their 30s and 40s, with a male predominance of almost 2:1. Patients are almost invariably heavy smokers of at least 30 pack-years. They generally present with dyspnea and cough. Pulmonary findings are similar to DIP, with a mild to moderate reduction in DLco and a mixed restriction and obstruction. Up to 10% of patients may present with normal physiology, and another 10% show significant bronchodilator response. On chest imaging, as many as 20% of patients may have normal plain chest radiographs. HRCT shows significant airway wall thickening, reticular and centrilobular abnormalities, and small patches of ground-glass opacity. The findings are bilateral and can be found in all five lung lobes and tend to be less extensive and involve less of the lung parenchyma than in DIP. BAL fluid typically shows an excess number of pigmented macrophages with black, golden, or brown inclusions, similar to that seen in otherwise healthy smokers. There may also be a modest neutrophilia.

The diagnosis of RBILD is typically made from the clinical context of a young, heavy smoker and the chest imaging pattern seen on HRCT. If definitive diagnosis is needed, surgical lung biopsy is indicated because transbronchial biopsy and BAL findings cannot provide this level of confidence. The histopathologic pattern is bronchiolocentric, involving first-order and second-order respiratory bronchioles with the peribronchiolar alveoli filled with tightly packed pigmented macrophages. These cells stain positive for periodic acid–Schiff (PAS). The lumen may also be filled with mucus (mucostasis). There is minimal fibrosis, limited to the peribronchial areas.

Prognosis and Therapy The prognosis is generally thought to be good. One study of 32 patients showed 75% of patients had a greater than 7 year survival, with only one patient dying of progressive ILD. Clinical improvement was seen in 28% and physiologic improvement was seen in 10%. In regards to therapy, symptoms may improve with smoking cessation alone and this should always be the initial intervention. If symptoms persist, a trial of corticosteroid therapy is often used, though this is based on expert opinion rather than interventional therapeutic trials.

DESQUAMATIVE INTERSTITIAL PNEUMONIA

Desquamative interstitial pneumonia is thought to be on a continuum of disease with RBILD, and is seen in a similar clinical context, heavy smokers in 60%-87% of cases. In contrast to RBILD, 20% of cases occur in the setting of CTD, viral infections or drug/toxin exposure. The DIP patient population is younger than those with IPF, typically in their 30s to 50s, with a 2:1 male predominance.

The most common pulmonary physiologic finding is a reduced DLco. The patient may also have mild restriction or mild mixed restrictive-obstructive patterns. HRCT typically shows ground-glass opacities in the lung periphery and bases without significant fibrosis or honeycombing. Other findings include traction bronchiectasis, centrilobular nodules, and cysts, which are typically less than 2 cm in diameter.

Surgical biopsy is required for a definitive diagnosis because BAL fluid and transbronchial biopsy show nonspecific findings. The histopathologic pattern reveals homogeneous and diffuse interstitial thickening. Alveoli are filled with iron-laden macrophages, resulting in the ground-glass pattern. Type II cell hyperplasia and diffuse alveolar septal thickening also are seen. In contrast to RBILD, the patient with DIP has more interstitial fibrosis, lymphoid follicles, giant cells, and eosinophils, although the patterns can show considerable overlap. Unlike UIP, fibroblast foci and honeycombing are not present in DIP. Given the smoking history, some emphysematous changes may also be seen.

Prognosis and Therapy Patients with DIP often show prolonged stability but can progress to end-stage fibrosis. Overall mortality is 6% to 30%, with mean survival of 12 years. Unlike patients with RBILD, patients with DIP can develop acute exacerbations. The main therapeutic intervention is smoking cessation. Corticosteroids and in those that respond, corticosteroid-sparing agents, have been used as an adjunct, but this is based on expert opinion. Patients with ground-glass opacities typically have some improvement of their symptoms and imaging findings, although disease progression occurs in up to 20% of patients. With continued progression, lung transplantation is an option. Interestingly, there have been rare cases of recurrence in the transplanted lung.

ACUTE INTERSTITIAL PNEUMONIA

Acute interstitial pneumonia (AIP) has been known by a variety of names over the years. Hamman and Rich described the first cases in 1935. More recently it was considered an idiopathic form of acute respiratory distress syndrome (ARDS) because their presentation and clinical characteristics are indistinguishable, but they are differentiated by the absence of a known cause or association in AIP. Symptoms include a rapid onset of dyspnea over days to less than 3 weeks, typically following a viral prodrome. Patients routinely develop significant hypoxia and respiratory failure, requiring assisted ventilation. The epidemiology includes a wide age range, with a mean age of 50 years, and affects both genders equally. There is no known association with smoking.

Chest imaging in AIP patients typically shows bilateral ground-glass infiltrates sparing the costophrenic angles and otherwise patchy distribution with associated air bronchograms. Pleural effusions are rare. HRCT in the early phase of disease shows diffuse bilateral ground-glass opacities. In the later stages, bilateral consolidative opacities, especially at the lung bases and in dependent regions are found, as well as bronchial dilation and architectural distortion with honeycombing and cysts.

The diagnosis of AIP is a diagnosis of exclusion. BAL fluid is primarily used to exclude overwhelming infection and reveals increased total cell numbers with red blood cells, neutrophils, and lymphocytes. The histopathologic pattern is diffuse alveolar damage, with hyaline membranes, diffuse septal fibrosis, and type II pneumocyte hyperplasia.

Prognosis and Therapy Mortality in patients with AIP is typically higher than 50%, with most deaths occurring in-hospital within 1 to 2 months from onset of symptoms. Those who survive are at increased risk of recurrence and chronic, progressive fibrotic lung disease, with 6-month mortality of 87% to 100%. There is currently no known specific therapy for AIP. Most experts treat it as ARDS, although corticosteroids are used more often in patients with AIP.

LYMPHOID INTERSTITIAL PNEUMONIA

Lymphoid interstitial pneumonia (LIP) rarely presents as an idiopathic lung disease and is most often seen in the setting of autoimmune disease, genetic abnormalities, infection (especially HIV, EBV, and HTLV-1), or dysproteinemia (e.g., polyclonal and monoclonal gammopathy). When seen as an idiopathic ILD, patients with LIP typically present with cough and progressive shortness of breath over months and rarely up to years. Symptoms can include fever, weight loss, and pleurisy.

Physical examination is consistent with crackles and less frequently digital clubbing (~10% of patients). Pulmonary physiology reveals a restrictive pattern with reduced DLCO. Chest imaging findings can vary and involve basilar reticular opacities, ground-glass opacities, or centrilobular nodularity. Suggestive perivascular cysts are seen in many patients. BAL fluid typically shows a lymphocytosis, but this is not diagnostic. For definitive diagnosis, surgical biopsy is recommended and shows confluent cellular infiltration of the alveolar septae (and less frequently peribronchial and perivascular septae) with lymphocytes, plasma cells, and histiocytes. Germinal centers, occasional non-necrotizing granulomas, and associated multinucleated giant cells are also seen. In later stages of LIP, fibrosis and even honeycombing can be seen. Genetic studies are important to rule out malignancy and monoclonality.

Treatment No randomized trials have identified the treatment for patients with LIP. Anecdotal evidence supports the use of corticosteroids for symptomatic patients and those with a decline in lung function. For those who do not respond or who have side effects, adding a steroid-sparing agent should be considered.

CONTROVERSIES AND PITFALLS

Establishing the correct diagnosis remains the crucial step in the assessment and management of patients with interstitial lung disease, because the diagnosis is the most important determinant of prognosis and appropriate treatment plan. The multidisciplinary approach involving the clinician, chest radiologist, and pulmonary pathologist is critical in piecing together the puzzle. However, this requirement for active multidisciplinary communication is often the rate-limiting step, and the clinician must expend considerable effort to make it work. Beyond the diagnosis, projecting the future disease activity remains an uncertain science, and multiple ongoing studies are underway in an attempt to identify biomarkers predictive of future disease behavior. A number of genetic risk factors for the development of pulmonary fibrosis have been identified, although the utility of these findings in clinical practice is uncertain at present.

Because no therapy used in the treatment of idiopathic pulmonary fibrosis has provided a survival, quality of life, or functional status benefit, the limitations of current treatment options leave plenty of room for controversy. As most interventional treatment trials use purported surrogate end points, the results of these trials will be difficult to interpret and will require the clinician to engage each patient fully to make informed decisions regarding treatment.

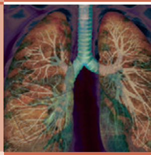
Section 8

PARENCHYMAL LUNG DISEASES



Chapter 48

Sarcoidosis

Manju Paul • Michael C. Iannuzzi

In the 130 years since Jonathan Hutchinson first described sarcoidosis as a skin disorder, involvement of every organ has been reported. The central abnormality in sarcoidosis is granuloma accumulation, leading to altered organ architecture and function. Although the inciting events in sarcoidosis remain unknown, in general, granulomas form to confine pathogens, restrict inflammation, and protect surrounding tissue. Clinical, epidemiologic, and family-based studies support the hypothesis that sarcoidosis is triggered by airborne exposure in a genetically susceptible person. The diagnosis is established when compatible clinical and radiologic findings are supported by evidence of noncaseating epithelioid cell granulomas in one or more organs in the absence of organisms or particles. Corticosteroids remain the therapeutic cornerstone for patients with organ-threatening or chronic progressive disease.

EPIDEMIOLOGY

Sarcoidosis occurs worldwide and may affect any person at any age, although more than 80% of patients are diagnosed between ages 20 and 50 years. In the United States, African Americans are three and a half times more commonly affected, with an age-adjusted incidence of 35.5 per 100,000 persons, compared with 10.9 per 100,000 in whites. African American women are most commonly affected, with a lifetime risk of approximately 2.7%. African Americans tend to have a more severe form of the disease with greater extrapulmonary involvement. The incidence in most European nations has been reported at less than 1 case per 100,000. In Scandinavian countries such as Sweden and Finland, incidence ranges from 11 to 64 per 100,000. Sarcoidosis is uncommon in Chinese and Southeast Asians; the Japanese, however, have a particular susceptibility to cardiac involvement.

ETIOLOGY AND RISK FACTORS

No single environmental sarcoidosis trigger has been identified. Recently, the multicenter ACCESS (A Case Controlled Etiologic Sarcoidosis Study) report found modestly increased risk with exposure to pesticides or moldy environments or working with building materials, hardware, or industrial organic dusts. Sarcoidosis was not associated with rural living conditions or exposure to wood dusts or heavy metals.

Several microorganisms and viruses have been suggested as potential sarcoid antigens. Mycobacterial catalase protein MkatG is the most promising agent thus far and has been found in tissue obtained from more than 50% of patients with sarcoidosis. A possible explanation for the difficulty in identifying an infectious cause for sarcoidosis is that an insoluble bacterial protein serves as antigen long after the infecting organism has been cleared.

Occupational clustering of sarcoidosis cases has been reported in ship workers, fire fighters, and rescue workers who were involved in the response to the World Trade Center attacks in the United States.

GENETIC FACTORS

Racial differences in incidence rates and disease clustering in families support the hypothesis that heredity contributes to sarcoidosis etiology. Having a first-degree relative with sarcoidosis increases the risk for the disease approximately five-fold. Screening for sarcoidosis among relatives is not recommended, because less than 1% will be found to have the disease. Several human leukocyte antigen (HLA) associations with sarcoidosis have been reported (Table 48-1), but HLA seems more likely to influence phenotype than susceptibility. The major histocompatibility complex (MHC) class I allele HLA-B8 is associated with acute sarcoidosis. HLA-DQB1*0201 and HLA-DRB1*0301 are strongly associated with acute disease and good prognosis.

Investigators have studied non-HLA candidate genes that influence antigen processing, antigen presentation, macrophage and T cell activation, and cell recruitment. Table 48-2 lists non-HLA candidate genes studied to date. Although these candidates are logical on the basis of function, their associations with sarcoidosis have not been consistently reproduced.

To date, two genome scans for sarcoidosis have been reported: one in German whites, with the strongest linkage signals localized to chromosomal short arms 3p and 6p, and the other in African Americans with signals at 5p and 5q. Thus far, two candidate genes from linked regions have been identified: *BTNL2*, located on 6p, encoding butyrophilin-like protein 2, a B7 family member that functions as a negative costimulatory molecule, and *ANXA11*, at chromosomal locus 10q22.2, encoding annexin A11, which may affect apoptosis.

PATHOPHYSIOLOGY

Sarcoidosis is a multisystem inflammatory disease characterized by T lymphocyte infiltration, granuloma formation, and microarchitecture distortion. The events leading to granuloma formation probably begin with antigen presented to T lymphocytes by way of MHC class II peptide in a genetically predisposed host (Figure 48-1). Serum amyloid A may have a role in the immune response in sarcoidosis and is capable of eliciting immune responses and triggering cytokine release through interaction with Toll-like receptors (TLRs). The oligoclonal T cell repertoire in sarcoidosis (α/β and δ/γ receptors) suggests that triggering antigens favor progressive accumulation and activation of selective T cell clones. Initially, macrophages process the antigens, which are then presented to $CD4^+$ T cells by class II MHC molecules. T cell activation occurs by means of T cell receptor (TCR), TLR, or cytokine or chemokine receptors. This leads to signal transduction and activation of transcription factors that promote gene expression controlling T cell proliferation, differentiation, and apoptosis and produce proinflammatory cytokines and chemokines. T cell signal transduction pathways are potential therapeutic targets in sarcoidosis. Macrophages, in the face of chronic cytokine stimulation, differentiate into epithelioid cells, gain secretory and bactericidal capability, lose some phagocytic capacity, and fuse to form multinucleate giant cells. In more mature granulomas, fibroblasts and collagen encase the ball-like cell cluster. As granulomas accumulate, alterations in organ architecture and function occur.

Granulomas can resolve with little clinical consequence or may progress to fibrosis. Acute granulomatous and chronic fibrotic sarcoidosis probably represent different immunopathogenic processes, which remain to be defined (Figure 48-2). A

Table 48-1 Summary of Human Leukocyte Antigen (HLA) Association Studies of Sarcoidosis

HLA	Risk Alleles	Finding
HLA-A	A*1	Susceptibility
HLA-B	B*8	Susceptibility in several populations
HLA-DPB1	*0201	Not associated with sarcoidosis
HLA-DQB1	*0201	Protection, Löfgren syndrome, mild disease in several populations
	*0602	Susceptibility/disease progression in several groups
HLA-DRB1	*0301	Acute onset/good prognosis in several groups
	*04	Protection in several populations
	*1101	Susceptibility in whites and African Americans
HLA-DRB3	*1501	Associated with Löfgren syndrome
	*0101	Susceptibility/disease progression in whites

Table 48-2 Non-HLA Candidate Genes Evaluated in Sarcoidosis

Candidate Gene	Findings
Angiotensin-converting enzyme gene (*ACE*)	Increased risk for ID and DD genotypes Moderate association between II genotype and radiographic progression
CC chemokine receptor 2 gene	Associated with protection/Löfgren syndrome
Chemokine receptor 5 gene	CCR5Δ32 allele more common in patients treated with corticosteroid; refuted with haplotype analysis and larger sample
CD80, CD86 genes	No association detected
Clara cell 10-kDa protein gene	An allele associated with sarcoidosis and with progressive disease at 3-year follow-up
Complement receptor-1 gene	Association with the GG genotype for the Pro1827Arg (C[5507]G) polymorphism
Cystic fibrosis transmembrane regulator gene (*CFTR*)	R75Q increases risk
Cytotoxic T lymphocyte antigen 4 (*CTLA4*)	No association with sarcoidosis
Heat shock protein 70–like gene	HSP(+2437)CC associated with susceptibility/Löfgren syndrome
Inhibitor kappa B-alpha gene	Associated with –297T allele Allele –827T in stage II
IL1α gene	The IL-1α -889 1.1 genotype increased risk
IL-4 receptor gene	No association detected
IL-18 gene	Genotype –607CA increased risk over AA
Interferon-γ gene	IFNA17 polymorphism (551T→G) and IFNA10 [60A]– IFNA17 [551G] haplotype increase risk
Macrophage migration inhibitory factor gene	No association with 5-CATT in Irish population
Natural resistance–associated macrophage protein gene (*NRAMP*)	Protective effect of (CA)(n) repeat in the immediate 5′ region of the *NRAMP1* gene
Toll-like receptor-4 gene (*TLR4*)	Asp299Gly and Thre399Ile mutations associated with chronic disease
Transforming growth factor gene (*TGF*)	TGF-β2 59941 allele, TGFβ3 4875 A and 17369 C alleles were associated with fibrosis on chest radiograph
Tumor necrosis factor-α gene	Genotype –307A allele associated with erythema nodosum/Löfgren syndrome and –857T allele with sarcoidosis –307A not associated in African Americans
Vascular endothelial growth factor gene	+813 CT and TT genotypes associated with protection
Vitamin D receptor gene (*VDR*)	*Bsm*I allele associated with sarcoidosis

Fibrinoid necrosis, but not overt caseation, may be seen in the center of granulomas. **D,** Myocardial biopsy specimen showing patchy granulomatous inflammation with giant cells.

switch from T_H1 to T_H2 cytokine profile, along with other mediators such as interleukin-6 (IL-6), transforming growth factor-β (TGF-β), osteopontin, and insulin growth factors (IGFs), is suggested to result in fibrosis. Sarcoidosis may develop or worsen in patients with immune reconstitution during treatment of HIV infection or in those undergoing treatment with interferon.

CLINICAL FEATURES

The clinical presentation of sarcoidosis varies. In up to two thirds of the cases, the patient is asymptomatic, and sarcoidosis is diagnosed incidentally on the basis of radiographic findings of hilar lymphadenopathy. Thoracic involvement is most common (over 90% of patients), followed by skin, eyes, liver, spleen, peripheral lymph nodes, central nervous system (CNS), and heart. Two well-recognized acute, febrile presentations of sarcoidosis are Löfgren syndrome (arthritis, erythema nodosum, and bilateral hilar adenopathy) and Heerfordt syndrome (uveitis, parotid gland enlargement, and facial nerve palsy). These acute presentations portend a good prognosis, with disease resolution within 1 to 2 years. Both syndromes are uncommon in African Americans.

PULMONARY MANIFESTATIONS

More than 90% of patients with sarcoidosis have pulmonary involvement. Common complaints include dry cough, vague chest discomfort, and dyspnea, particularly with exertion. Pleuritic chest pain is uncommon. Wheezing may occur with endobronchial involvement or hyperreactive airways. Sputum production and hemoptysis occur in advanced fibrocystic disease. Pleural involvement is seen in only 2% to 4% of patients and can manifest with pleural effusions, pleural thickening, pneumothorax, and chylothorax. The diagnosis of sarcoidosis often is delayed, especially in patients presenting with predominantly pulmonary symptoms.

Chest auscultation may reveal fine, late, or mid-expiratory crackles, but comparatively less than that heard in pulmonary fibrosis. In view of the marked chest radiographic abnormalities, physical examination of the lungs is surprisingly unrevealing. Clubbing is rare but when present usually is associated with advanced bronchiectasis or liver disease.

Pulmonary Hypertension

The prevalence of pulmonary arterial hypertension and right ventricular dysfunction ranges from 4% to 28%. Pulmonary hypertension is more common in patients with advanced lung disease and has been reported in up to 74% of patients with sarcoidosis who are awaiting a lung transplant. Several potential causes of pulmonary hypertension in sarcoidosis include interstitial lung disease, fibrous destruction of the pulmonary vascular bed, compression of pulmonary arteries by lymphadenopathy, pulmonary venoocclusion, portopulmonary hypertension, myocardial dysfunction, and an intrinsic sarcoid vasculopathy. Patients with pulmonary hypertension are more likely to be listed for a lung transplant and exhibit a 10-fold increase in mortality over that for patients with isolated pulmonary sarcoidosis. Prognosis is poor, with a 5-year survival rate of only 59%. The management of pulmonary hypertension involves

reversal of resting hypoxia. Use of corticosteroids for pulmonary hypertension in sarcoidosis is controversial. The data supporting the benefit of endothelin receptor antagonist and phosphodiesterase-5 inhibitors are very limited.

Chest Radiology

Chest radiographs obtained in patients with sarcoidosis are classified by appearance into four patterns (Figure 48-3). Unfortunately, these radiographic patterns have been termed “stages,” leading to the erroneous assumption that they represent disease stages rather than chest x-ray patterns.

Stage 0: Absence of radiographic abnormalities
Stage I: Bilateral hilar and/or mediastinal adenopathy without pulmonary parenchymal abnormalities
Stage II: Hilar and/or mediastinal lymphadenopathy with pulmonary parenchymal abnormalities (generally a diffuse interstitial pattern)
Stage III: Diffuse parenchymal disease without nodal enlargement
Stage IV: Pulmonary fibrosis with evidence of volume loss or cystic or honeycomb changes

The initial radiographic pattern at initial presentation generally predicts likelihood of radiographic resolution. Resolution of radiographic abnormalities occurs in approximately 60% to 80% of patients who present with a stage I pattern on the chest radiograph and in 50% to 60% with a stage II pattern, but in less than 30% with a stage III pattern.

Intrathoracic lymphadenopathy and parenchymal infiltrates (stage II chest radiograph) are the most commonly encountered radiographic finding, occurring in 85% of patients. Symmetric hilar adenopathy is most commonly seen. Unilateral hilar adenopathy is unusual and is seen in only 3% to 5%. Mediastinal lymphadenopathy without hilar adenopathy is rare; an alternate diagnosis must be considered in this setting. The

pulmonary parenchymal changes have a strong predilection for the upper lung fields, unlike those noted in other diffuse parenchymal diseases such as pulmonary fibrosis, which are basilar-predominant. High-resolution computed tomography (HRCT) typically demonstrates symmetric mediastinal or hilar lymphadenopathy, parenchymal changes with upper lobe predominance, or multiple small nodules in a perivascular distribution along bronchovascular bundles, interlobular septa, and subpleural regions. Larger, more well-defined nodular infiltrates may mimic malignancy (Figure 48-4). Chest computed tomography (CT) also may reveal bronchiectasis (Figure 48-5). In patients with fibrocystic lung disease (Figure 48-6), mycetomas may occur. Remarkable discrepancy among radiographic findings, pulmonary function testing abnormalities, and severity of symptoms often exist.

HRCT does not often aid in diagnosis or in guiding therapy when compared with standard chest radiography. HRCT is indicated in the following scenarios: (1) hemoptysis, (2) a radiographic pattern or new finding that does not suggest sarcoidosis, (3) evaluation for transplant candidacy, and (4) search for a mycetoma.

^{18}F-fluorodeoxyglucose–labeled positron emission tomography (FDG-PET) can be useful for evaluating activity in sarcoidosis and is more sensitive than gallium scanning. The

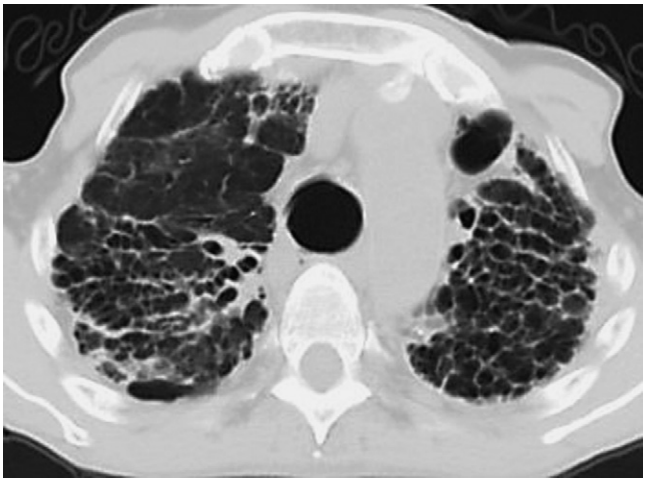

Figure 48-5 Fibrotic bronchiectasis in sarcoidosis. The appearance of the upper lobes with multiple small cystic areas is called honeycombing, readily seen on this computed tomography image.

combination of L-[3-^{18}F]-α-methyltyrosine with conventional FDG-PET is useful in discriminating sarcoidosis from malignancy.

Pulmonary Function Testing

Pulmonary function testing assesses the impact of pulmonary sarcoidosis. The two most common abnormalities are reductions in lung volume and vital capacity, representing a restrictive ventilatory defect, with a reduction in diffusing capacity (DLCO). A decreased DLCO generally is the first laboratory abnormality detected and the last value to return to normal with disease resolution. A reduction in DLCO is related not only to the restrictive disease but also to sarcoidosis-associated pulmonary hypertension. Obstructive ventilatory defects also may be seen in up to 30% of nonsmokers with sarcoidosis and may represent endobronchial involvement and stenosis, reactivity, or distortion of the airway from parenchymal involvement. Obstructive defects are increasingly seen with fibrosis and bullous transformation. Tests for bronchial hyperreactivity give a positive result in up to 30% of patients.

The prognosis in patients with isolated pulmonary sarcoidosis generally is good. Most patients undergo spontaneous remission or disease stabilization within 2 to 5 years after diagnosis. In a small number of patients, the condition may progress to end-stage lung disease. For those patients with progressive decline in pulmonary function, assessment for oxygen desaturation with exertion should be performed, with consideration of the need for oxygen therapy.

EXTRAPULMONARY SARCOID

Sarcoidosis may affect any organ system. The most commonly involved extrapulmonary organs include the skin (30%), eyes (25%), and lymph nodes, liver, and spleen (20%). Abnormalities in calcium metabolism (hypercalciuria followed by hypercalcemia) are detected in approximately 15% of patients. Clinically apparent cardiac and nervous system involvement have each been reported to occur in about 5% of patients, but magnetic resonance imaging (MRI) and PET scans demonstrate that these organs are more commonly involved. In general, patients who present initially with extrapulmonary disease have a worse prognosis.

Skin

Cutaneous involvement varies and may include erythema nodosum, plaques, nodules, papules, macules, vitiligo, ulcerations, psoriasis-like lesions, and acneiform eruptions. Lesions may be single or occur in crops, may arise in scars and tattoos, and commonly involve the trunk, scalp, nape of the neck, and extremities (Figure 48-7). Skin lesions in African American patients frequently leave scars, pits, and pale depigmented areas. Cutaneous involvement usually occurs along with systemic disease, although skin manifestations may precede other organ involvement. Careful examination of the skin is essential at initial presentation, because biopsy of a sarcoidal lesion has a high yield.

Erythema nodosum is a nonspecific hypersensitivity reaction. It occurs in approximately 10% of patients and usually manifests as tender, subcutaneous nodules, often on the anterior tibial surface (Figure 48-8). It is more common in women and among persons from Europe, Puerto Rico, and Mexico and is less common in African Americans and Japanese. The onset of erythema nodosum usually is sudden and accompanied by constitutional symptoms such as fever, malaise, and polyarthralgias. The constellation of erythema nodosum, bilateral hilar adenopathy, fever, and polyarthralgias constitutes Löfgren syndrome, an acute form of sarcoidosis that usually is self-limited and carries a good prognosis. Erythema nodosum usually lasts 3 weeks and can recur. Biopsy of the characteristic nodules will show nonspecific septal panniculitis and does not provide histologic support of the diagnosis of sarcoidosis. Biopsy of skin lesions other than those of erythema nodosum usually yields granulomas.

Lupus pernio (Figure 48-9), a violaceous, indurated lesion, affects the midface, particularly the nose, nasal alae, malar and periorbital areas, and areas around the eyes. With subsequent erosion into underlying cartilage and bone, as seen in some cases, lupus pernio can be extremely disfiguring. It is more common in women and is associated with chronic disease.

Eyes

Ocular involvement occurs in 25% of patients with sarcoidosis. Any part of the eye can be affected. Black patients and women younger than 40 years are more likely to have ocular involvement. Lacrimal gland involvement is common and usually is asymptomatic (Figure 48-10). Conjunctival involvement can manifest as dry or red eyes. The entire uveal tract may be involved. Anterior uveitis (iritis, iridocyclitis) is more common than posterior uveitis (choroiditis). Acute anterior uveitis

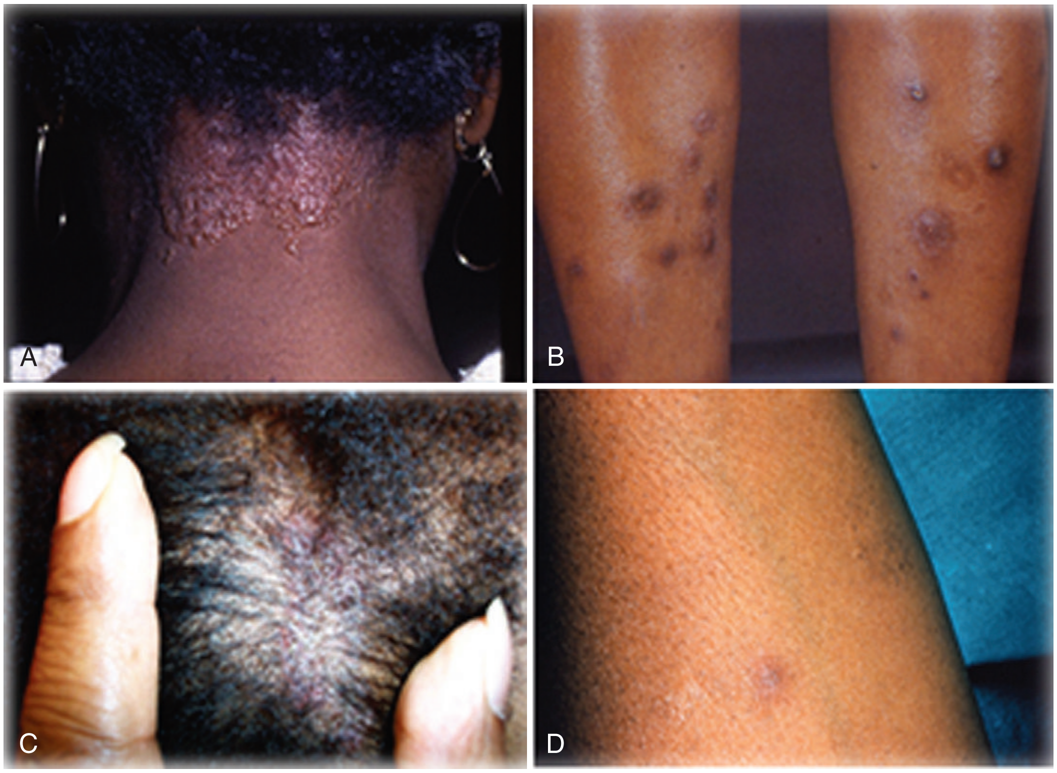

Figure 48-7 Skin lesions in sarcoidosis. **A,** Cluster of waxy papules on nape of the neck. **B,** Raised darkened granulomatous nodules. **C,** Dark, crusting scalp nodules. **D,** Red, nontender nodules.

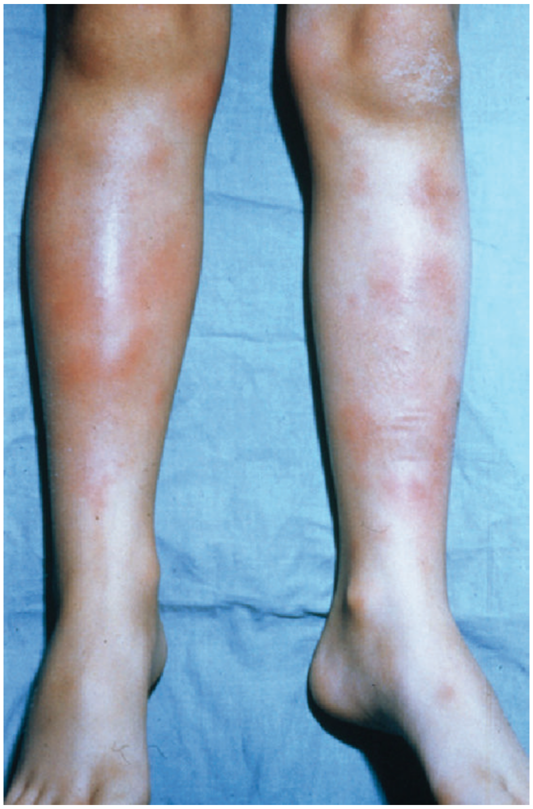

Figure 48-8 Erythema nodosum of the anterior tibia in a patient with sarcoidosis. Raised nodules that were tender to touch are visible on the anterior tibial surface.

manifests with photophobia, eye pain, and blurry vision. Chronic anterior uveitis is more common than acute and may silently result in vision loss and glaucoma. Posterior uveitis can lead to proliferative retinopathy, resulting in loss of vision, and is associated with CNS disease. Approximately 15% of patients with ocular involvement have both anterior and posterior uveitis. Routine dilated funduscopic examination and slit lamp examination by an ophthalmologist are recommended. Biopsy of the conjunctiva and lacrimal glands has a high diagnostic yield.

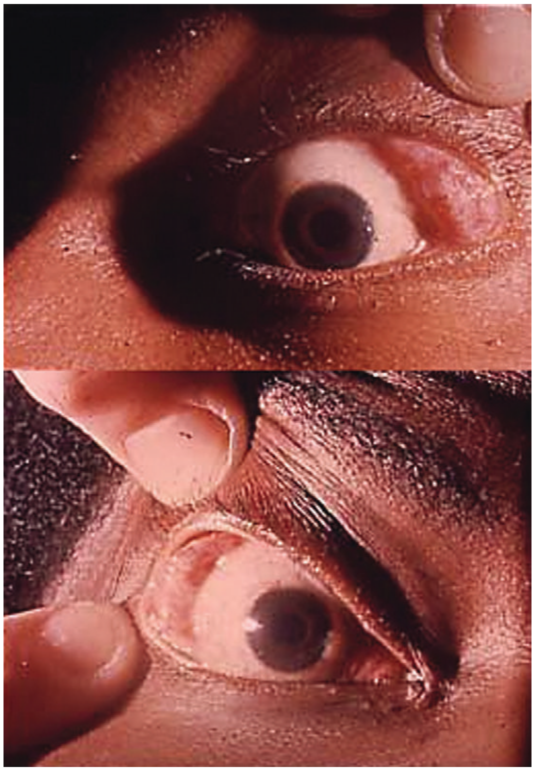

Figure 48-10 Bilateral enlarged nodular lacrimal glands in a patient with sarcoidosis.

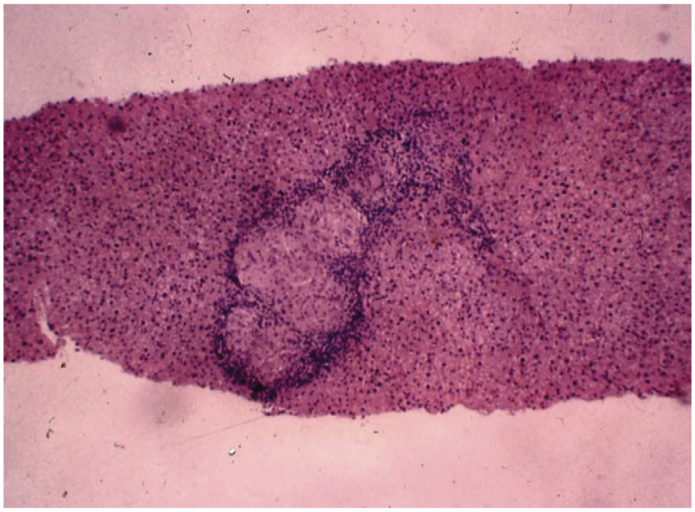

Figure 48-11 Liver granuloma, seen in a specimen from a patient with sarcoidosis.

Liver and Spleen

In up to 80% of patients with sarcoidosis, granulomas will be present on liver biopsy (Figure 48-11). Liver involvement in African Americans is at least twice as common as in whites. The liver is palpable in 15% of patients. Sarcoid liver disease manifestations may include asymptomatic liver enzyme elevation, chronic cholestasis, portal hypertension with variceal bleeding, hepatopulmonary syndrome with refractory hypoxemia, and cirrhosis with liver failure. Granulomatous hepatitis in sarcoidosis often results in marked constitutional signs and symptoms such as fever, night sweats, anorexia, right upper quadrant pain, and weight loss. If results of liver function testing are abnormal, tests for viral hepatitis and serum antimitochondrial antibodies to rule out primary biliary cirrhosis should be performed. Alkaline phosphatase and γ-glutamyl transferase are predominantly elevated. Splenomegaly occurs in 6% of patients. Abdominal ultrasound imaging and CT scan may reveal a characteristic hypodense nodular pattern.

Gastrointestinal Tract

Sarcoidosis has been shown to involve the stomach, esophagus, appendix, colon, rectum, and pancreas. Gastric sarcoidosis manifests with epigastric pain, early satiety, and hematemesis secondary to either peptic ulcerations, narrowing of the gastric lumen from granulomatous inflammation, or fibrosis of the gastric wall resulting in pyloric obstruction. Chronic atrophic gastritis with antiparietal cell antibodies resulting in a pernicious anemia–type picture has been reported.

Lymphatics

Although intrathoracic lymph node enlargement is the most common lymphatic manifestation, all lymph node–bearing sites may be involved. Peripheral lymph nodes may be small or grow to several centimeters in diameter and usually are mobile and nontender.

Heart

Cardiac sarcoidosis is most common in Japan, with one autopsy series demonstrating cardiac sarcoidosis in almost half of the cases. In the United States, clinically apparent cardiac involvement occurs in approximately 5% to 10% of patients with sarcoidosis; as suggested by findings with newer imaging techniques such as MRI and PET scanning, however, cardiac inflammation may be more common in North Americans than has been previously appreciated.

The left ventricular free wall is most commonly involved, followed by the basal aspect of the ventricular septum, the right ventricular free walls, and the atrial walls. Conduction abnormalities ranging from first-degree atrioventricular (AV) block to complete heart block are common cardiac manifestations of sarcoidosis. Complete heart block occurs in 30% of affected patients, often heralded by syncope. The most feared extrapulmonary complication is sudden death due to ventricular fibrillation or tachycardia. Because this complication may occur in any patient with sarcoidosis, complaints of dizziness, palpitations, or abnormalities on ECG such as first-degree AV block should trigger cardiac evaluation. Other, less common cardiac manifestations include mitral regurgitation, ventricular aneurysms, pericarditis, pericardial effusions, and tamponade.

Every patient should have a routine electrocardiogram on initial assessment. Further cardiac evaluation may include an echocardiogram, right and/or left cardiac catheterization, electrophysiologic study, and cardiac MRI or PET scan to identify myocardial irritability, left ventricular dysfunction, or pulmonary arterial hypertension. Cardiac biopsy is not useful because sarcoidal granulomas are patchy in distribution and they tend to accumulate in the free left ventricular wall and high interventricular septum, where endomyocardial biopsy generally is avoided. Oral corticosteroid therapy and the need for pacemaker or automatic implantable cardiac defibrillator placement should strongly be considered in patients with arrhythmias or markedly diminished left ventricular function. Because cardiac sarcoidosis mostly occurs in the absence of obvious disease elsewhere, it should be considered as a cause in patients presenting with nonischemic cardiomyopathy, particularly with rhythm disturbances.

Central Nervous System

Neurosarcoidosis occurs in 5% to 15% of patients. The most common manifestation is cranial neuropathy, with unilateral or bilateral seventh nerve palsy seen in 50% to 70% of cases. Cranial neuropathies may resolve spontaneously or with corticosteroid therapy and rarely recur. Optic neuritis, the second most common neuropathy, can result in blurred vision, field defects, and blindness. CNS involvement also includes mass lesions, leptomeningeal disease manifesting as aseptic or chronic meningitis, obstructive hydrocephalus, and hypothalamic and/or pituitary dysfunction. Seizures, headache, change in mental status, confusion, and diabetes insipidus may be presenting manifestations. Spinal cord involvement can produce myelopathies and radiculopathies. Patients with dural lesions, cranial nerve lesions, and nonenhancing brain lesions have a better prognosis than patients with leptomeningeal, enhancing brain parenchymal, and spinal lesions.

Calcium Metabolism

Sarcoid granulomas cause increased conversion of 1-hydroxyvitamin D_3 to the active, 1,25-dihydroxyvitamin D_3 secondary to an increase in 1α-hydroxylase activity. Hypercalcemia is present in 5% of patients, often manifesting as kidney stones. Hypercalciuria is more common than hypercalcemia, and a 24-hour urine collection for total calcium should be included in the initial evaluation. Occasionally, patients present with signs and symptoms of severe hypercalcemia. Typically, calcium abnormalities respond to relatively low doses of corticosteroids.

Other Organ Systems

Patients may complain of nasal and sinus congestion, hoarseness, and noisy breathing, which are secondary to granulomatous infiltration of nasopharyngeal mucosa, sinus, and vocal cord. Sarcoidosis of the upper respiratory tract is associated with chronic disease. Endoscopic sinus surgery may provide symptomatic relief in patients with nasal obstruction or chronic sinusitis secondary to obstruction from sinonasal sarcoidosis. Parotid and salivary gland enlargement occurs in approximately 10% of patients. Bone and muscle involvement often is asymptomatic, but MRI with gadolinium often locates abnormalities in patients with persistent muscle, joint, or bone pain. Direct bone marrow involvement with cytopenia is not uncommon.

QUALITY OF LIFE

Sarcoidosis has a considerable impact on quality of life and is associated with stress, fatigue, pain, and sleep disturbances. One study revealed that 60% of patients reported symptoms of clinical depression. Other studies indicate that quality of life worsens when patients are placed on corticosteroid therapy. Improved communication between physicians and patients is essential, and a multidisciplinary management approach should be considered.

DIAGNOSIS

Because sarcoidosis manifests with nonspecific signs and symptoms, it may be difficult to diagnose. Considerations in the differential diagnosis include infectious causes such as tuberculosis, fungal infections, and other specific infections (e.g., brucellosis, chlamydial infection, tularemia), and autoimmune disorders such as Wegener granulomatosis, Churg-Strauss syndrome, and malignancies. Occupational and environment-induced diseases such as chronic beryllium disease (CBD), hypersensitivity pneumonitis, and drug-induced lung disease also should be considered in the differential diagnosis.

CBD, an occupational hypersensitivity disorder, is elicited by beryllium exposure. Historically, workplace exposure has occurred in the defense, nuclear, aerospace, computer, and electronic industries. CBD is characterized by noncaseating granulomas within affected organs, predominantly lung and skin. Differentiating berylliosis from sarcoidosis can be extremely difficult and relies on a thorough occupational history and demonstrating beryllium sensitization with the beryllium lymphocyte proliferation test. Unsuspected CBD may be misdiagnosed as sarcoidosis, especially in patients with ongoing exposure and presumed corticosteroid resistance. The prognosis with CBD is worse than with sarcoidosis, with an estimated 25% mortality rate. Thus, both establishing the diagnosis of CBD and termination of exposure to beryllium are important, because these measures may lead to resolution of the disease.

In suspected sarcoidosis, a diagnosis should be established with biopsy whenever possible, except in patients presenting with Löfgren syndrome. The key pathologic finding is the noncaseating granuloma. Histologic confirmation can be made noninvasively by the Kveim-Siltzbach test, performed by intradermal injection of a suspension made from the spleen or lymph node of a patient with sarcoidosis. The test result is considered positive if a papule forms at the site of injection within 4 weeks and papule biopsy demonstrates granulomas. This test has a sensitivity of 50% and specificity of 98%. The drawbacks of the test are that it requires 4 to 6 weeks to demonstrate positivity and that it is not widely available. This test is most useful in patients whose lesions are not easily accessible for biopsy and who do not require immediate immunosuppressive therapy.

Fiberoptic bronchoscopy (FOB) is an important tool for diagnosis. FOB can identify endobronchial lesions through direct airway visualization (**Figure 48-12**). The sensitivity of transbronchial lung biopsy, with 4 to 6 pieces collected, ranges from 40% to 90%, and is operator dependent. Additional endobronchial biopsies, transbronchial needle aspiration (TBNA), or endoscopic ultrasonography (EUS)–guided biopsy of lymph nodes can improve yield to up to 90%. Endobronchial ultrasound–guided transbronchial needle aspiration (EBUS-TBNA) has a diagnostic yield of 85% to 92% and has been found to be superior to conventional TBNA sampling in patients with subcentimeter lymph nodes. Because of the high diagnostic yield with EBUS-TBNA, other procedures such as mediastinoscopy are seldom required. The $CD4^+/CD8^+$ ratio in bronchoalveolar lavage (BAL) fluid obtained from patients with sarcoid is greater than 3.5, but BAL cell counts are neither diagnostic nor prognostic.

No specific diagnostic blood test for sarcoidosis exists. Mild anemia, lymphopenia, hypercalcemia, elevated total protein, and abnormalities on liver function testing may be seen. Elevated serum angiotensin-converting enzyme (SACE) levels are present in 50% to 75% of cases, but this finding has low specificity. Observed decline of elevated SACE levels may be used as a marker of corticosteroid therapy compliance. Polymorphisms of the *ACE* gene cause changes in the SACE levels. The polymorphism with insertion (I) or deletion (D) of a portion of gene affects enzyme activity, with DD having higher SACE levels than II polymorphisms. Accordingly, genotype-corrected reference values may be more useful for interpretation.

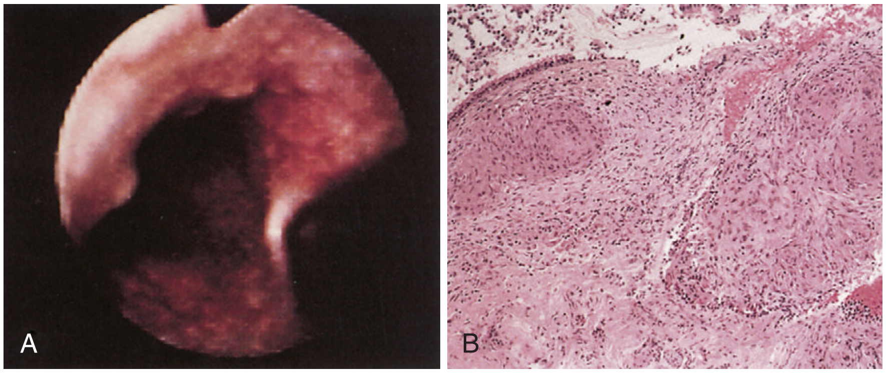

Figure 48-12 Endobronchial sarcoidosis. **A,** Bronchoscopic view shows extensive nodularity of bronchial mucosa—that is, "cobblestoning" of the airway. Rarely, Wegener granulomatosis, tuberculosis, or fungal disease may be associated with similar airway abnormalities. **B,** Endobronchial biopsy specimen demonstrating several granulomas and giant cells beneath bronchiolar epithelium.

BIOMARKERS OF DISEASE ACTIVITY

Interleukin-2 (IL-2), a T_H1 cytokine that induces T cell proliferation, is elevated in serum and BAL fluid of patients with sarcoidosis and may have prognostic value. Chitotriosidase, which is an enzyme involved in the degradation of chitin, is expressed by activated macrophages. Higher levels of chitotriosidase were found in the serum of patients with active sarcoidosis than in those with inactive disease.

TREATMENT

Sarcoidosis often is a mild, self-limited disease and frequently does not require treatment. Clinical assessment, radiography, and sequential lung function testing with particular attention to any significant decline will establish a basis on which to gauge treatment decisions. Table 48-3 summarizes the recommended approach to treatment of sarcoidosis.

CORTICOSTEROIDS

Corticosteroid treatment is indicated when patients with sarcoidosis are dyspneic, with commensurately poor values on lung function tests, and in those showing deterioration of health as judged clinically and radiologically, and particularly by progressive impairment of lung function on such testing. Corticosteroids suppress disease activity and produce symptomatic, radiographic, and functional improvement. Uncertainty remains regarding their effect on the overall natural history of the condition. When treatment is required, corticosteroids constitute the first line of therapy.

Long-standing fibrotic lung changes typically show little objective response to these agents, although hypercalcemia and hypercalciuria usually can be controlled with moderate doses of prednisolone. Cessation of short-term corticosteroid treatment is almost always followed by resurgence of the active manifestations. Thus, the effect of corticosteroids usually is one of suppression of the manifestations of sarcoidosis. In a number of controlled situations, the disease progression in patients with pulmonary sarcoidosis receiving specific regimens of corticosteroid treatment has been compared with that of similar groups not receiving corticosteroids. These studies in patients treated for periods of up to 18 months confirmed that corticosteroids could suppress active granulomas and relieve symptoms but did not improve long-term prognosis.

Oral corticosteroid therapy should be strongly considered in the following clinical situations:

- Hypercalcemia or hypercalciuria
- CNS involvement
- Anterior or posterior uveitis that is unresponsive to local therapy
- Active cardiac involvement
- Progressive involvement in any organ system (e.g., progressive respiratory symptoms, abnormal pulmonary function parameters such as reduced diffusion or vital capacity, or worsening radiographic abnormalities)

The optimal dose and duration of corticosteroid treatment have not been determined in randomized, prospective trials. The treatment regimen is individualized on the basis of symptoms and response rate. For pulmonary sarcoidosis, the initial dose generally is 30 to 40 mg/day of prednisone, with 5-mg taper every 2 weeks down to a dose of about 10 to 20 mg/day. Patients should be observed for either symptomatic or pulmonary function improvement at 1 to 3 months. Patients who fail to respond to an initial 3-month course are unlikely to respond to more prolonged therapy. Among responders, treatment should be continued for 9 to 12 months and tapered thereafter if appropriate. Inhaled corticosteroids may be beneficial in patients with endobronchial sarcoidosis with airway hyperreactivity and persistent cough.

Long-term use of corticosteroids is associated with early cataract formation, glaucoma, reduced bone density resulting in osteoporosis, osteonecrosis, and immunosuppression. Judicious use of calcium or vitamin D therapy is important to prevent hypercalcemia and hypercalciuria. Bisphosphonate therapy often is used, especially when bone scans show reduced bone density.

RELAPSE RATES

Relapse rates are higher in patients who achieve medically induced remission than in patients in whom spontaneous remission occurs. Relapse rates were found to be similar in white and in African American patients, but whites maintained a sustained remission with twice the frequency of that in African Americans.

IMMUNOSUPPRESSIVE AND OTHER ALTERNATIVE THERAPIES

Various immunomodulatory and immunosuppressive therapies may be tried if either corticosteroid therapy is poorly tolerated,

Table 48-3 Treatment of Sarcoidosis

Drug Group and Indications	Specific Drug	Dosage and Duration	Side Effects
Corticosteroids for pulmonary or systemic sarcoidosis	Prednisone	*Initial regimen*: 40 mg q24h for 2 weeks 30 mg q24h for 2 weeks 25 mg q24h for 2 weeks 20 mg q24h for 2 weeks 10-15 mg q24h for 6-8 months Taper to 2.5 mg every 2-4 weeks; if relapse occurs, reinstitute lowest previous effective dose	Increased appetite, weight gain Cushingoid habitus Hyperglycemia Adrenal axis suppression Emotional lability, depression Psychosis, pseudotumor cerebri Hypertension Sodium, fluid retention Glaucoma, cataracts Osteoporosis, osteonecrosis Compression fractures Myopathy Pancreatitis Striae, easy bruisability, acne
Antimalarials for mucocutaneous sarcoidosis	Chloroquine phosphate	500 mg q24h for 2 weeks, then 500 mg q48h for 6 months, followed by 6-month drug-free period	Retinopathy Gastrointestinal upset Headache Discoloration of nailbeds
	Hydroxychloroquine sulfate	200 mg q12h or q24h, may be given indefinitely	Reversible dermatitis Retinopathy (rare) Gastrointestinal symptoms Dermatitis
Alternative therapies for:			
Mild disease or as corticosteroid-sparing agent	Pentoxifylline	400 mg q6h or q8h, may be given indefinitely	Gastrointestinal upset Headache
Severe, refractory sarcoidosis and as corticosteroid-sparing agent	Azathioprine	50 mg q24h for 2 weeks Increase by 50 mg every 2-4 weeks Maximum suggested: 150-200 mg q24h	Bone marrow suppression Hepatic toxicity Gastrointestinal toxicity Carcinogenicity Opportunistic infections
	Methotrexate	10-20 mg once a week PLUS folic acid 1 mg/day	Hepatic toxicity Gastrointestinal toxicity Pulmonary toxicity (hypersensitivity pneumonitis) Bone marrow suppression Opportunistic infections (hypersensitivity pneumonitis) Bone marrow suppression Opportunistic infections
Experimental	Doxycycline	200 mg/day	Photosensitivity Gastrointestinal upset
	Minocycline	200 mg/day	
	Thalidomide	100-150 mg qhs	Teratogenicity Peripheral neuropathy Sedation Skin reactions
	Infliximab	Infusion	Infusion reactions Opportunistic infections Tuberculosis, fungal infections, serious infections, sepsis Hypersensitivity reactions
	Etanercept	Injection	Injection site reactions, serious infections, sepsis, death Central nervous system demyelination disorders

or the immunomodulators or other drugs can be used as steroid-sparing agents.

Hydroxychloroquine

The antimalarial drug hydroxychloroquine may be an effective steroid-sparing agent and is particularly useful in patients with neurosarcoidosis, skin involvement, and abnormalities in calcium metabolism. It is contraindicated for use in patients with posterior uveitis, because retinitis is a potential toxic effect. For patients placed on hydroxychloroquine treatment, ophthalmologic examinations should be conducted every 6 months during therapy to monitor for this potential rare ocular toxicity. Women of childbearing age should be counseled to use birth control while taking hydroxychloroquine.

Azathioprine, Methotrexate, Cyclophosphamide, and Mycophenolate Mofetil

Azathioprine, methotrexate, and cyclophosphamide all have been used in the treatment of sarcoidosis. Although these agents benefit selected patients, no studies exist that clearly delineate when these drugs should be used for therapy. Systematic reviews could identify only four randomized trials comparing these agents, and the results were largely inconclusive. The exact mechanism of action of methotrexate (an antimetabolite that reversibly inhibits dihydrofolate reductase) in sarcoidosis is unknown but may involve both cytotoxic and antiinflammatory effects. It has been shown to be useful in uveitis and appears to be a steroid-sparing agent. Mycophenolate mofetil (MMF), a prodrug of mycophenolic acid, which inhibits lymphocyte proliferation, has been reported to be beneficial in patients with cutaneous, neurologic, and renal sarcoidosis. Because MMF does not intercalate into DNA, it has less oncologic potential than azathioprine and cyclophosphamide. MMF also has a rapid onset of action in comparison with other immunosuppressive agents. New agents that are currently being investigated include leflunomide, a methotrexate analogue.

Tetracyclines

Doxycycline and minocycline may be of benefit in some cases of cutaneous sarcoidosis but have not been shown to be effective for management of other organ involvement.

Antitumor Necrosis Factor Therapy

Pentoxifylline

Although pentoxifylline inhibits tumor necrosis factor (TNF), clinical experience indicates that the drug has limited efficacy but may be helpful to lessen systemic symptoms such as fatigue. Gastrointestinal side effects may limit dosing.

Thalidomide

Small clinical series have found that thalidomide may be beneficial in cutaneous sarcoidosis, particularly lupus pernio. Sedation, peripheral neurotoxicity, and teratogenicity limit its usefulness.

Tumor Necrosis Factor-α Blockers

Infliximab, a chimeric monoclonal antibody directed against soluble and membrane-bound TNF-α, recently has been shown to be effective in refractory sarcoidosis, specifically ocular disease. Of interest, etanercept, another TNF-α blocker, was found to be ineffective. Another TNF-α inhibitor, adalimumab, is being investigated for the treatment of cutaneous sarcoidosis. Clinical trials involving cyclosporine, a calcineurin inhibitor, in pulmonary sarcoidosis have not shown any benefit.

The immunomodulatory properties of statins, particularly the suppression of $CD4^+$ T_H1 cell differentiation, which can limit the production of chemokine in alveolar macrophages, appear promising in the treatment of sarcoidosis. A randomized, double-blind, placebo-controlled study is under way at the National Institutes of Health Clinical Center to determine if atorvastatin has steroid-sparing effects in patients being treated for pulmonary sarcoidosis.

LUNG TRANSPLANTATION

Lung transplantation is an appropriate option for patients with sarcoidosis with severe physiologic impairment refractory to medical therapy. Timing of transplantation relative to the disease course is challenging, because mortality rates are high (27% to 53%) among patients with sarcoidosis awaiting a lung transplant. Furthermore, models predicting mortality have not been validated. The most recently published guidelines for lung transplant candidate selection do not delineate disease-specific guidelines for referral. Extrapolating from idiopathic pulmonary fibrosis, the following recommendations for lung transplantation have been suggested: (1) a forced vital capacity (FVC) less than 60% of predicted, (2) diffusing capacity less than 50% of predicted, (3) at-rest or exercise-induced hypoxemia, or (4) failure to maintain lung function despite treatment with steroids or other immunosuppressive agents. These recommendations seem reasonable, because the mortality rate for patients with sarcoidosis on the lung transplant waiting list is similar to that for patients with pulmonary fibrosis.

Specific risk factors for mortality in sarcoidosis patients awaiting lung transplantation have been identified. One study showed an elevated right atrial pressure as the only variable independently associated with mortality in multivariate analysis. A right atrial pressure higher than 15 mm Hg resulted in a 5.2-fold increase in risk of death. Of interest, the mean pulmonary artery pressure (mPAP) at the time of lung transplantation was significantly higher than at the time of listing. Almost all of the patients studied experienced marked progression of pulmonary hypertension while awaiting transplantation, suggesting that more careful right ventricular hemodynamic monitoring can identify those persons who are at increased risk for death. Although repeated right heart catheterizations may not be feasible, repeat echocardiograms and/or monitoring B-type natriuretic peptide (BNP) levels may be helpful to identify worsening pulmonary hypertension.

In a recent review of 405 patients with sarcoidosis listed for lung transplantation in the United Network for Organ Sharing (UNOS) database, no significant difference was found between pulmonary function testing parameters in survivors and those in nonsurvivors. However, underlying pulmonary hypertension, the amount of supplemental oxygen required, and African American race were significant predictors of mortality. Although mPAP was elevated in both survivors and nonsurvivors, mPAP in patients who died while on the waiting list was 33% higher. The marked pulmonary hypertension noted in nonsurvivors was not thought to reflect either cardiac sarcoidosis or chronic left ventricular dysfunction, because of the nearly normal cardiac indices and pulmonary capillary wedge pressures. These data suggest that referral guidelines should be modified to include these particular risk factors, at least until further prospective studies are performed.

Early referral allows for timely evaluation for possible listing. If the risks specific to transplantation in sarcoidosis are considered and carefully evaluated, outcomes match those for other disorders. Recurrence of sarcoidosis in the lung allografts has been reported but does not affect survival or risk for complications.

CLINICAL COURSE

Between 30% and 60% of patients with sarcoidosis are symptomatic. African Americans tend to have more severe disease at presentation. Up to two thirds of patients have spontaneous resolution or improvement in disease activity. Of those with remission, one third have symptom resolution within 1 year and 85% within 2 years. Only 1% to 5% of patients die of sarcoid-related disease, which usually is a result of severe

Box 48-1 Sarcoidosis Risk Factors

Risk Factors Associated With Worsened Outcomes in Sarcoidosis

African-American ethnicity
Lupus pernio
Chronic uveitis
Onset after the age of 40 years
Chronic hypercalcemia
Nephrocalcinosis
Progressive or prolonged symptoms for longer than 6 months
Absence of erythema nodosum
Splenomegaly
Nasal mucosal involvement
Cystic bone lesions
Neurosarcoidosis
Myocardial involvement
Involvement of more than 3 organ systems
Stage III/IV pulmonary disease

Risk Factors Associated With Death of Patient on Lung Transplant Waiting List

Elevated right atrial pressure
Underlying pulmonary hypertension
Higher required levels of supplemental oxygen
African American race

pulmonary, cardiac, or neurologic dysfunction. Sarcoidosis does not affect pregnancy, nor does pregnancy affect sarcoidosis. Corticosteroids, as in asthma, are viewed as safe. Use of other immunosuppressive therapy and hydroxychloroquine is contraindicated in pregnancy. Earlier studies have outlined multiple risk factors associated with worsened prognosis in sarcoidosis (Box 48-1). Taken together, the prospect of multisystem involvement and the effect of this illness on the patient's psychosocial well-being highlight the need for a multidisciplinary approach.

CONTROVERSIES AND PITFALLS

The diagnosis of sarcoidosis should be considered early during the evaluation of systemic and respiratory complaints, particularly with additional clues of uveitis, peripheral lymphadenopathy, skin rash, or cranial nerve involvement. To obtain histologic confirmation of the diagnosis, the least invasive approach should be considered. Biopsy of skin, lacrimal gland, peripheral lymph node, and lung or thoracic lymph nodes through bronchoscopy has a high diagnostic yield. Bronchoscopy with endobronchial and transbronchial biopsy, even in patients with a stage I pattern on the chest radiograph, has more than a 60% yield and should be considered before mediastinoscopy. Lymph node aspiration guided by endobronchial ultrasound imaging will add to the diagnostic yield. Cardiac sarcoidosis should be considered in those patients without risk for coronary artery disease who have unexplained arrhythmias and cardiac dysfunction.

The lack of randomized, controlled treatment trials limits treatment options. Corticosteroids remain the most commonly used therapeutic agents. The role of corticosteroid-sparing medications continues to evolve. When corticosteroids are not tolerated in serious disease, hydroxychloroquine, methotrexate, azathioprine, and anti-TNF agents are used.

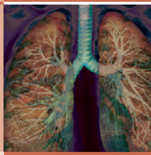
PARENCHYMAL LUNG DISEASES



Chapter 49

Eosinophilic Lung Disease

Vincent Cottin • Jean-François Cordier

THE EOSINOPHIL LEUKOCYTE AND EOSINOPHILIC PNEUMONIA

The eosinophilic lung diseases are characterized by prominent infiltration of the lung structures by eosinophils, leading to several distinct clinical disorders, especially eosinophilic pneumonia. The most important eosinophilic lung diseases other than eosinophilic pneumonia are allergic bronchopulmonary aspergillosis (ABPA) and hypereosinophilic asthma, which primarily affect the airways.

THE EOSINOPHIL LEUKOCYTE

Eosinophils play a major role in immunity against bacteria, viruses, parasites, and tumors and participate in the pathogenesis of allergic diseases. They also take part in the pathogenesis of numerous inflammatory processes and may be the major cause of tissue injury in eosinophilic disorders. Advances have been made recently in elucidation of the complex role of eosinophils in health and disease through the study of several models of genetically engineered murine cell lines deficient in the eosinophil lineage. Approaches that selectively target the eosinophil lineage in vivo are being developed with a therapeutic perspective, such as use of the humanized antiinterleukin (IL)-5 antibody mepolizumab.

The role of the eosinophil leukocyte as a multifunctional cell is now well appreciated in both innate and adaptive immunity. Eosinophils express Toll-like receptors (TLRs) and participate in the nonspecific inflammatory reaction in tissues in response to various ligands; however, they also play a major role by interacting with T cells. Once perceived as a terminal effector cell in parasitic infections and allergy, the eosinophil is now recognized to be able to modulate T cell responses, by presenting the antigen to naive as well as to antigen-primed T cells, thereby inducing T helper cell type 2 (T_H2) development, cytokine production, and T cell migration to sites of inflammation. T cells can then secrete T_H2-type cytokines (the interleukins IL-4, IL-5, and IL-13), which further enhance the recruitment of eosinophils. Secretion of IL-4 and IL-13 by the eosinophil in turn amplifies the T_H2 response in the lung in a positive loop. In addition, eosinophils may present antigens from the airways or the lung tissue to T_H0 cells in the draining lymph node in the context of major histocompatibility complex (MHC) class II. Eosinophil precursors differentiate in the bone marrow under the action of several cytokines, including interleukin (IL)-5, IL-3, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Eosinophils are recruited in response to diverse stimuli from the circulation into inflammatory foci, including sites in the lung, where they have the potential to modulate immune responses. Recruitment of eosinophils involves cell adhesion and attraction, diapedesis, and chemotaxis by cytokines (mainly IL-5 and eotaxin) and the chemokine receptor CCR3. In tissues, the eosinophils may be triggered through engagement of receptors for cytokines, immunoglobulins, and complement, with ensuing release of active mediators, including proinflammatory cytokines, arachidonic acid–derived mediators, enzymes, reactive oxygen species, complement proteins, chemokines, chemoattractants, metalloproteases, and other toxic granule proteins, especially cationic proteins. Indeed, activation and degranulation of the eosinophil releases specific cationic proteins, including major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), protein eosinophil peroxidase (EPO), and MBP homologue. These proteins released mostly by degranulation have proinflammatory properties, through the upregulation of chemoattraction, expression of adhesion molecules, regulation of vascular permeability, contraction of smooth muscle cells, and direct cytotoxicity. The eosinophils also express receptors for cytokines, complement, immunoglobulins, chemokines, and apoptotic signals; regulate mast cell functions; and interact with basophils, endothelial cells, macrophages, platelets, and fibroblasts. However, histopathologic lesions in eosinophilic pneumonias are largely reversible with treatment, with the possible exception of bronchial wall damage in ABPA.

HISTOPATHOLOGIC FEATURES OF EOSINOPHILIC PNEUMONIA

The diagnosis of eosinophilic pneumonia only exceptionally requires lung biopsy, and histopathologic features were described several decades ago. Eosinophilic pneumonia as exemplified by idiopathic chronic eosinophilic pneumonia (ICEP) is characterized by the prominent infiltration of the lung structures by eosinophils. The lung interstitium is infiltrated by eosinophils, and essentially the alveolar spaces are filled with eosinophils and a fibrinous exudate, with conservation of the global architecture of the lung. Immunohistochemical and electron microscopic studies have demonstrated eosinophil degranulation within involved lung tissue.

Some overlap is common between eosinophilic and organizing pneumonia, with organization of the alveolar inflammatory exudate (less prominent than in cryptogenic organizing pneumonia). In addition, eosinophilic microabscesses and a nonnecrotizing vasculitis are common in ICEP and idiopathic acute eosinophilic pneumonia (IAEP). Macrophages and occasional multinucleate giant cells may be present within the infiltrate. The histopathologic pattern in IAEP usually comprises intra-alveolar and interstitial eosinophilic infiltrates, diffuse alveolar

Box 49-1 Diagnosis of Eosinophilic Pneumonias

Characteristic Clinical-Imaging Features

- Chronic eosinophilic pneumonia (onset >1 month earlier)

OR

- Acute eosinophilic pneumonia (onset <1 month earlier)

OR

- Löffler syndrome (transient mild dyspnea, cough, fever, and pulmonary infiltrates)

Demonstration of Eosinophilia (Preferably Alveolar)

- Bronchoalveolar lavage (BAL) analysis with >25% eosinophils and preferably >40%

OR

- Markedly elevated peripheral blood eosinophilia (eosinophil cell count >1000/μL and preferably 1500/μL)

OR

- Lung biopsy demonstrating eosinophilic pneumonia (if performed)

Box 49-2 Clinical Classification of the Eosinophilic Lung Diseases

Eosinophilic Lung Disease of Determined Origin

Eosinophilic Pneumonias of Parasitic Origin
Tropical eosinophilia
Ascaris pneumonia
Larva migrans syndrome
Strongyloides stercoralis infection
Eosinophilic pneumonias in other parasitic infections

Eosinophilic Pneumonias of Other Infectious Causes

Allergic Bronchopulmonary Aspergillosis and Related Syndromes
Allergic bronchopulmonary aspergillosis
Other allergic bronchopulmonary syndromes associated with fungi or yeasts
Bronchocentric granulomatosis

Iatrogenic and Toxic Agent–Induced Eosinophilic Pneumonias
Drugs
Radiation therapy to the breast
Toxic agents

Eosinophilic Lung Disease of Undetermined Origin

Limited to the Lung
Idiopathic chronic eosinophilic pneumonia
Idiopathic acute eosinophilic pneumonia

Associated with Systemic Disease
Churg-Strauss syndrome
Hypereosinophilic syndromes (lymphocytic and myeloproliferative variants)

Lung Diseases with Possible (Usually Minor) Associated Eosinophilia

Organizing pneumonia
Asthma, eosinophilic bronchitis
Idiopathic interstitial pneumonias
Langerhans cell granulomatosis
Sarcoidosis
Lung transplantation

damage, intraalveolar fibrinous exudates, organizing pneumonia, and non-necrotizing vasculitis.

DIAGNOSIS OF EOSINOPHILIC PNEUMONIA

The diagnosis of eosinophilic pneumonia relies on both characteristic clinical-imaging features and the demonstration of alveolar eosinophilia and/or peripheral blood eosinophilia (Box 49-1). Bronchoalveolar lavage (BAL) is a noninvasive alternative to lung biopsy in this setting. The percentage of eosinophils in BAL fluid is less than 2% in normal control subjects, and a differential cell count for eosinophils of 2% to 25% may be found in nonspecific conditions. Therefore, a cutoff value of 25% eosinophils or more in BAL fluid, and preferably 40% or more, is recommended for the diagnosis of eosinophilic pneumonia. The presence of marked eosinophilia in BAL fluid obviates the need for lung biopsy in this disorder, especially when the eosinophils are the predominant cell population in BAL fluid (macrophages excepted). Markedly elevated peripheral blood eosinophilia (greater than 1000/μL and preferably 1500/μL) together with typical clinical radiologic features are highly suggestive of the diagnosis of eosinophilic pneumonia, and BAL may not be always mandatory in such patients, although other disorders may be associated with pulmonary infiltrates and peripheral eosinophilia (e.g., bacterial pneumonia, parasitic pneumonia, infiltrates related to lymphoma). Peripheral blood eosinophilia may be absent at presentation, especially in IAEP and in patients receiving corticosteroid treatment.

Eosinophilic pneumonia may be separated into that of undetermined origin, which usually may be included within well-individualized syndromes, and that with a definite cause (mainly infection and drug reaction) (Box 49-2). Potential causes must be thoroughly investigated, because identification of a cause may lead to effective therapeutic measures.

EOSINOPHILIC LUNG DISEASES OF KNOWN ORIGIN

EOSINOPHILIC PNEUMONIA IN PARASITIC DISEASES

Parasite infestation is the main cause of eosinophilic pneumonia worldwide. Clinical manifestations are nonspecific. Tropical pulmonary eosinophilia is a disease of decreasing prevalence caused by the filarial parasites *Wuchereria bancrofti* and *Brugia malayi*, deposited in the skin by mosquitoes. The clinical features of tropical eosinophilic pneumonia largely result from an immune response of the host to the antigenic constituents of circulating microfilariae trapped in the lung vasculature (leading to cough that may be associated with fever, weight loss, and anorexia). Patients with tropical pulmonary eosinophilia do not usually have clinical features of lymphatic filariasis. The chest radiograph shows bilateral infiltrative opacities. Blood eosinophilia with counts of more than 2000/μL eosinophils is characteristic of the early stage, occasionally with counts of up to 60,000/μL during the chronic phase of disease. Microfilariae are not detectable in the blood. The diagnosis of filariasis may be established by a strongly positive result on serologic testing in patients residing in an endemic area, with persisting and prominent blood eosinophilia at counts of more than 3000/μL and IgE levels exceeding 10,000 ng/mL. It is further supported by clinical improvement in the weeks after treatment with diethylcarbamazine; the addition of corticosteroids may be beneficial in severe cases.

The nematode *Ascaris lumbricoides* is the most common helminth infecting humans. The disease is transmitted through consumption of food contaminated by human feces containing parasitic eggs. Löffler syndrome (transient mild eosinophilic pneumonia) may develop during the migration of the larvae through the lung. Signs and symptoms often are limited to cough, wheezing, and transient fever, which resolve within a few days, but blood eosinophilia with counts as high as 20,000/μL may be present and last for several weeks. The diagnosis usually is obtained by the delayed finding of the worm or ova in the stools within 3 months of onset of the pulmonary manifestations; larvae may occasionally be found at an earlier stage in sputum or gastric aspirates.

Visceral larva migrans syndrome caused by *Toxocara canis* occurs throughout the world. Humans and especially children become infected after ingestion of eggs released in feces of infected dogs (especially in the soil of urban public playgrounds). Fever, seizures, fatigue, and pulmonary manifestations may occur (cough, dyspnea, wheezes, or crackles heard on pulmonary auscultation and pulmonary infiltrates evident on the chest radiograph). Blood eosinophilia may be present initially or may develop only in the following days. The diagnosis of toxocariasis is obtained by serologic methods, especially enzyme-linked immunosorbent assay (ELISA). Symptomatic treatment is recommended; the use of antihelmintics is controversial.

Strongyloides stercoralis is an intestinal nematode, the larvae of which infect humans through the skin by contact with damp soil. Eosinophilia is present in recently infected persons. Strongyloidiasis may cause severe disease, affecting all organs (hyperinfection syndrome), especially in immunocompromised patients, sometimes years after the initial infection, with or without peripheral eosinophilia and bilateral patchy infiltrates on chest radiograph. The diagnosis of strongyloidiasis depends on the demonstration of larvae in the feces or in any secretion or tissue specimen (including sputum and BAL fluid). Immunodiagnostic assays by ELISA methods may be useful for diagnosis and screening. Treatment with thiabendazole is recommended.

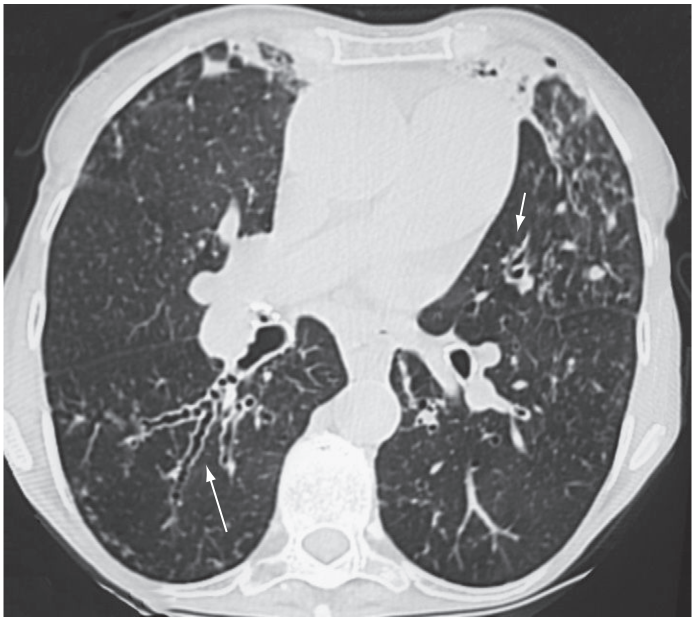


Figure 49-1 Bilateral bronchiectasis in a patient with allergic bronchopulmonary aspergillosis. Affected structures (*arrows*) are well visualized on this computed tomography scan, which also shows some infiltrative opacities.

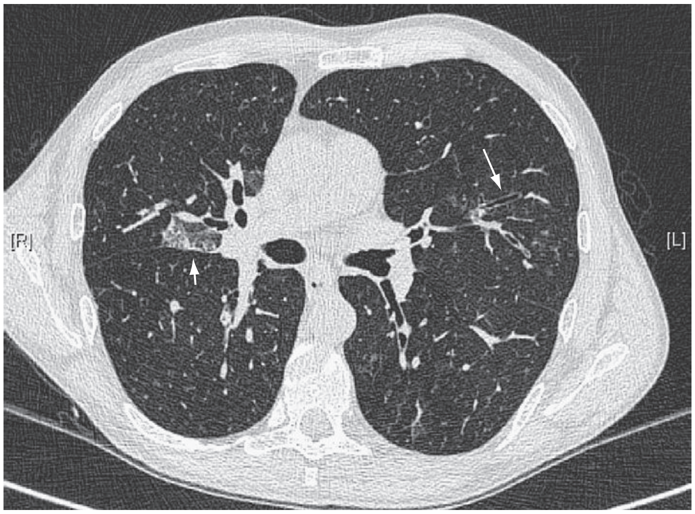

Figure 49-2 Bronchiectasis (*arrows*) in another patient with allergic bronchopulmonary aspergillosis. The computed tomography scan also shows ground glass opacities (*arrowhead*) and centrilobular micronodules.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

ABPA occurs mainly in adults with preexisting asthma (with an estimated prevalence of 1% to 2%) and in patients with cystic fibrosis (with an estimated prevalence of up to 7% to 10%). It results from a complex allergic and immune reaction in the bronchi and the adjacent lung parenchyma in response to antigens from *Aspergillus* colonizing the airways of patients with asthma. A pattern of allergic bronchopulmonary mycosis similar to that in ABPA has rarely been reported with infections caused by other fungi or yeasts, including *Penicillium*, *Drechslera*, *Torulopsis*, *Mucor*, *Candida*, *Pseudallescheria*, *Bipolaris*, *Curvularia*, *Fusarium*, *Cladosporium*, and *Saccharomyces*. The immunologic response to the fungus combines both type I and type III hypersensitivity in an allergic host and is mediated by the immunoglobulins IgG, IgE, and IgA, as well as the helper T cell subset 2 (T_H2) $CD4^+$ cells, and by activation and degranulation of mast cells and eosinophils, resulting in progressive damage to the bronchial and surrounding pulmonary tissue. Mucous plugs containing *Aspergillus* obstruct the airways, with subsequent atelectasis, bronchial wall damage, and proximal bronchiectasis predominating in the upper lobes. Of note, IgE sensitization to *Aspergillus* in nonasthmatic patients who do not fulfill criteria for ABPA is associated with reduced lung function. ABPA may be associated with allergic *Aspergillus* sinusitis in a syndrome called sinobronchial allergic aspergillosis. Genetic susceptibility to develop ABPA has been demonstrated, with an increased prevalence of heterozygotic cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations in non–cystic fibrosis patients with ABPA, the association of ABPA with a polymorphism within the IL-4 receptor α-chain gene, and association with certain human leukocyte antigen (HLA) DR subtypes.

Early ABPA is characterized by fever, expectoration of mucous plugs, peripheral blood eosinophilia with counts higher than 1000/μL, and pulmonary infiltrates caused by eosinophilic pneumonia, or segmental or lobar atelectasis caused by mucous plugging. Chronic ABPA is characterized by asthma, eosinophilia, and bronchopulmonary manifestations including bronchiectasis (Figures 49-1 and 49-2 and Box 49-3). The presence of bronchiectasis on computed tomography (CT) images in a patient with asthma is therefore highly suggestive of ABPA; however, typical proximal bronchiectasis may be absent, and such cases are designated ABPA-seropositive. Centrilobular

Box 49-3 Minimal Essential Diagnostic Criteria for Allergic Bronchopulmonary Aspergillosis (ABPA) in Patients With Asthma

Patients With Asthma and Central Bronchiectasis

1. Asthma
2. Central bronchiectasis (involving inner two thirds of chest CT field)
3. Immediate cutaneous reactivity to *Aspergillus*
4. Total serum IgE concentration <417 kU/L (1000 ng/mL)
5. Elevated serum IgE–*A. fumigatus* and/or IgG–*A. fumigatus*

(Infiltrates on chest radiograph and serum precipitating antibodies to *A. fumigatus* may be present but are not minimal essential diagnostic criteria.)

Patients With Asthma and ABPA-Seropositive Status

Patients with the foregoing criteria 1, 3, 4, 5

(Infiltrates may be present on chest radiograph, but this finding does not constitute a minimal essential diagnostic criterion.)

Patients With Cystic Fibrosis

1. Clinical deterioration (increased cough, wheezing, exercise intolerance, increased sputum, decrease in pulmonary function)
2. Immediate cutaneous reactivity to *Aspergillus* or presence of IgE–*A. fumigatus*
3. Total serum IgE concentration <417 kU/L (1000 ng/mL)
4. Precipitating antibodies to *A. fumigatus* or serum IgG–*A. fumigatus*
5. Abnormalities on chest radiograph (infiltrates, mucous plugging, or a change from earlier films)

nodules and mucoid impaction on CT scan (typically characterized by a V-shaped lesion, with the vertex pointing toward the hilum) also are highly suggestive of ABPA. The expectoration of mucous plugs, the presence of *Aspergillus* in sputum, and late skin reactivity to *Aspergillus* antigen also are common at this stage; however, *Aspergillus* is not reliably identified in sputum or BAL fluid samples of patients with ABPA, and positive cultures are not required for diagnosis. The finding of *Aspergillus* organisms may reflect colonization and thus is not specific for ABPA. Total serum IgE levels of at least 1000 IU/mL constitute a hallmark of ABPA. Peripheral blood eosinophilia is common but is not a required diagnostic criterion.

Identification of immunologic hypersensitivity to *Aspergillus fumigatus* in patients with asthma contributes to the diagnosis of ABPA; it may consist in immediate reaction to prick test for *Aspergillus* antigen, precipitating serum antibodies against *A. fumigatus*, and/or elevated specific serum IgE against *A. fumigatus*. Among approximately 40 antigenic components of *Aspergillus* that can bind with IgE antibodies, specific antibodies to Asp f4 and Asp f6 may be particularly helpful for diagnostic purposes.

Suspicion of ABPA should prompt the measurement of serum total IgE level and skin testing for *Aspergillus*. Early recognition of ABPA allows treatment of exacerbations of ABPA with corticosteroids (with initiation of prednisone at approximately 0.5 mg/kg per day for 2 to 4 weeks then tapered) to prevent the progression of the disease to the irreversible end-stage. Inhaled corticosteroids may reduce the need for long-term oral corticosteroids. Oral itraconazole used at a dose of 200 mg twice daily for 4 to 6 months is a useful adjunct to corticosteroids, reducing the burden of fungal antigenic stimulation, allowing reduction of the corticosteroid oral dose, reducing the rate of exacerbations, and possibly improving the long-term outcome. The newer antifungal agent voriconazole has been used as a corticosteroid-sparing agent in ABPA only in isolated case reports and currently is not indicated in ABPA. Omalizumab, an anti-IgE recombinant antibody, has been used successfully in some cases; however, clinical experience is limited.

Box 49-4 Drugs That Can Cause Eosinophilic Pneumonia*

Acetylsalicylic acid
Captopril
Carbamazepine
Diclofenac
Ethambutol
Fenbufen
Granulocyte-macrophage colony-stimulating factor (GM-CSF)
Ibuprofen
L-Tryptophan
Minocycline
Naproxen
Paraaminosalicylic acid (4-aminosalicylic acid)
Penicillins
Phenylbutazone
Piroxicam
Pyrimethamine
Sulindac
Sulfamides, sulfonamides
Tolfenamic acid
Trimethoprim-sulfamethoxazole

*A more detailed list of drugs reported to cause eosinophilic pneumonia may be found at www.pneumotox.com.

IATROGENIC EOSINOPHILIC PNEUMONIAS SECONDARY TO DRUGS, TOXIC AGENTS, AND RADIATION THERAPY

Drugs taken in the weeks preceding clinical onset of eosinophilic pneumonia must be thoroughly investigated, including illicit drugs (cocaine or heroin). Eosinophilic pneumonia has been reported in association with many drugs, but causality has been confidently established for fewer than 20 specific agents (Box 49-4).

Drug-induced eosinophilic pneumonia may develop progressively and manifest as chronic eosinophilic pneumonia, as a syndrome of transient pulmonary infiltrates with eosinophilia (Löffler syndrome), and occasionally as an acute pneumonia sometimes requiring mechanical ventilation. Acute eosinophilic pneumonia may occur in the context of drug rash with eosinophilia and systemic symptoms (DRESS), with frequent reactivation of human herpesvirus type 6, especially that due to anticonvulsant therapy, antibiotics (minocycline), allopurinol, and nonsteroidal antiinflammatory agents.

Corticosteroids often are given concomitantly with drug withdrawal to accelerate clinical improvement. When present, associated cutaneous rash or pleural effusion increases the likelihood of the diagnosis.

As with ICEP, chronic eosinophilic pneumonia has been described after radiation therapy for breast cancer in women. The clinical syndrome is similar to that for radiation-induced organizing pneumonia.

OTHER LUNG DISEASES WITH ASSOCIATED EOSINOPHILIA

Eosinophilia may be found in other bronchopulmonary disorders in which eosinophilic pneumonia is not prominent.

Eosinophilic inflammation of the airways is a pathologic feature defining a phenotype of asthma. Some mild increase in eosinophils in peripheral blood and BAL fluid differential cell count (usually less than 5%) may be found in patients with asthma. Monitoring of the sputum eosinophil count may help in adapting the treatment and reducing asthma exacerbations and hospital admissions. Patients with the eosinophilic phenotype of asthma are considered to have greater airway remodeling and more frequent exacerbations than those without tissue eosinophilia. Mepolizumab, a humanized monoclonal antibody against IL-5, has been demonstrated to reduce the number of severe exacerbations in patients with refractory eosinophilic asthma (as defined by sputum eosinophil percentage of more than 3% on at least one occasion in the previous 2 years despite high-dose inhaled corticosteroid treatment); mepolizumab also improved the quality of life related to asthma and lowered eosinophil counts in blood and sputum. Some sparing of prednisone therapy and reduction in blood and sputum eosinophil counts also were obtained using mepolizumab therapy in patients with sputum eosinophilia (more than 3% eosinophils) and prednisone-dependent asthma. The therapeutic effect of mepolizumab confirms the role of eosinophils as an effector cell in the minority of asthma patients with the eosinophilic phenotype. More important, blood eosinophilia (i.e., counts of more than 1500/µL) may occasionally occur in the absence of any determined cause or context of systemic disease—a condition referred to as *hypereosinophilic asthma*, which frequently is severe and requires systemic corticosteroid therapy. Hypereosinophilic asthma may evolve to ICEP or overt Churg-Strauss syndrome (CSS), or it may remain solitary, with frequent dependency on oral corticosteroids.

Eosinophilic bronchitis (without asthma) with a high percentage of eosinophils (up to 40%) in sputum is a well-characterized cause of chronic cough responsive to corticosteroid treatment. Bronchial asthma and bronchial hyperreactivity are absent. Patients usually have normal lung function. Eosinophilic bronchitis may exceptionally reveal the myeloid variant of the hypereosinophilic syndrome.

Bronchocentric granulomatosis is a rare condition with nonspecific clinical and radiologic manifestations (fever, cough, and blood eosinophilia with counts generally greater than 1000/µL), diagnosed by lung biopsy. Corticosteroids constitute the mainstay of treatment.

Mildly increased levels of eosinophils may be found on the BAL fluid differential cell count in idiopathic interstitial pneumonias; this finding is associated with a poor prognosis. Focal eosinophilic pneumonia has been reported in cases of usual interstitial pneumonia, nonspecific interstitial pneumonia, and desquamative interstitial pneumonia. The typical clinical and imaging features of cryptogenic organizing pneumonia may closely mimic those of ICEP; some clinical or pathologic overlap between these two diseases is likely, although BAL fluid eosinophilia usually is mild, with differential cell counts less than 20%, in cryptogenic organizing pneumonia. Eosinophilia (usually mild) may be present in pulmonary Langerhans cell histiocytosis and in sarcoidosis.

EOSINOPHILIC LUNG DISEASE OF UNKNOWN ORIGIN

IDIOPATHIC CHRONIC EOSINOPHILIC PNEUMONIA

ICEP is characterized by the progressive development of respiratory and systemic symptoms over several weeks. Cough, dyspnea, and chest pain are often accompanied by prominent fatigue, malaise, fever, and weight loss. Wheezes or crackles are found in one third of patients. Chronic rhinitis or sinusitis is present in approximately 20% of patients.

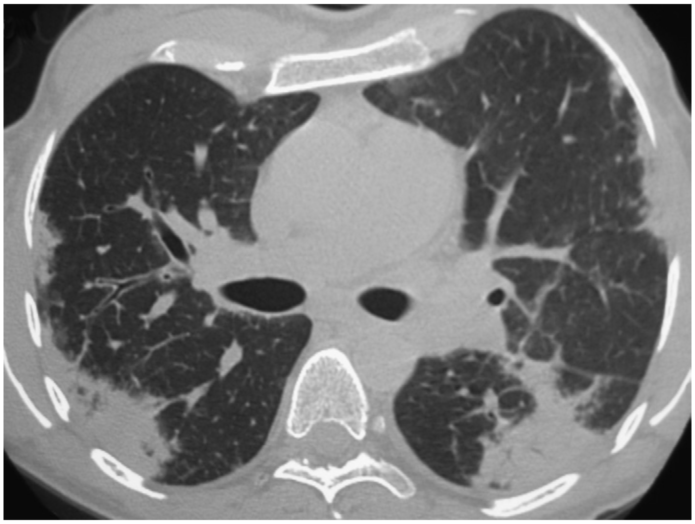

Figure 49-3 Bilateral peripheral patchy opacities are evident on this computed tomography scan of the thorax of a patient with idiopathic chronic eosinophilic pneumonia.

Most patients are nonsmokers. ICEP predominates in women (2 : 1 female-to-male ratio), with a mean age of 45 years at diagnosis, and a previous history of atopy in approximately half of the patients. Previous asthma is present in up to two thirds of the patients (it may get worse after the occurrence of ICEP), but it also may occur concomitantly with the diagnosis of ICEP or develop after it. Nonrespiratory minor manifestations are possible in ICEP, suggesting some overlap with CSS; however, any nonrespiratory manifestation (and particularly cardiac manifestations) should systematically prompt further evaluation for possible systemic disease, especially CSS.

Imaging features of ICEP (Figure 49-3) characteristically consist of alveolar opacities, with ill-defined margins and variable density, ranging from ground glass to consolidation. Migration of the infiltrates highly suggestive of the diagnosis occurs in approximately a quarter of the cases; however, it also may occur in cryptogenic organizing pneumonia. A peripheral predominance of the lesions (described as the classic pattern of "photographic negative of pulmonary edema") is seen in approximately one fourth of patients. On high-resolution computed tomography (HRCT), the opacities are almost always bilateral and predominate in the upper lobes, with coexisting peripheral ground glass and consolidation opacities. In addition, septal line thickening, bandlike opacities parallel to the chest, or mediastinal lymph node enlargement may be seen. Small pleural effusions are present in only 10% of cases at HRCT.

High-level peripheral blood eosinophilia is the key to the diagnosis (mean blood eosinophil count of approximately 5500/µL) (Box 49-5). Alveolar eosinophilia, with BAL fluid differential cell count usually more than 40%, is a hallmark of ICEP. Because the BAL eosinophil cell count drops within days after institution of corticosteroid treatment, assessment for alveolar eosinophilia should be undertaken before any corticosteroid intake. Sputum eosinophilia also may be present; however, its diagnostic value has not been evaluated. C-reactive protein levels are elevated. Total blood IgE level is increased in approximately half the cases.

Box 49-5 Diagnostic Criteria for Idiopathic Chronic Eosinophilic Pneumonia

- Diffuse pulmonary alveolar consolidation with air bronchogram and/or ground glass opacities on chest imaging, especially with peripheral predominance
- Eosinophilia on BAL fluid differential cell count: ≥40% (or peripheral blood eosinophilia, with counts $\geq 1.0 \times 10^9$ cells/L)
- Respiratory symptoms present for at least 2 to 4 weeks
- Absence of other known causes of eosinophilic lung disease (especially exposure to any of various drugs known to induce pulmonary eosinophilia)

BAL, bronchoalveolar lavage.

Lung function tests in ICEP show an obstructive ventilatory defect in approximately half and a restrictive ventilatory defect in half the cases. Usually mild hypoxemia is present in most of the patients.

ICEP responds dramatically to corticosteroid treatment. We use an initial dose of 0.5 mg/kg of oral prednisone per day for 2 weeks, followed by 0.25 mg/kg per day for 2 weeks, then corticosteroids are progressively reduced over a total duration of about 6 months and stopped. Improvement of the symptoms occurs within 2 days, and chest radiograph opacities clear within 1 week and eventually disappear without sequelae in almost all patients. Death resulting from ICEP is extremely rare. Relapses occur in more than half the patients while decreasing or after stopping the corticosteroid treatment and respond very well to resumed corticosteroid treatment; a dose of 20 mg per day of prednisone usually is sufficient to treat the relapses. Most patients need corticosteroids for more than 6 months, and often for several years. Relapses of ICEP may be less frequent in asthmatic patients who receive inhaled corticosteroids after stopping maintenance oral corticosteroids.

IDIOPATHIC ACUTE EOSINOPHILIC PNEUMONIA

IAEP differs from ICEP not only in its acute onset (less than 1 month) and severity but also in the absence of relapse after recovery. This acute pneumonia develops in previously healthy people, with possible respiratory failure, and may be misdiagnosed as infectious pneumonia or acute respiratory distress syndrome (ARDS). Patients with IAEP often are admitted to the intensive care unit. Blood eosinophilia, often lacking at presentation, contrasts with frank alveolar eosinophilia in BAL fluid. Current diagnostic criteria are listed in Box 49-6.

IAEP occurs mainly in young adults, with a male predominance and no previous asthma history. In several cases, IAEP developed soon after the initiation of tobacco smoking or change in smoking habits. Potential respiratory exposures within the days before onset of disease have been reported (e.g., cave exploration, heavy dust inhalation, inhalation of smoke), suggesting that exposure to inhaled contaminants or any nonspecific injurious agent may trigger the disease.

IAEP manifests with the acute onset of cough, dyspnea, fever, and chest pain, sometimes with abdominal complaints or myalgias. Tachypnea, tachycardia, and crackles are present on examination. The chest radiograph shows bilateral infiltrates (see Figure 49-4), with mixed alveolar interstitial and opacities, especially Kerley lines. Chest CT mainly shows ground glass opacities and air space consolidation, together with poorly defined nodules, interlobular septal thickening, and bilateral pleural effusions (in two thirds of patients)—an imaging pattern very distinct from that of ICEP that may evoke the diagnosis of IAEP.

Box 49-6 Diagnostic Criteria for Idiopathic Acute Eosinophilic Pneumonia

- Acute onset with febrile respiratory manifestations (present for ≤1 month, and especially ≤7 days before medical examination)
- Bilateral diffuse infiltrates on imaging
- PaO_2 on room air ≤60 mm Hg, or PaO_2/FIO_2 ≤300 mm Hg, or oxygen saturation on room air <90%
- Lung eosinophilia, with ≥25% eosinophils on BAL fluid differential cell count (OR eosinophilic pneumonia at lung biopsy, if done)
- Absence of determined cause of acute eosinophilic pneumonia, including infection or exposure to drugs known to induce pulmonary eosinophilia, although patient history may include recent onset of tobacco smoking or exposure to inhaled dusts

BAL, bronchoalveolar lavage.

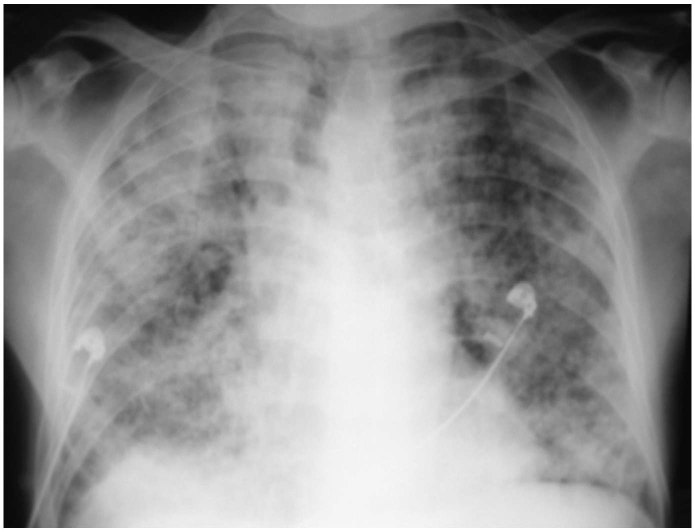

Figure 49-4 Chest radiograph showing diffuse infiltrative pulmonary opacities in a patient with idiopathic acute eosinophilic pneumonia with respiratory failure.

Blood eosinophilia usually is lacking at presentation, and the diagnosis of eosinophilic lung disease may not be considered on admission. The finding of BAL fluid eosinophilia usually is sufficient, with differential counts greater than 25%, to obviate the need for lung biopsy; bacterial cultures of BAL fluid are sterile. The peripheral blood eosinophil count often rises over a few days during the initial course of disease—an evolution suggestive of the diagnosis. Eosinophilia also may be found in pleural effusion or sputum samples. High levels of IgE may be present as well.

Lung function tests are performed only in the less severe cases and will show a mild restrictive ventilatory defect, reduced carbon monoxide transfer capacity, and increased alveolar-arterial oxygen gradient, measured as $PO_2(A–a)$. Severe hypoxemia may be present, with most patients fulfilling diagnostic criteria for acute lung injury (including a PaO_2/FIO_2 ratio of 300 mm Hg or less) or for ARDS (PaO_2/FIO_2 ratio of 200 mm Hg or less), with mechanical ventilation necessary in most of them. In marked contrast with ARDS, extrapulmonary organ failure or shock is exceptional; however, a few cases of fatal IAEP have been reported.

Lung biopsy generally is not necessary, and the diagnosis is established on clinical, radiologic, and BAL findings. The histopathologic features of IAEP include acute and organizing diffuse alveolar damage together with interstitial alveolar and bronchiolar infiltration by eosinophils, intraalveolar eosinophils, and interstitial edema. Although recovery may occur without corticosteroid treatment, corticosteroid treatment usually is given for 2 to 4 weeks, with a starting dose of oral prednisone or intravenous methylprednisolone of 1 to 2 mg/kg per day. Complete clinical and radiologic recovery occurs rapidly after initiation of corticosteroids, with no relapse (in contrast with ICEP). A careful search for a potential cause of IAEP is mandatory, especially infectious agents, parasites, and drugs, including illicit and over-the-counter drugs.

CHURG-STRAUSS SYNDROME

CSS (see also Chapter 59) is included in the group of small-vessel vasculitides and is defined as an eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels; it is associated with asthma and eosinophilia. All of the pathologic lesions—initially described from autopsied cases—are seldom found in a single biopsy specimen, and abnormalities often are limited to an eosinophilic perivascular infiltration of the tissues characteristic of the early (prevasculitic) phase of the disease. CSS is one of the pulmonary vasculitides associated with antineutrophil cytoplasmic antibodies (ANCA), together with granulomatosis with polyangiitis (Wegener) and microscopic polyangiitis, with ANCA found only in about 40% of cases of CSS.

CSS is a very rare disorder, occurring especially in the fourth and fifth decades of life, with no gender predominance. About one third of the patients have evidence of allergy, mostly perennial allergies to dust mites. The natural history of CSS usually incorporates three phases: rhinosinusitis and asthma, blood and tissue eosinophilia, and eventual emergence of systemic vasculitis. Eosinophilic rhinitis, present in three fourths of the cases, often is accompanied by relapsing paranasal sinusitis and nasal polyps; however, septal nasal perforation or saddle nose deformity is rare. Asthma becomes progressively cortico-dependent, usually preceding the onset of vasculitis by 3 to 9 years (however, these conditions may be contemporary). The severity of asthma may worsen before onset of the vasculitis, with attenuation thereafter, and further improvement on remission of the vasculitis.

The chest radiograph may remain normal in appearance throughout the course of the disease. Lung opacities, present in more than half of patients, correspond to eosinophilic pneumonia and consist mainly of ill-defined pulmonary infiltrates, sometimes migratory and transient. Pleural eosinophilic exudate, present in approximately one fourth of patients, must be distinguished from the transudate associated with cardiac failure resulting from cardiac eosinophilic involvement with severe cardiomyopathy. HRCT mainly shows areas of ground glass attenuation or air space consolidation, with peripheral predominance or random distribution (Figure 49-5). Centrilobular nodules, bronchial wall thickening or dilatation, interlobular septal thickening, and hilar or mediastinal lymphadenopathy are less common. These abnormalities are nonspecific and resemble those seen in ICEP, although the subpleural distribution of consolidation is less pronounced, centrilobular nodules within ground glass opacities are more frequent, and traction bronchiectases are less frequent in CSS than in ICEP. Pulmonary cavitary lesions are exceptional.

Blood eosinophilia, with cell counts greater than 1500 and often 5000/μL, usually parallels disease activity. It disappears with dramatic rapidity after the initiation of corticosteroid treatment. Eosinophilia also is evident on the BAL fluid differential cell count, which may be more than 60%, and sometimes in the pleural fluid. IgE levels usually are markedly increased. High levels of urinary EDN may represent an indicator of disease activity.

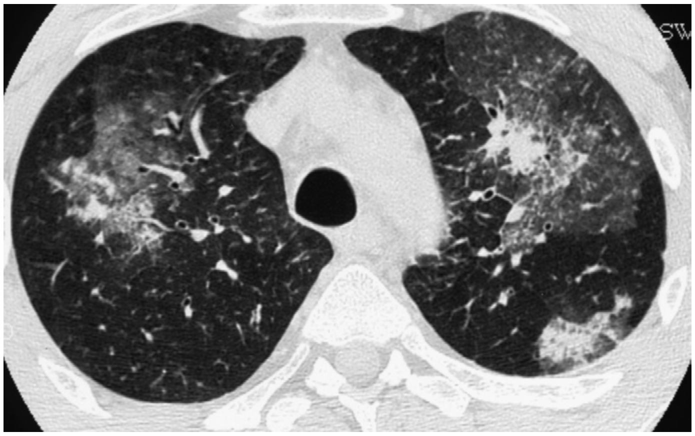

Figure 49-5 Computed tomography scan of the thorax showing ground glass opacity and consolidation with central predominance in a patient with Churg-Strauss syndrome.

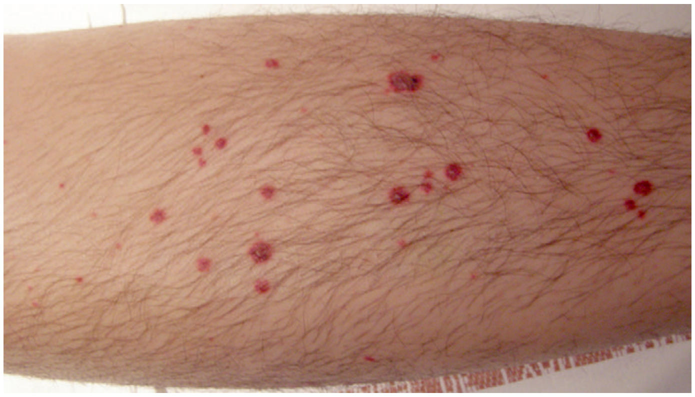

Figure 49-6 Vasculitic palpable purpura on the forearm of a patient with Churg-Strauss syndrome.

Extrapulmonary manifestations of CSS usually include asthenia, weight loss, fever, arthralgias, and/or myalgias. Neurologic involvement typically consists of mononeuritis multiplex or asymmetric polyneuropathy. Cardiac involvement manifesting as eosinophilic myocarditis (or, more rarely, coronary arteritis) often is of insidious onset and asymptomatic and may lead to dilated cardiomyopathy, although marked clinical improvement may follow corticosteroid treatment. Pericardial effusion is common, but tamponade is rare. Endomyocardial fibrosis is rare, in contrast with the idiopathic hypereosinophilic syndrome. Myocardial involvement is a common finding in systematic studies by echocardiography or magnetic resonance imaging (MRI), and its frequency may have been heretofore underestimated. Digestive tract involvement usually manifests as isolated abdominal pain or diarrhea, but intestinal vasculitis (with ulcerations, perforations, or hemorrhage) and cholecystitis may occur. Cutaneous lesions, seen in approximately half of the patients, consist mainly of palpable purpura (Figure 49-6) on the extremities, subcutaneous nodules, erythematous rashes, and urticaria. Renal involvement, present in a fourth of the cases, usually is mild.

Box 49-7 Practical Diagnostic Criteria of Churg-Strauss Syndrome

1. Asthma
2. Peripheral blood eosinophilia ≥1500/µL and/or alveolar eosinophilia ≥25%
3. Extrapulmonary clinical manifestations of disease (other than rhinosinusitis), with at least one of the following:
   - Systemic manifestation typical of the disease: mononeuritis multiplex, or cardiomyopathy confidently attributed to the eosinophilic disorder, or palpable purpura
   - Any extrapulmonary manifestation with histopathologic evidence of vasculitis as demonstrated especially by skin, muscle, or nerve biopsy
   - Any extrapulmonary manifestation with evidence of antineutrophil cytoplasmic antibodies with antimyeloperoxidase or antiproteinase-3 specificity
   - Presence of a single extrapulmonary manifestation attributable to the systemic disease: so-called *forme fruste* of Churg-Strauss syndrome

Table 49-1 Clinical Phenotypes of Churg-Strauss Syndrome

Feature	Vasculitic Phenotype	Tissue Disease Phenotype
Respective frequency	~40%	~60%
ANCA	Present (mostly p-ANCA with antimyeloperoxidase specificity)	Absent
Predominant clinical and histopathologic features	Glomerular renal disease Peripheral neuropathy Purpura Biopsy-proven vasculitis	Cardiac involvement (eosinophilic myocarditis) Eosinophilic pneumonia Fever

ANCA, antineutrophil cytoplasmic antibodies; *p-ANCA*, perinuclear ANCA.

Currently used diagnostic criteria for CSS are shown in Box 49-7. ANCA also may be considered a major diagnostic criterion when present. Conversely, absence of ANCA does not exclude the diagnosis of CSS. A histopathologic diagnosis of CSS may be obtained by examination of skin, nerve, or muscle biopsy specimens. Lung biopsy and transbronchial biopsy are not helpful. The diagnosis of CSS may be difficult, especially at an early stage, with mild or limited manifestations corresponding to "formes frustes" of CSS. These may consist of cases in which the disease has been partly controlled by corticosteroids given for asthma.

ANCA are found in only approximately 40% of patients and consist mainly of perinuclear ANCA (p-ANCA), with a specificity for myeloperoxidase on ELISA, whereas other ANCA (especially cytoplasmic ANCA [c-ANCA] with proteinase-3 specificity) are very rare in CSS. Of interest, two phenotypes of CSS can be distinguished on the basis of these antibodies (Table 49-1): Patients with ANCA have a vasculitic phenotype (with more frequent vasculitis on biopsy, renal involvement, peripheral neuropathy, and purpura), whereas patients without ANCA have more frequent cardiac and pulmonary involvement. Therefore, patients with CSS seen in respiratory medicine departments or chest clinics are at high risk for cardiac involvement, which can be subclinical (with especially no chest pain) and should be systematically evaluated with measurement of serum troponin, electrocardiogram, echocardiography, and possibly MRI of the heart, which can identify impaired cardiac function and myocardial involvement. Serum measurement of eotaxin-3 and of CCL17/thymus and activation–related chemokine may reflect disease activity and merits further study as a potential biomarker of disease monitoring.

A role for triggering or adjuvant factors such as vaccines or desensitization in the development of CSS has been postulated. Drug-induced eosinophilic vasculitis with pulmonary involvement has been occasionally reported. The possible responsibility of leukotriene-receptor antagonists in the development of CSS is still debated, and these agents must be avoided in patients with asthma and eosinophilia or with extrapulmonary manifestations compatible with smoldering CSS.

Corticosteroids are the mainstay of treatment of CSS, starting with 1 mg/kg per day of prednisone, with progressive tapering over several months. Initial intravenous pulses of methylprednisolone (15 mg/kg/day for 1 to 3 days) are useful in the most severe cases. Approximately half of the patients without poor prognostic factors at onset achieve complete remission with corticosteroid treatment alone and do not experience relapse. Relapses of CSS must be distinguished from relapse or persistence of difficult asthma (generally accompanied by less than 500/µL blood eosinophils). Long-term monitoring of lung function is warranted, because a proportion of patients develop fixed airflow obstruction.

Intravenous pulses of cyclophosphamide (usually up to six pulses) in addition to corticosteroids are indicated in patients with poor prognostic factors at onset (proteinuria with greater than 1 g/day protein excretion; renal insufficiency with serum creatinine greater than 15.8 mg/L; gastrointestinal tract involvement; cardiomyopathy; central nervous system involvement). Immunosuppressive treatment using oral azathioprine also is considered in patients who relapse despite more than 20 mg of prednisone daily. Rituximab, intravenous high-dose immunoglobulins, cyclosporine, and subcutaneous interferon-α have been of recognized benefit in patients with treatment-refractory CSS. The anti-IgE agent omalizumab has been used successfully to treat persistent asthma in patients with CSS; it does not control the systemic disease, however, so careful clinical monitoring is warranted. The prognosis for CSS has improved considerably over the years, with more than 90% of patients alive at 5 years according to current data.

IDIOPATHIC HYPEREOSINOPHILIC SYNDROMES

The historical definition of the idiopathic hypereosinophilic syndromes (HESs) included a persistent eosinophilia with counts greater than 1500/µL for longer than 6 months, a lack of evidence for a known cause of eosinophilia, and presumptive signs and symptoms of organ involvement. Recent studies have demonstrated that HESs fitting this definition may result especially from clonal proliferation of lymphocytes or of the eosinophil cell lineage itself.

HES, as described in older series, was much more common in men than in women (9 : 1), with an age at onset between 20 and 50 years. The typical clinical presentation includes insidious onset of weakness, fatigue, cough, and dyspnea, with a mean eosinophil count at presentation of up to 20,000/µL. Nonrespiratory manifestations of the HESs mainly target the skin, heart, and nervous system.

Cardiac involvement, present in 60% of patients, manifests mainly as characteristic endomyocardial fibrosis, often associated with development of intracavitary thrombi along the endocardium, and clinically associated with restrictive cardiomyopathy. Echocardiography shows mural thrombus, ventricular apical obliteration, and involvement of the posterior mitral leaflet.

Lung involvement, present in up to 40% of patients, is nonspecific. Cough may be the predominant feature. Asthma, pleural effusion, and pulmonary opacities on the chest CT scan (mostly patchy ground glass attenuation, consolidation, and small nodules) have been reported, and this aspect of HES must be distinguished from pleural effusion secondary to cardiac failure.

The *lymphocytic* variant of HES, which may account for approximately 30% of the cases, is a T cell disorder resulting from the production of chemokines (especially IL-5) by clonal T_H2 lymphocytes bearing an aberrant antigenic surface phenotype (such as $CD3^-CD4^+$). IgE level typically is elevated as a consequence of IL-4 and IL-13 production by T_H2 lymphocytes. Most patients initially have cutaneous papules or urticarial plaques infiltrated by lymphocytes and eosinophils. Diagnosis is obtained by lymphocyte phenotyping and analysis of the rearrangement of the T cell receptor genes in specialized laboratories.

The *myeloproliferative* variant of HES, accounting for approximately 20% of cases, is distinguished on the basis of clinical and biologic features in common with those of chronic myeloproliferative syndromes, including hepatomegaly, splenomegaly, anemia, thrombocythemia, increased serum vitamin B_{12} and leukocyte alkaline phosphatase, and circulating leukocyte precursors. Mucosal ulcerations may be prominent. Severe cardiac manifestations are frequent and may be resistant to corticosteroid treatment. Myeloproliferative HES is attributed to a constitutively activated tyrosine kinase fusion protein (Fip1L1-PDGFRα) due to an interstitial chromosomal deletion in 4q12. Imatinib, a tyrosine kinase inhibitor used to treat chronic myelogenous leukemia, proved to be efficacious in patients with the myeloproliferative variant of HES.

Only approximately half of the patients with HES respond to corticosteroid treatment. Other treatments include chemotherapeutic agents (hydroxyurea, vincristine, etoposide), cyclosporine, interferon-α (particularly for the myeloproliferative variant), and the anti–IL-5 antibody mepolizumab. Imatinib has become the major drug used in patients with the myeloproliferative variant of HES, especially when the FipL1-PDGFRα fusion protein is present. The prognosis with HES has improved markedly, with approximately 70% survival at 1 year.

A large proportion of affected patients have idiopathic HES—no cause can be found despite exhaustive analysis, with neither clonal proliferation of lymphocytes nor fusion protein activity detected. Improvement may be obtained with oral corticosteroids or imatinib. Respiratory manifestations in these patients have not been properly studied but seem to be of generally mild severity.

CONTROVERSIES AND PITFALLS

- The diagnosis of parasitic diseases in patients with eosinophilic pneumonia may be difficult and requires appropriate serologic tests and repeated search for parasites in the feces. Such diseases must be considered in any patient who lived in or visited an endemic area.
- Eosinophilic pneumonia has been reported in association with a variety of drugs, but causality has been confidently established for fewer than 20 specific agents.
- The dose and duration of treatment of ICEP with corticosteroids have not been established. Disease control must be balanced with treatment side effects.
- "Idiopathic" acute eosinophilic pneumonia may be misdiagnosed as severe infectious pneumonia.
- Established diagnostic criteria for CSS currently are lacking. ANCA are found in about 40% of patients, and true vasculitis is a feature in only a minority of cases.
- Asthma is a common denominator in most patients with ICEP and CSS.
- The respiratory manifestations of the lymphocytic and myeloid variants of the HESs have not been described in detail.

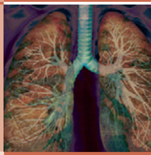
Section 8
PARENCHYMAL LUNG DISEASES



Chapter 50
Organizing Pneumonia

Vincent Cottin • Jean-François Cordier

DEFINITION

Organizing pneumonia (OP) is a histopathologic diagnosis defined by a well-recognized pattern of changes underlying a characteristic clinical-pathologic entity. OP may occur in the absence of etiologic context, in which case it is known as *cryptogenic organizing pneumonia* (COP), or in association with a known causative agent or inflammatory disorder such as connective tissue disease, where it is called *secondary organizing pneumonia*.

Initially described as the specific histopathologic pattern resulting from organization of an inflammatory exudate in the lumen of alveoli of unresolved pneumonia, OP is characterized by intraalveolar buds of granulation tissue with fibroblasts and myofibroblasts intermixed with loose connective matrix (Figure 50-1). Similar lesions may be present within the lumen of the bronchioles—hence the formerly synonymous term *bronchiolitis obliterans with organizing pneumonia* ("BOOP"). The latter designation has been abandoned, however, because OP (rather than bronchiolitis) is clearly the major lesion, and furthermore, use of the older term was a potential source of confusion between this entity and bronchiolitis with airflow obstruction occurring, for example, after lung or hematopoietic stem cell transplantation. Although the condition is not strictly interstitial, COP is included in the American Thoracic Society/European Respiratory Society international consensus classification of the idiopathic interstitial pneumonias, because of its idiopathic nature and occasional similarities with interstitial pneumonias.

PATHOGENESIS

OP is a unique condition characterized by intraalveolar accumulation of intermixed fibroblasts and connective matrix, especially collagen, that is reversible with corticosteroids, in contrast with other presentations of pulmonary fibrosis and especially that of usual interstitial pneumonia or idiopathic pulmonary fibrosis.

The first event of the sequence leading to the formation of intraalveolar buds is alveolar epithelial injury with necrosis of pneumocytes (especially type I) (Figure 50-2). The epithelial basal laminae are denuded and injured, resulting in formation of gaps. Capillary endothelial injury often is associated. The consequence of alveolar injury is flooding of the alveolar lumen by plasma proteins (permeability edema), including coagulation factors. The balance between coagulation and fibrinolysis is clearly tipped in favor of coagulation (especially because of decreased fibrinolysis), leading to accumulation of fibrin deposits that are soon populated by migratory inflammatory cells and fibroblasts.

Fibroblasts differentiate into myofibroblasts that organize and represent the predominant cell of fibroinflammatory buds. Inflammatory cells and fibrin are progressively replaced by aggregated fibroblasts/myofibroblasts intermixed with a loose connective matrix tissue rich in collagen (especially collagen III) and fibronectin. This process, resembling that of cutaneous wound healing, is similarly reversible, without significant sequelae. It is likely that the relative preservation of the alveolar basal laminae is crucial in determining the reversibility of the lesions. Although COP and secondary OP appear very similar, the microvascular density and the density of collagen fibers within intraalveolar air spaces may be higher in secondary OP than in COP.

Mouse models of intraluminal inflammation have been developed using reovirus infection to induce the histopathologic changes. Lesions similar to OP have been obtained by intranasal inoculation of moderate doses of virus only in a susceptible strain of mice (CBA/J), suggesting that genetic background may contribute to pathogenesis of the condition in mice. Alveolar macrophages and T lymphocytes were implicated in the disease process. Of interest, diffuse alveolar damage with hyaline membrane formation was obtained with the same animal model when higher doses of virus were used. These experimental studies suggest that the intensity of the initial epithelial injury and yet undetermined factors inherent to the host may influence the evolution to either OP or diffuse alveolar damage. Other animal models of OP have been developed in rats inoculated with bacteria and in pigs infected with a circovirus.

The cellular origin of fibroblasts that populate the distal air spaces is unclear. The respective contribution of proliferating lung fibroblasts, fibrocytes or bone marrow–derived fibroblasts, and epithelial-mesenchymal transition has not been evaluated in OP. The mechanism by which corticosteroids facilitate the rapid resolution of OP also is unclear. Several studies have highlighted some characteristics that distinguish the reversible fibrotic budding characteristic of OP from the uncontrolled process of accumulation of fibroblastic foci and collagen deposition seen in usual interstitial pneumonia, including a distinct pattern of expression of metalloproteases, the increased vascularity of fibrotic buds, and a lower apoptotic activity in granulation tissue. In addition, the expression of tumor necrosis factor-α receptor-1 and Fas by alveolar macrophages is higher in patients with OP than in control subjects or patients with idiopathic pulmonary fibrosis. Overall, OP may be considered as a model of normal wound repair, contrasted with the uncontrolled aberrant repair and fibrosing process observed in usual interstitial pneumonia of idiopathic pulmonary fibrosis.

CLINICAL AND IMAGING FEATURES

CRYPTOGENIC ORGANIZING PNEUMONIA

Clinical Features

The mean age at onset of COP is approximately 50 to 60 years, with no gender predilection. It is more common in nonsmokers or former smokers. The initial manifestations are fever, cough, malaise, anorexia, and progressive weight loss, with a subacute onset over a few weeks. The median duration of the clinical syndrome is less than 3 months. Dyspnea usually is mild. Hemoptysis, chest pain, and severe dyspnea are rare. Crackles may be heard at pulmonary auscultation over involved areas, with clinical features of consolidation in rare instances. Finger clubbing is absent. In many patients, the diagnosis is considered after they have received antibiotics for presumed infectious pneumonia without improvement.

Lung function tests in COP show a mild to moderate restrictive ventilatory pattern and may occasionally yield normal results. The carbon monoxide transfer factor is reduced in most

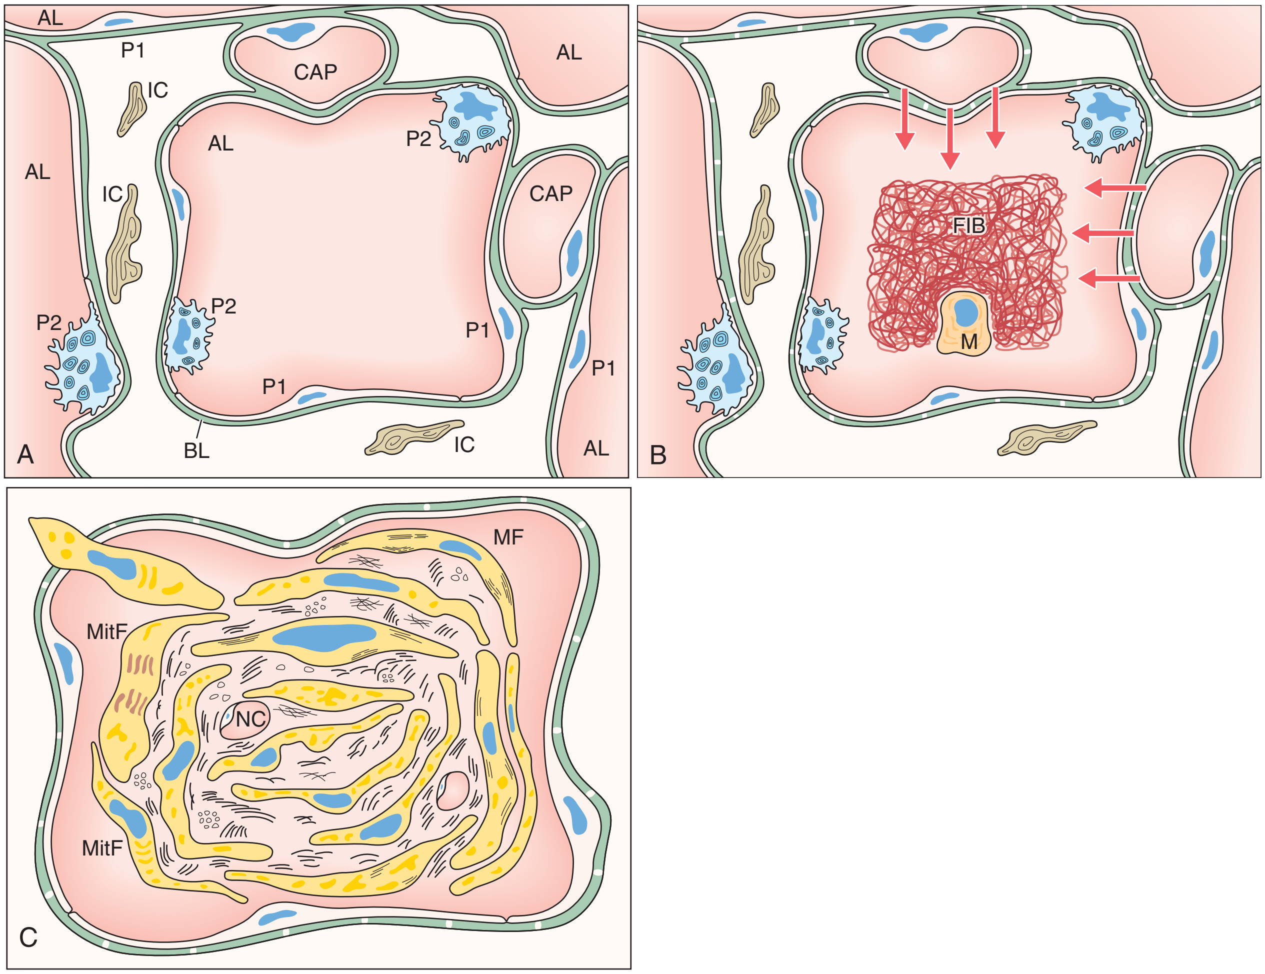

Figure 50-2 Formation of the intraalveolar buds of granulation tissue characterizing organizing pneumonia. **A,** Structure of the normal alveolar space. *AL*, alveolar lumen; *BL*, basal laminae; *CAP*, capillaries; *IC*, interstitial cells; *P1*, type 1 pneumocytes; *P2*, type 2 pneumocytes. **B,** Alveolar injury with alteration and necrosis of alveolar epithelial cells (especially type 1 pneumocytes), denudation of basal laminae with formation of gaps, and leaking of plasma proteins, especially coagulation factors (*arrows*) with formation of fibrin (*FIB*) within the alveolar lumen. Some inflammatory cells and macrophages (*M*) are present. **C,** The intraluminal alveolar fibrin network has been colonized by mitotic fibroblasts (*MitF*), with some acquiring a myofibroblast (*MF*) phenotype characterized by presence of myofilaments beneath the cytoplasmic membrane. Fibroblasts and myofibroblasts have a developed rough endoplasmic reticulum and produce a loose connective matrix (composed of collagen types I and III, fibronectin, and proteoglycans) interspersed between the cells. Neoformed capillaries (*NC*) are present within this intraalveolar bud of granulation tissue, resembling those characteristic of the wound healing process.

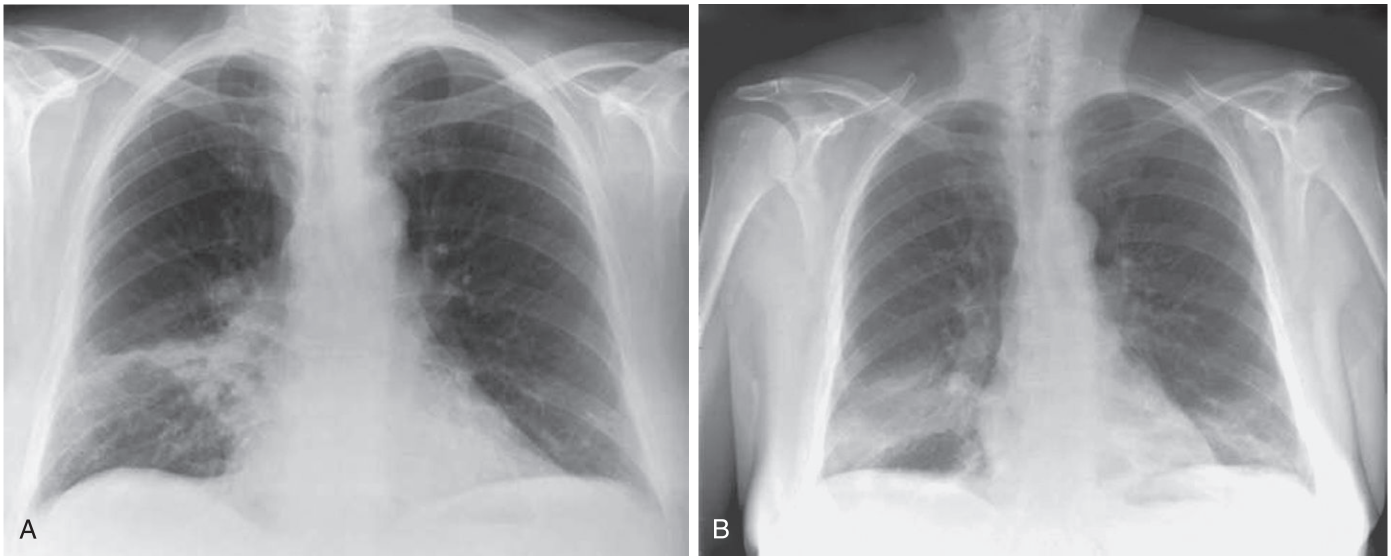

Figure 50-3 Chest radiographs showing the typical imaging pattern in cryptogenic organizing pneumonia. **A,** Patchy alveolar opacity. **B,** Six days later, the distribution of the right lower lobe opacity has changed, with appearance of a new contralateral basal opacity.

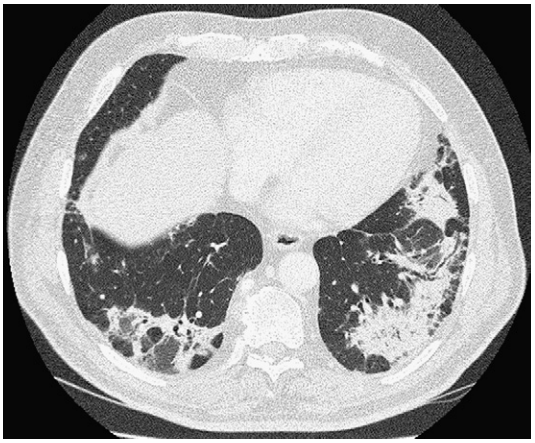

Figure 50-4 High-resolution computed tomography (HRCT) features of typical cryptogenic organizing pneumonia (COP). Patchy bilateral consolidation with peripheral predominance and air bronchogram, associated with ground glass opacities in the right lower lobe, are evident.

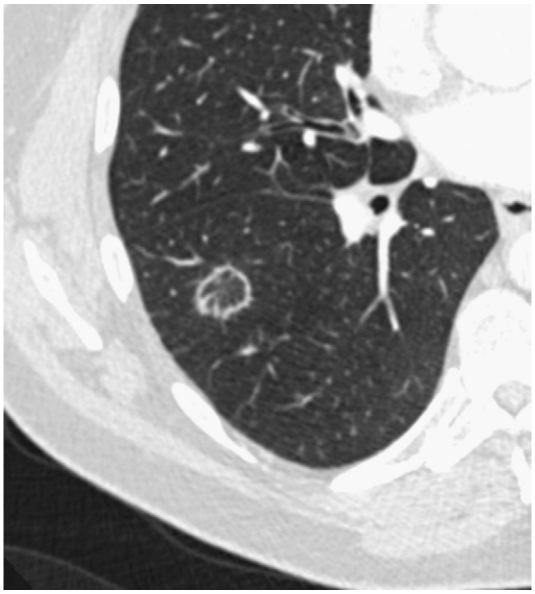

Figure 50-5 Reverse halo sign (atoll sign) on high-resolution computed tomography (HRCT) scan.

patients, whereas the carbon monoxide transfer coefficient (*K*CO) is within normal limits. Hypoxemia usually is mild. When present, severe hypoxemia may be associated with diffuse infiltrative opacities or right-to-left shunting in perfused areas of lung consolidation.

Blood tests often show moderate leukocytosis and increased C-reactive protein but no significant peripheral blood eosinophilia.

Imaging Features

The imaging features of COP may consist of a variety of high-resolution computed tomography (HRCT) findings, some of which are highly suggestive of the diagnosis. The most typical imaging pattern in COP consists of multiple patchy alveolar opacities (Figures 50-3 and 50-4). These usually are bilateral, with a subpleural distribution, and sometimes migratory (with attenuation or clearing in some areas and appearance of new opacities in others), ranging in density from ground glass to consolidation with air bronchogram, with no predominance in cranial versus caudal distribution. The size of the opacities may vary, ranging from 1 to 2 cm to involvement of an entire lobe. Consolidation at imaging corresponds pathologically with intraalveolar buds of granulation tissue within the distal air spaces, whereas areas of ground glass opacity reflect the cell infiltration of alveolar wall by inflammatory cells, with some OP changes in the distal air spaces. This imaging pattern with multiple patchy alveolar opacities, especially those of a migratory nature, is so characteristic of typical COP that it should immediately suggest the diagnosis. The main other consideration in the differential diagnosis at this stage is idiopathic chronic eosinophilic pneumonia (in the latter, blood eosinophilia with cell counts usually greater than 1500/μL is present; conversely, nodules may be found more frequently in COP than in chronic eosinophilic pneumonia).

Patchy ground glass opacities frequently are observed, usually associated with consolidation. The reverse halo sign or atoll sign (Figure 50-5), consisting of a circular consolidation

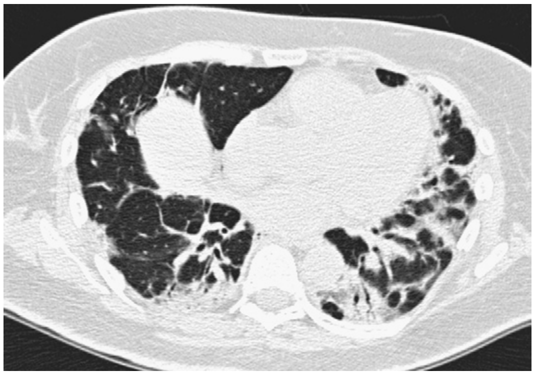

Figure 50-6 High-resolution computed tomography (HRCT) features of progressive organizing pneumonia (OP). The patient had idiopathic inflammatory myopathy. Reticular, hazy, perilobular opacities are evident in the lower lobes.

pattern (corresponding histopathologically to organizing pneumonia in the distal air spaces) surrounding an area of ground glass opacities (corresponding to alveolar wall inflammation), also is highly suggestive of the diagnosis, although not specific.

Another imaging pattern in COP is a solitary focal nodule or mass-like area of consolidation that may mimic lung carcinoma especially when associated with hypermetabolism on positron emission tomography. It commonly is located in the upper lobes and usually is asymptomatic. An air bronchogram may be present. Diagnosis often is obtained by surgical resection of the lesion in the suspicion of cancer. Solitary focal COP likely represents nonresolving infectious pneumonia in a number of cases.

The infiltrative (or progressive fibrotic) pattern of OP associates interstitial opacities, with small superimposed alveolar opacities on HRCT (with possible perilobular pattern consisting of bowed or polygonal opacities with poorly defined margins bordering the interlobular septa). Honeycombing is not present. Infiltrative or progressive COP may overlap on both histopathologic and imaging studies with idiopathic nonspecific interstitial pneumonia (NSIP), with uniform alveolar and interstitial cellular inflammation (with more or less fibrosis), with the possible presence of foci of organizing pneumonia. Such imaging presentation of OP seems to be particularly frequent in patients with idiopathic inflammatory myopathy (Figure 50-6).

Several less common imaging presentations of COP have been occasionally reported, including multiple nodules, cavitary opacities, perilobular opacities, centrilobular or peribronchovascular ill-defined nodules, bronchocentric areas of consolidation, and linear subpleural bands (Box 50-1). A few mediastinal lymphadenopathies are not rare in COP. Pleural effusion is uncommon.

Whereas mimics of COP with typical imaging features are few, mimics of COP presenting as nodules, masses, or infiltrative lung diseases are many (Box 50-2).

Box 50-2 Mimics of Cryptogenic Organizing Pneumonia (COP) on Chest Imaging

Multiple patchy alveolar opacities (classic COP pattern)
  Eosinophilic pneumonia (especially chronic idiopathic)
  Pneumonic-type invasive mucinous adenocarcinoma of the lung
  Primary pulmonary lymphoma (low-grade B cell lymphoma of mucosa-associated lymphoid tissue [MALT])
  Others: infectious pneumonia, tuberculosis or nontuberculous mycobacterial infection, granulomatosis with polyangiitis (Wegener granulomatosis), diffuse alveolar hemorrhage, multiple-infarct lesions, aspiration pneumonia
Solitary focal nodule or mass (focal pattern)
  Lung carcinoma
  Round pneumonia or abscess
  Inflammatory pseudotumors
  Others: all causes of coin lesions or masses
Diffuse infiltrative opacities (progressive or fibrosis pattern)
  Idiopathic interstitial pneumonias, especially nonspecific interstitial pneumonia and idiopathic pulmonary fibrosis (especially acute exacerbation)
  Interstitial pneumonias overlapping with organizing pneumonia
  Others: all causes of infiltrative opacities, especially of infectious or neoplastic origin

SECONDARY ORGANIZING PNEUMONIA

Most cases of OP occur as a reaction pattern and are considered to represent secondary OP, resulting from a determined cause, often infectious or drug-associated, or occurring in the context of systemic disorders (e.g., connective tissue disease) or other specific conditions. The clinical, laboratory, and imaging features and outcome of secondary OP generally parallel those of COP, with minor differences reported that probably reflect the nature of the underlying disease (e.g., higher lymphocyte percentage on a differential bronchoalveolar lavage [BAL] fluid cell count). A careful etiologic investigation is thus necessary in any patient presenting with OP without evident cause, and especially with relapsing OP. In most cases of secondary OP, corticosteroid treatment is effective.

Secondary Organizing Pneumonia of Known Cause

A histopathologic diagnosis of OP prompts a search for a number of potential underlying causes, including a variety of infectious agents (bacteria, viruses, fungi, parasites) (Box 50-3). Diagnosis of the infection (which is no longer active at the time of OP) may be difficult and is based on the clinical history, a rise in antibody titers against the infectious agent, or occasionally direct identification of the infectious agent by use of specific stains and histopathologic analysis of the lung specimens.

Several drugs have been reported to cause OP (Box 50-4). All drugs taken in the weeks or months preceding onset of symptoms must be systematically recorded. Any drug suspected to be a cause of OP should be withdrawn if possible

Box 50-3 Infectious Agents Associated With Organizing Pneumonia

Bacteria
Chlamydia pneumoniae
Coxiella burnetii
Legionella pneumophila
Mycoplasma pneumoniae
Nocardia asteroides
Staphylococcus aureus
Streptococcus pneumoniae
Serratia marcescens
Pseudomonas aeruginosa

Viruses
Human immunodeficiency virus
Influenza virus
Parainfluenza virus
Herpesvirus
Hepatitis C virus

Parasites
Plasmodium vivax

Fungi
Cryptococcus neoformans
Penicillium janthinellum
Pneumocystis jiroveci (in AIDS)

Box 50-4 Drugs Commonly Reported as Etiologic Agents of Organizing Pneumonia

5-Aminosalicylic acid
Amiodarone
Amphotericin B
Beta blockers
Bleomycin
Busulfan
Carbamazepine
Dihydroergocryptine
Everolimus
Interferon-α
Interferon-β
Mesalazine
Methotrexate
Minocycline
Nilutamide
Nitrofurantoin
Penicillamine
Phenytoin
Statins
Rituximab
Sirolimus
Sulfasalazine
Tacrolimus
Thalidomide
Trastuzumab

Box 50-5 Miscellaneous Causes and Clinical Settings Associated With Organizing Pneumonia

Identified Causes
Infections (see Box 50-3)
Drugs (see Box 50-4)
Distal to airway obstruction
Fumes and toxic exposures (e.g., aerosolized textile dye Acramin FWN, mustard gas)

Clinical Settings
Occult aspiration pneumonia
Connective tissue disease
Primary biliary cirrhosis
Inflammatory bowel diseases (ulcerative colitis, Crohn disease)
Transplantation (lung, liver), bone marrow graft
Hematologic malignancies (leukemias: myeloblastic, lymphoblastic, myelomonocytic, T cell; Hodgkin disease)
Cancers and thoracic radiotherapy, especially for breast cancer
Others: common variable immune deficiency, Sweet syndrome, polymyalgia rheumatica, Behçet disease, thyroid diseases, vasculitis, sarcoidosis

(and rechallenge should be avoided). The diagnosis of drug-induced OP may be difficult, however, because it has no specific clinical-radiologic presentation.

A recent study surprisingly identified aspiration of food and of other particulate matter as a frequent feature in patients with OP, suggesting that aspiration pneumonia may be a more frequent cause of OP than was previously suspected. Aspiration was suspected on clinical grounds in less than 10% of cases; however, predisposing factors for aspiration frequently were identified (e.g., esophageal or gastric causes, drug use, neurologic conditions). The presence of multinucleate giant cells, acute bronchopneumonia or bronchiolitis, and/or suppurative granulomas on a background of OP changes should therefore direct the pathologist to look for foreign material and particulate matter on the lung biopsy specimen, and should prompt the clinician to evaluate for possible aspiration.

Radiation therapy to the breast after resection for cancer may precipitate the development of OP, with an incidence of approximately 2.5% in treated women and a mean delay of approximately 3 to 6 months after the completion of irradiation. In contrast with radiation pneumonitis, the alveolar opacities of OP (often migratory) also may appear in nonirradiated areas of the lungs. The opacities respond well to corticosteroid treatment, but relapses are common when corticosteroids are reduced or stopped. Of interest, radiation therapy to the breast is followed by bilateral lymphocytic alveolitis seen on examination of BAL fluid, with development of OP in only a minority of patients. This observation suggests that a “second trigger” and/or genetic susceptibility may be necessary for OP to occur, in addition to radiation-primed lymphocytic alveolitis.

Secondary Organizing Pneumonia Occurring Within a Specific Context

OP occurs mainly in dermatomyositis or polymyositis and rheumatoid arthritis (it is less common in systemic lupus and Sjögren syndrome and is unusual in systemic sclerosis). Overlapping features of OP and nonspecific interstitial pneumonia seem particularly frequent in patients with dermatomyositis or polymyositis. OP may precede the development of the connective tissue disease or occur concomitantly, although it is seen more frequently during the course of the disease.

Multiple causes of and clinical settings for secondary OP have been reported, a nonexhaustive listing of which is provided in Box 50-5.

DIAGNOSIS

A thoracoscopic lung biopsy is recommended for a definitive histopathologic diagnosis of OP, also ruling out other conditions that may mimic OP.

When nonspecific clinical manifestations associated with typical imaging features suggest the diagnosis of COP, fiberoptic bronchoscopy (which excludes any bronchial obstruction) with BAL is first necessary, and transbronchial biopsy may be contributive. The BAL fluid differential cell count in COP often shows a mixed pattern with increased levels of lymphocytes (20% to 40%), neutrophils (approximately 10%), and eosinophils (5%); some mast cells and plasma cells may be present. The transbronchial lung biopsy specimens may show typical buds of granulation tissue within alveoli. Infectious agents must be systematically searched for on BAL fluid preparations (and on transbronchial biopsy specimens by specific staining, if performed). The combination of a typical clinical-radiologic pattern and a mixed pattern on BAL fluid differential cell count is considered highly suggestive of OP (and of COP in the appropriate clinical context). A decreased ratio of $CD4^+$ to $CD8^+$ lymphocytes in BAL has been reported in COP.

OP is a nonspecific consequence of interstitial inflammation that may be present as an accessory finding in many disorders, including nonspecific interstitial pneumonia, organizing diffuse alveolar damage, aspiration pneumonia, vasculitides, distal obstruction of the airways, and occult aspiration pneumonia. Some histopathologic overlap may exist with chronic eosinophilic pneumonia or the OP-like variant of granulomatous polyangiitis (Wegener granulomatosis). Additional findings suggestive of another diagnosis in secondary OP include necrosis or microabscesses (seen in infectious processes and necrotizing vasculitis) and organic debris (as in occult aspiration pneumonia).

With transbronchial biopsy, the small size of specimens obtained by this method does not allow exclusion of other histopathologic patterns, so the findings should therefore be considered diagnostic of OP only in patients with a typical clinical-imaging profile. The sensitivity and specificity of transbronchial biopsy for the diagnosis of OP have not been rigorously evaluated. Core needle biopsy generally is safe and may be appropriate in a minority of patients with suspected OP, especially with focal consolidation at imaging. Videothoracoscopic lung biopsy remains the most appropriate procedure to obtain specimens of sufficient size both to make a definitive diagnosis of OP and to exclude other processes. When performed, the biopsy should be done before corticosteroids are initiated and should be planned in a preoperative discussion between the surgeon and the physician or a radiologist. Microbiologic analysis also may be performed on the lung specimen.

A reasonable alternative to lung biopsy is to proceed with appropriate management, to include presumptive treatment as indicated, in the absence of confirmation of the histopathologic pattern of OP. Although this approach commonly is used in clinical practice, it carries the risk of misdiagnosing alternative conditions that may mimic OP, including eosinophilic pneumonia, low-grade primary pulmonary lymphoma, and bronchioloalveolar carcinoma (see Box 50-2). Only patients in whom typical findings on imaging studies (e.g., multiple patchy consolidation) are associated with compatible clinical and BAL features should be treated without biopsy; particular attention must be paid to any clue to an alternative diagnosis (e.g., peripheral blood and/or BAL fluid eosinophilia, suggestive microbiologic findings in BAL fluid). When pathologic investigation is not available or consists of only transbronchial biopsy, the diagnosis should be reconsidered whenever the observed clinical response is unusual (especially in case of incomplete response to corticosteroids or relapse despite more than 20 mg/day of oral prednisone).

As in other conditions among the group of idiopathic interstitial pneumonias, the "gold standard" for diagnosis of OP is now the clinical-radiologic-pathologic approach, which effectively ensures that imaging and clinical data, as well as pathology data when available, are consistent with and specific for this entity. Although interobserver agreement for a clinically based diagnosis usually is fair to good, the multidisciplinary approach is particularly useful in cases with histopathologic features overlapping with those of eosinophilic pneumonia, nonspecific interstitial pneumonia, or diffuse alveolar damage. The clinical assessment must include a careful history and evaluation for the presence of comorbid diseases such as connective tissue disease (including formes frustes of connective tissue disease or undifferentiated connective tissue disease), cancer, thoracic radiotherapy for breast cancer, exposure to drugs, inflammatory bowel disease, aspiration, or less common conditions such as common variable immune deficiency (see Box 50-5). A final diagnosis of COP can be made only after all available data including findings on etiologic investigations have been reviewed in a dynamic process requiring close communication among the clinician, the radiologist, and the pathologist.

TREATMENT OF CRYPTOGENIC ORGANIZING PNEUMONIA

Corticosteroid treatment is standard therapy for COP and results in rapid clinical and imaging improvement in typical cases. With institution of therapy, consolidation evolves to ground glass opacities and reticulation and eventually regresses completely within a month; the less frequent linear or reticular opacities may not resolve. The optimal doses and duration of treatment have not been established, and treatment should aim at the best balance between disease control and side effects. We start with prednisone, 0.75 mg/kg per day for 4 weeks, and then continue with progressively decreasing doses for a total duration of treatment of 24 weeks (Table 50-1). This regimen limits intense and prolonged corticosteroid treatment with ensuing risk of iatrogenic complications. Other treatment protocols with slower tapering of dosage have been proposed. Parenteral corticosteroid therapy at higher doses often is used as the initial treatment in patients with the progressive or fibrotic variant of COP. Cyclophosphamide or azathioprine may be used in patients whose clinical condition deteriorates despite corticosteroid therapy. Of note, spontaneous improvement has been reported in some cases of COP. Macrolides have been suggested

Table 50-1 **Proposed Therapeutic Regimen for Typical Cryptogenic Organizing Pneumonia**

Step	Duration	Prednisone Dosage
Treatment of Initial Episode		
1	4 weeks	0.75 mg/kg/d
2	4 weeks	0.5 mg/kg/d
3	4 weeks	20 mg/d
4	6 weeks	10 mg/d
5	6 weeks	5 mg/d
Treatment of Relapse		
1	12 weeks	20 mg/d
2	6 weeks	10 mg/d
3	6 weeks	5 mg/d

for their antiinflammatory properties as an alternative option in patients who are intolerant to corticosteroids or who experience frequent relapses; however, the benefit initially observed in case reports is not confirmed with empirical routine use of these drugs. Secondary OP requires treatment of the underlying condition (connective tissue disease, infection) or withdrawal of the causative drug or exposure. Focal COP does not require corticosteroid therapy after surgical resection (performed for suspected lung cancer).

Most cases of typical COP with alveolar consolidation have a rapid and sometimes dramatic improvement with initiation of corticosteroid therapy, but a minority of patients will have persistent disease, especially those with reticulation on HRCT. Relapses are common (occurring in up to 60% of cases) on decreasing or after stopping treatment and may be treated with prednisone in doses of 20 mg per day given for 2 weeks and then progressively decreased. Relapses of the disease should prompt a search for a persisting cause of OP, especially drug intake. Relapses occurring with daily doses of more than 15 to 30 mg of prednisone (depending on body weight) should prompt extensive reappraisal of the diagnosis and further clinical-radiologic-pathologic consultation, especially when a large sample is not available for histopathologic analysis. The overall prognosis with typical COP is excellent.

SEVERE ORGANIZING PNEUMONIA

Cases of severe COP have been reported, with potentially severe respiratory failure necessitating mechanical ventilation. Such cases only occasionally are found to be associated with “pure OP” histopathologic lesions. They usually represent overlap of COP with one of the following disorders: acute respiratory distress syndrome (ARDS) with pathologic features of diffuse alveolar damage undergoing organization, acute fibrinous and organizing pneumonia (AFOP), or usual interstitial pneumonia exacerbation. In patients with acute exacerbation of idiopathic pulmonary fibrosis, features of diffuse alveolar damage and/or of OP are found in association with preexisting usual interstitial pneumonia. In such cases, the response to corticosteroids is not as favorable as in classic COP. Immunosuppressive agents (especially cyclophosphamide) usually are added to corticosteroids (often used at a higher dose, starting with 1 to 2 mg/kg per day of intravenous methylprednisolone), with variable outcome.

ACUTE FIBRINOUS AND ORGANIZING PNEUMONIA

AFOP is a histopathologic pattern first reported in patients with acute respiratory failure, with predominantly basal and bilateral areas of consolidation at imaging. It is characterized by abundant fibrin deposition within the alveolar air spaces, with hyperplasia of type II pneumocytes, associated organizing-type pneumonia, and absence of hyaline membranes (which constitute the hallmark of diffuse alveolar damage). AFOP currently is considered to be a histopathologic variant of OP that may be associated with more rapid progression of disease. As with OP, AFOP may be encountered in the context of various underlying conditions, including infection.

CONTROVERSIES AND PITFALLS

- OP is defined as a nonspecific histopathologic pattern found in many disorders, especially nonresolving infectious pneumonia. Assessing its clinical significance may be difficult. OP may be difficult to distinguish histopathologically from focal areas of organizing-type pneumonia seen as an accessory finding in another disorder (e.g., nonspecific interstitial pneumonia, organizing diffuse alveolar damage).
- In complex cases, overlap with other recognized histologic patterns may occur, especially with nonspecific interstitial pneumonia (especially secondary OP).
- What differentiates the pathogenic fibrosing process of OP (which resolves with corticosteroids) from that of uncontrolled idiopathic pulmonary fibrosis (resistant to steroids) is poorly understood.
- In cases with typical clinical, radiologic, and BAL findings, initiation of therapy without histopathologic confirmation may be considered; however, the diagnosis must be reconsidered whenever the outcome is unusual. The optimal dose and duration of corticosteroid therapy have not been established. Disease control must be balanced with treatment side effects.
- Whether AFOP represents a variant of OP or a distinct entity is unknown.

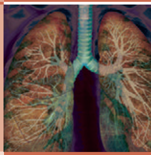
Section 8

PARENCHYMAL LUNG DISEASES



Chapter 51

Silicosis and Coal Worker's Pneumoconiosis

Cyrielle Jardin • Benoit Wallaert

Pneumoconiosis has been defined as the non-neoplastic reaction of the lung to inhaled mineral or organic dust. Prolonged inhalation of coal mine dust may result in the development of pneumoconiosis, silicosis, and industrial chronic bronchitis and emphysema, either singly or in various combinations. *Coal worker's pneumoconiosis* (CWP) is the term generally applied to interstitial disease of the lung resulting from chronic exposure to coal dust, its inhalation and deposition, and the tissue reaction of the host to its presence, whereas *silicosis* refers to lung disease due to inhalation of dust containing silica. Pneumoconioses differ in a number of ways from acute allergic and toxic interstitial diseases associated with exposure to organic dusts, principally because of their long latency periods (usually 10 to 20 years or more) between exposure onset and disease recognition.

SOURCES OF EXPOSURE

Coal is not a mineral of fixed composition. It is graded by rank, reflecting its carbon content and thus combustibility: Anthracite is the highest-ranked coal, with a carbon content of approximately 98%. Lower-ranked coals, bituminous and subbituminous, have carbon contents of approximately 90% to 95% carbon. The rank of coal has an influence on the risk of disease: Higher-rank coals entail higher risk than lower-rank coals. However, exposure to coal dust with a quartz concentration greater than 15% is associated with a high risk for development of a rapidly progressive form of pneumoconiosis that has the characteristics of silicosis. In open mines, dust levels rarely approach those of underground mines.

The most common form of crystalline silica is quartz. Quartz is almost pure silicone dioxide but often contains traces of other elements. Other crystalline forms of silica are cristobalite and tridymite. The importance of silica as a health hazard is due to its ubiquity (Table 51-1). Diatomite is a siliceous sedimentary rock used for filtration; for heat and sound insulation; as an adsorbent and filtering agent; as a filler material in plastics, paper, and insecticides; and in the manufacture of floor coverings.

It seems that development and progression of silicosis depend on the total amount of quartz to which workers are exposed, the time over which that exposure occurs, and the presence of other minerals that may interfere with the toxicity of the quartz.

EPIDEMIOLOGY

CWP was first recognized in Scottish miners in 1830. In recent decades, the incidence of CWP has been declining in industrial countries thanks to improved dust controls, although increased mechanization in the mid-1960s led to a temporary increase in dust levels. In parallel, in a report from the United Kingdom, for the period 1950 to 1980, the annual rate of CWP recognition for state compensation in current and retired miners decreased from approximately 7% to 1% to 2%. The overall prevalence of CWP, which reflects more distant exposure and earlier incidence, declined from approximately 13% to 5%, but regional differences in reported rates were substantial. Similar regional differences and similar declines have been noted in the United States and other countries.

Since the 2000s, however, new sources of silicosis have emerged, especially in developing countries—for example, in Turkey, where the denim industry has been responsible for more than 75 cases thus far. Denim sandblasting is used to give jeans a more "worn-out" appearance and requires highly pressurized sand projection, often performed by young persons without any respiratory protection. In a recent epidemiologic study, among 145 workers recruited from the outpatient clinic at Atatürk University, 77 (53%) presented with radiologic evidence of silicosis.

Other, more anecdotal sources of silica exposure have been described, such as heat-dried mud inhalation in workers engaged in the manufacture of tatami mats in China, and handling quartz-containing fillers by dental supply factory workers in the United States. All of these "new forms" of silicosis underscore the fact that it will always remain a concern for respiratory clinicians worldwide, despite the decline of the mining industry in Western countries.

PATHOPHYSIOLOGY

Three groups of factors are known to influence the character and severity of lung tissue reaction to mineral dusts. The first category is the *intensity and duration of exposure*, followed by *individual susceptibility*, which explains why, among a group of workers exposed to the same dust, only a fraction will develop pneumoconiosis. Finally, the *nature and properties of the dust* are to be considered. For each mineral, geometric and aerodynamic properties, chemistry, and surface properties vary. Particles that can cause pneumoconiosis are aerodynamically and

Table 51-1 Major Industries Associated With Silica Exposure

Occupation	Exposure
Sand blaster	Ship building, oil rig maintenance, preparing steel for painting
Miner	Surface coal mining, roof bolting, shot firing, drilling, tunneling
Miller	Silica flour
Glass maker	Polishing with sand and enamel work
Potter cleaner	Crushing flint and fettling, foundry work, mold making and vitreous enameling, manufacture of cultured quartz crystal
Quarry and stone worker	Cutting of slate, sandstone, and granite
Abrasive worker	Inhalation of fine particles during grinding

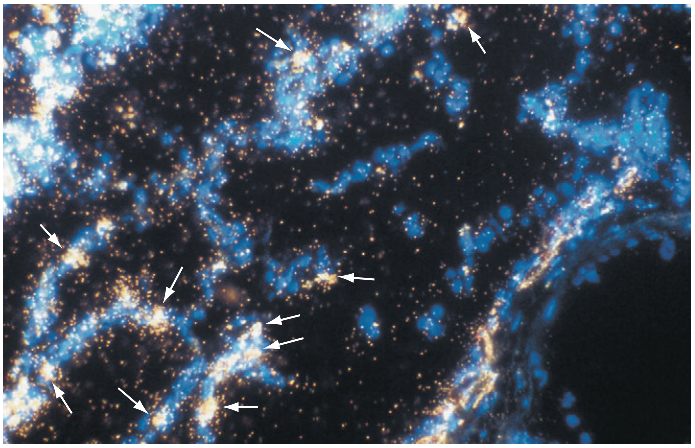


Figure 51-1 Tumor necrosis factor-α messenger RNA (as demonstrated by in situ hybridization) is expressed in alveolar macrophages (*arrows*) in this lung section from a patient with coal worker's pneumoconiosis.

geometrically small enough to reach the respiratory bronchioles and be deposited there—this generally means spherical particles of 0.5 to 5 μm in diameter.

The pathogenesis of pneumoconiosis is similar to that of all interstitial lung diseases. The condition begins as a chronic inflammatory state (alveolitis) in which inflammatory cells are activated, with consequent damage to the pulmonary architecture. Inorganic particles are phagocytosed by alveolar macrophages, causing their activation and the release of inflammatory mediators such as cytokines and arachidonic acid metabolites. These mediators, in turn, induce the recruitment of other inflammatory cells within the alveolar wall and on the alveolar epithelial surface. Toxic oxygen derivatives and proteolytic enzymes are released by the inflammatory cells, which cause cellular damage and disruption of the extracellular matrix.

The inflammatory phase is followed by a reparative phase, in which growth factors stimulate the recruitment and proliferation of mesenchymal cells and regulate neovascularization and reepithelialization of injured tissues. During this phase, abnormal or possibly uncontrolled reparative mechanisms may result in the development of fibrosis. Fibrogenic particles activate proinflammatory cytokine production within the respiratory tract. Tumor necrosis factor (TNF)-α seems to play a key role in the recruitment of inflammatory cells induced by toxic dusts (Figure 51-1). In addition, neutrophils recruited in the area of inflammation may contribute to the alveolitis, and respiratory and endothelial cells may play a further role by releasing various chemokines such as interleukin (IL)-8. Finally, growth factors such as platelet-derived growth factor, insulin-like growth factor, fibroblast growth factor, and transforming growth factor-β are involved in the pathogenesis of lung fibrosis and in the proliferative response of type II epithelial cells, which occurs in progressive massive fibrosis (PMF).

GENETICS

More recently, associations of polymorphisms in genes coding for inflammatory cytokines such as TNF-α, IL-6, IL-18, and their receptors with CWP incidence, prevalence, and progression have been reported. In silicosis, a significant association was found between disease severity and the TNF-α –238 variant. Irrespective of disease severity, the TNF-α –308 and IL-1 receptor type A (RA) +2018 variants conferred an increased risk for development of silicotic disease. The TNF-α polymorphisms in positions 238, 376, and 308 of the promoter region also were found to be associated with severe silicosis in South African miners. In French coal miners differentially exposed to coal dust and cigarette smoke, the TNF-α –308 single-nucleotide polymorphism (SNP) showed an interaction with erythrocyte glutathione peroxidase (GSH-Px) activity in workers with high occupational exposure, whereas the lymphotoxin-α (LTA) *Nco*I polymorphism was associated with CWP prevalence in miners with low blood catalase activity. Certain NFKB1 and FAS-1377 gene polymorphisms also have been described as potential risk factors in a population of Chinese silicotic patients, as compared with a similar group of disease-free silica-exposed miners.

An understanding of genetic variability and environmental factors is crucial to the identification of persons at high risk for development of CWP and to the prevention and treatment of this disease.

HISTOPATHOLOGIC CHANGES

CWP lesions are focal. Simple CWP is associated with macular and nodular lesions, whereas complicated CWP is associated with PMF and lesions of rheumatoid pneumoconiosis (Caplan syndrome, discussed later on).

The pleural surfaces of a coal worker's lung show an irregular pattern of bluish-black pigmentation that corresponds to the junction sites of septal-lymphatic vessels and the pleura. Peribronchial, hilar, and paratracheal lymph nodes are enlarged, black, and firm. The initial lesions in the lung are the coal dust macules, which correspond macroscopically to focal areas of black pigmentation. On microscopic examination, the macule is seen to be composed of coal dust–laden macrophages within the walls of the respiratory bronchioles and adjacent alveoli (Figure 51-2). Focal emphysema around the coal dust macule is common and is considered an integral part of the lesion of simple CWP.

The histopathologic hallmark of simple CWP is the nodule. The nodules are rounded lesions with collagenous centers. On microscopic examination, the nodule can be divided into three zones: a central zone composed of whorls of dense, hyalinized fibrous tissue; a middle zone made up of concentrically arranged collagen fibers (onion-skinning); and a peripheral zone of more randomly oriented collagen fibers mixed with dust-laden macrophages and lymphoid cells (Figure 51-3). "Old" inactive

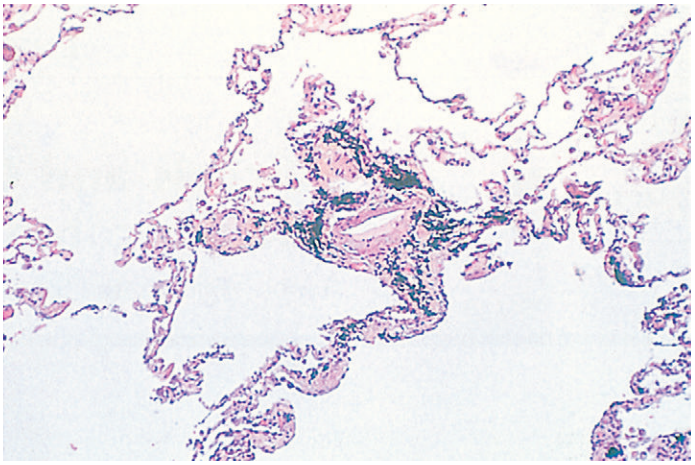

Figure 51-2 Macular lesion of coal worker's pneumoconiosis. This coal macule consists of collections of macrophages, laden with coal dust, seen extending into the connective tissue surrounding the respiratory bronchioles.

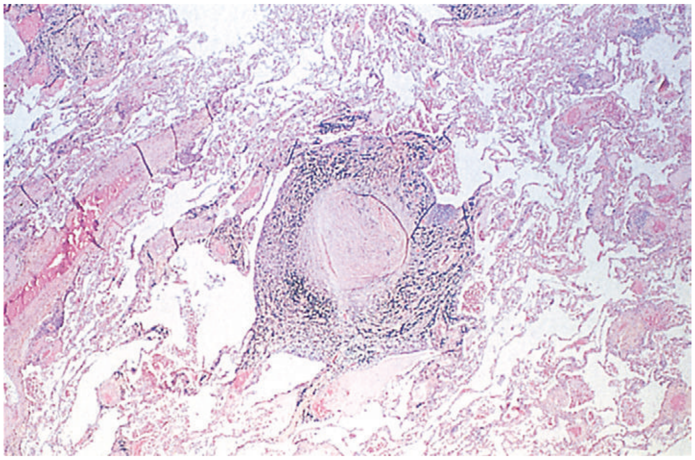

Figure 51-3 Coal nodule, seen here as a rounded lesion with a collagenous center and a peripheral anthracotic pigmented area. The nodule shows a smooth, sharp border, with dust-laden macrophages and laminated collagen deposition within the interstitium of the lung. The small central area is pale and rich in collagen, and the periphery contains a variable amount of fibrogenic dust.

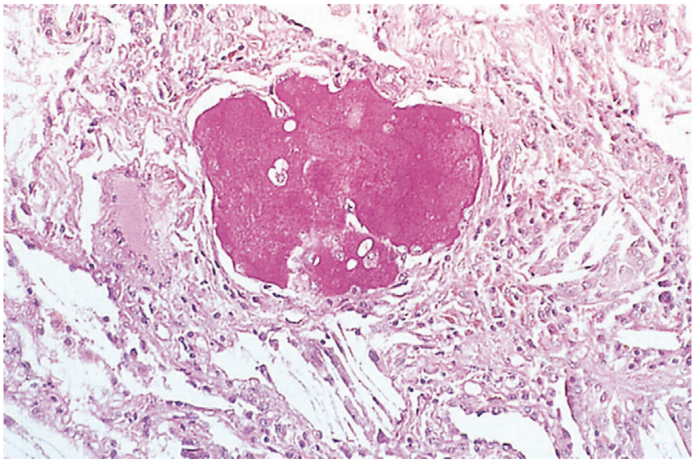

Figure 51-4 Acute silicosis. Infiltration of the alveolar walls by plasma cells and lymphocytes is evident. Note the alveoli filled with an eosinophilic coagulum.

nodules often are relatively acellular. Particles of silica may be demonstrated in the nodules as birefringent particles under polarized light. Nodules represent a form of mixed-dust fibrosis (i.e., coal dust plus silica exposure), usually are found in association with macules, and in some instances may develop from preexisting macules. They are not confined to the respiratory bronchioles but also are seen in the subpleural and peribronchial connective tissues. Nodules tend to cluster and eventually coalesce to produce PMF. Degenerative changes commonly are observed in the nodular lesions, including calcification, cholesterol clefts, and cavitation. In severe silicosis, structural alterations of the pulmonary vasculature may result from the accumulation of dust in the adventitia of large vessels, and involvement of the smaller blood vessels by silicotic nodules also may be seen.

Progressive massive fibrosis is defined as an opacity or fibrotic pneumoconiotic lesion of 1 cm in diameter or greater. These lesions appear as black fibrotic masses that may be round, oval, or irregular in shape. The lung and bronchovascular rays become markedly distorted. Microscopically, the lesions are composed of bundles of haphazardly arranged hyalinized collagen fibers and/or reticulin fibers and coal dust. Dust particles near the periphery of the lesion are found mainly within macrophages, whereas in the center, the dust tends to lie free in clefts and cavities. The nodules are confluent, emphysematous bullae often surrounding the areas of massive fibrosis. Focal interstitial fibrosis can be observed in the lungs of workers exposed to dust containing a combination of silica and silicates, with sometimes sufficiently advanced lesions to result in honeycombing-type changes. Areas of liquefactive necrosis containing fragments of degenerating collagen as well as cholesterol crystals are frequently observed.

The histopathologic pattern in acute silicosis is quite different from that in the chronic form. Infiltration of the alveolar walls with plasma cells, lymphocytes, and fibroblasts, with some collagenation, is typical. The alveoli are filled with an eosinophilic coagulum (Figure 51-4). Electron microscopy shows widening of alveolar walls, with some collagen and clusters of type II cells; the alveolar spaces contain degenerating cells that probably are type II alveolar cells and macrophages. Silica particles may be demonstrated in the lungs and lymph nodes; silicotic nodules are few or absent.

CLINICAL FEATURES AND DIAGNOSIS

CWP and silicosis generally are first recognized from characteristic changes on the plain chest radiograph, which also is critical in evaluating disease progression. Requirements for the diagnosis include a history of significant exposure, radiographic features consistent with these illnesses, and the absence of any other disease that may mimic pneumoconioses (primarily infections with a predominantly miliary radiographic pattern, such as tuberculosis, fungal infections, or sarcoidosis). The radiographic appearances are most usefully described using the coding system devised for classification of findings on standard chest films in pneumoconiosis under the auspices of the International Labour Office (ILO) (Table 51-2). In clinical practice, simple CWP is characterized by small rounded opacities (nodules) rather than small irregular opacities, although the latter may be seen in much lesser profusion (as described in Table 51-2, profusion categories 0 to 3 refer to the relative abundance of small opacities apparent on the chest radiograph). For designation of disease characterized by large opacities, either *PMF* or *complicated CWP* is in common use.

Table 51-2 **International Labour Organization (ILO) Radiographic Classification of Pneumoconioses**

Small Opacities*	Regular	Irregular
<1.5 mm in diameter	p	s
>1.5 mm but <3 mm in diameter	q	t
>3 mm but <10 mm in diameter	r	u

Categories

Small Opacities

The four profusion categories, 0 to 3, refer to the concentration (density) of small opacities apparent on the radiograph: category 0, small opacities are absent or less profuse than in category 1; 1, opacities are few in number; 2, opacities are numerous; 3, opacities are very numerous and obscure the normal radiographic markings.

Large Opacities

Complicated pneumoconiosis or progressive massive fibrosis (PMF) is divided into categories A to C based on the size of the large opacities. To be classified as PMF, at least one nodule should be 1 cm or greater in diameter.

A—Sum of diameters of lesions is not more than 50 mm.

B—Total area occupied by lesions is not greater than the area of the right upper zone.

C—Total area occupied by lesions is greater than the area of the right upper zone.

*Small opacities are defined by their average size and profusion.

CLINICAL FEATURES

Simple CWP and category A–complicated CWP are not associated with respiratory symptoms. As in most populations engaged in manual work, breathlessness and cough in coal miners usually are a consequence of cigarette smoking. However, coal mine dust may itself cause chronic bronchitis and chronic obstructive pulmonary disease, which together are known as *industrial bronchitis*. The evidence that coal dust exposure is associated with the development of significant respiratory impairment has led to its designation as a compensable disease despite the absence of CWP.

By contrast, patients with complicated pneumoconiosis (i.e., PMF) of categories B and C may present with undue breathlessness and productive cough. Melanoptysis is the result of necrosis within the conglomerate, coal-containing lesions that characterize PMF. Progressive, undue exertional dyspnea usually is the dominant symptom, but rarely, breathlessness may be present at rest.

No specific abnormal physical signs are found in CWP. Finger clubbing and fine inspiratory crackles are not features of the disease, so if these are present, another explanation should be sought. Only in a small proportion of severe cases of complicated disease does CWP evolve to produce chronic respiratory failure and cor pulmonale.

Other than PMF, CWP may be associated with a number of other disorders—most notably the autoimmune disorders of rheumatoid disease and progressive systemic sclerosis. The combination of rheumatoid disease and CWP is known as *Caplan syndrome* (Figure 51-5). This diagnosis is suggested by the association of coal dust exposure, rheumatoid arthritis, and multiple well-defined large, rounded opacities (nodules greater than 10 mm in diameter) on the chest radiograph. Spontaneous disappearance is common, with or without initial cavitation, and new nodules frequently emerge in different locations. The Caplan nodule also is more likely to cavitate, thereby producing a concentric ring pattern, so this lesion also is known as a necrobiotic nodule. Central necrosis is rare in nodules of CWP, although it may occur in conglomerate lesions.

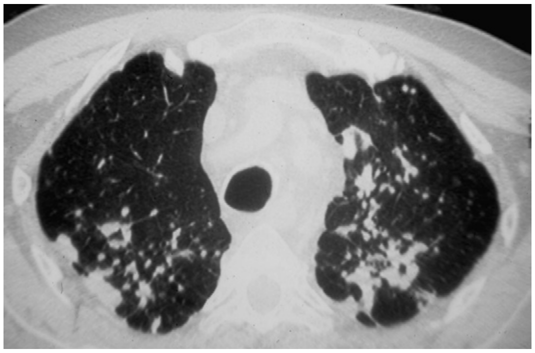

Figure 51-5 Caplan syndrome. High-resolution computed tomography scan obtained at the level of the upper lobes shows bilateral parenchymal micronodules and coalescence in the right upper lobe. Note the cavitation of the nodule in the left upper lobe.

CWP has been linked with a number of specific infections, the most prominent of which has been tuberculosis. Silicosis is recognized to increase the risk for pulmonary tuberculosis, which can be difficult to diagnose in patients with preexisting abnormalities on plain chest radiographs. Diagnostic skin tests also may show lesser sensitivity in silicotic patients, owing in part to their age and general condition. Silicotic patients can suffer from malnutrition in later stages of the disease because of chronic respiratory failure and elevated metabolism. Protein deficiency may impair immunoglobulin production and thus lessen the skin tests' sensitivity (as they rely on adaptive immune response). In these particular patients, interferon-gamma assays could be used to improve diagnostic performance. In contrast with silicosis, however, CWP does not increase significantly the risk for infection with *Mycobacterium tuberculosis*. The association observed with coal mining (and hence CWP) in some countries appears to have been a consequence only of close contact during long hours of work in the confined mine environment. Nontuberculous mycobacteria, on the other hand, may infect lungs damaged by CWP and other types of pneumoconiosis with greater-than-usual frequency, so CWP does seem to increase the risk for infection with opportunistic organisms. *Mycobacterium avium* probably is the most important of these and is poorly sensitive to antibiotic agents. *Mycobacterium kansasii* and *Mycobacterium malmoense* also may be pathogenic in this setting. It may similarly be difficult to attribute change in the radiographic appearances to advancing infection or worsening PMF. Experimental studies also suggest that mycobacterial infection is a factor that helps explain the progression from simple to complicated pneumoconiosis.

Other opportunistic infections reported in association with CWP have included nocardiosis, sporotrichosis, and cryptococcosis. *Aspergillus* spp. have been noted to colonize cavities in conglomerate lesions of complicated CWP.

A further association with complicated CWP, if manifested by bullous emphysema, is spontaneous pneumothorax. The advanced stages of complicated CWP also are associated with recurrent episodes of acute and subacute bronchitis. Persistent productive cough is common in coal miners in the absence of CWP. No evidence of a causal relationship between silicosis and carcinoma of the lung has been found, although association is consistent for silicotics and limited nonsilicotic workers. The available data leave open the issue of whether silica per se materially increases lung cancer risk in absence of silicosis. In

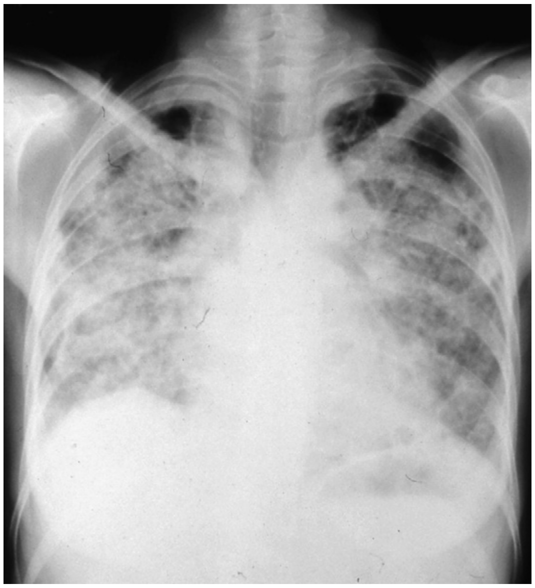

Figure 51-6 Chest radiograph showing alveolar filling in acute silicosis. The patient was a 28-year-old woman who had inhaled fine particles of silica from abrasive powder. The clinical disease that developed was rapidly progressive silicosis, which typically is fatal over the next several years.

1997, the International Agency for Research on Cancer (IARC) classified crystalline silica dust exposure as a known human carcinogen, group 1. Currently, CWP and silicosis should be considered conditions that predispose workers to an increased risk of lung cancer.

Accelerated silicosis is rare and is clinically identical to the classic forms of silicosis, except that the time from initial exposure to the onset of disease is shorter and the rate of progression of disease is dramatically faster.

Acute silicosis is rare. Presenting signs and symptoms include cough, weight loss, and fatigue, with rapid progression to fulminant respiratory failure over several months in some cases. Chest auscultation reveals diffuse crackles, and in patients with this clinical picture, the rapid development of cor pulmonale eventuating in respiratory death is characteristic. Survival after the onset of symptoms often is less than 2 years. Diffuse alveolar filling, most apparent at the bases, is the most prominent finding on the chest radiograph (Figure 51-6). Although serial chest radiographs from workers with this illness have been infrequently reported, it seems that the bibasilar filling pattern progresses into large opacities located in the middle zones rather than the upper zones.

CHEST RADIOLOGY

The radiographic pattern in simple CWP typically is one of small rounded opacities that appear first in the upper zones (Figure 51-7). The middle and lower zones become involved as the number of opacities increases. The nodules increase in profusion with increasing dust exposure; a change in profusion after dust exposure has ceased is very unusual. Calcification of the nodules may occur (in 10% to 20% of cases).

Complicated pneumoconiosis is defined as presence of a lesion of 1 cm or greater in longest diameter. The large opacities usually are predominant in the upper lobes, may be unilateral or bilateral, and are symmetrically or asymmetrically distributed (Figure 51-8). The pattern of change in size is variable and unpredictable. In most but not all cases, PMF occurs on a background of simple pneumoconiosis, and it may appear after dust exposure has ceased. Cavitation can develop within a PMF lesion (Figure 51-9), and occasionally a dense peripheral arc or rim may be seen at its lower pole that represents calcification. Dense calcification with the lesion also is sometimes seen. PMF often is associated with bullous emphysema and fibrotic scarring, leading to distortion of the lung and shift of the trachea and mediastinum to the affected side. Irregular, mainly basal opacities also may be seen on standard radiographs. Eggshell calcification is uncommon in CWP but may occur in intrapulmonary, hilar, or mediastinal lymph nodes, possibly because of concomitant exposure to silica. Pleural effusion is uncommon in CWP. Its presence may be related to an associated infection or an interaction with a systemic collagen vascular disease.

In simple CWP, computed tomography (CT) shows parenchymal lesions that can be detected in miners with normal-appearing chest radiographs. CT thus shows greater sensitivity

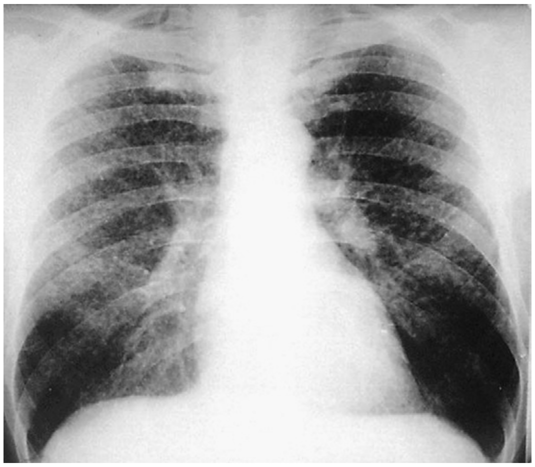

Figure 51-7 Chest radiograph appearance in simple coal worker's pneumoconiosis. The patient was a 55-year-old man who had worked for 18 years in an underground coal mine. He was a nonsmoker with a chronic cough and normal lung function. The radiograph shows a diffuse distribution of small rounded opacities, more prominent in the upper zones than in the lower zones.

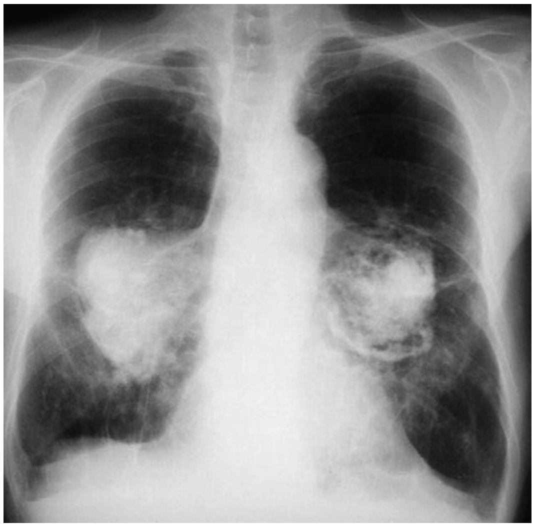

Figure 51-8 Chest radiograph appearance in progressive massive fibrosis. The patient was a 66-year-old man who had worked for 30 years in an underground coal mine. The radiograph shows bilateral masses corresponding to the lesions of progressive massive fibrosis.

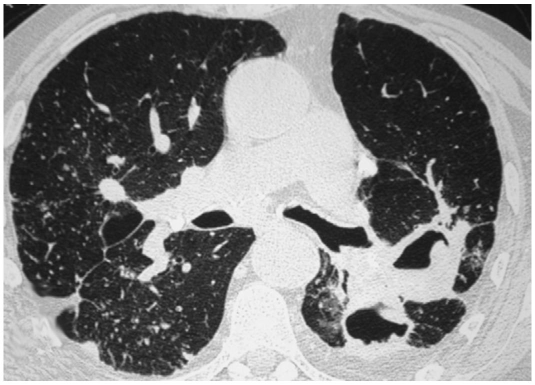

Figure 51-9 Cavitation within progressive massive fibrosis lesion. High-resolution computed tomography scan shows cavitation of the left lung masses. Note the diffuse micronodulation and associated emphysema.

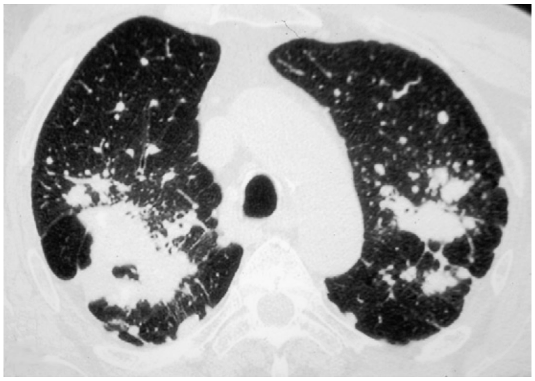

Figure 51-11 Aseptic necrosis. Computed tomography scan shows bilateral masses with necrosis of the right upper lobe mass and bilateral emphysema.

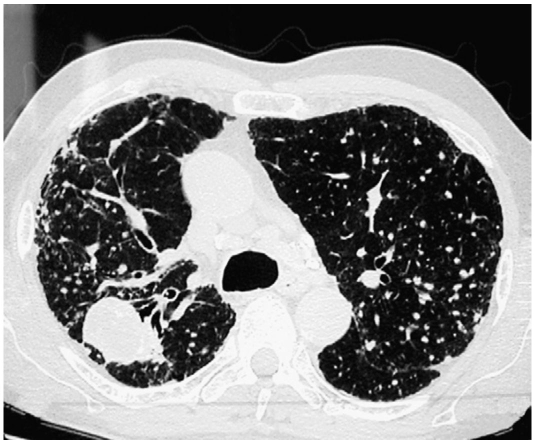

Figure 51-10 Progressive massive fibrosis. High-resolution computed tomography scan shows bilateral masses consistent with progressive massive fibrosis. There is a background of nodules associated with bullous changes around progressive massive fibrosis lesions; this imaging pattern defines paracicatricial emphysema. Note the calcifications within the masses and the lymph nodes.

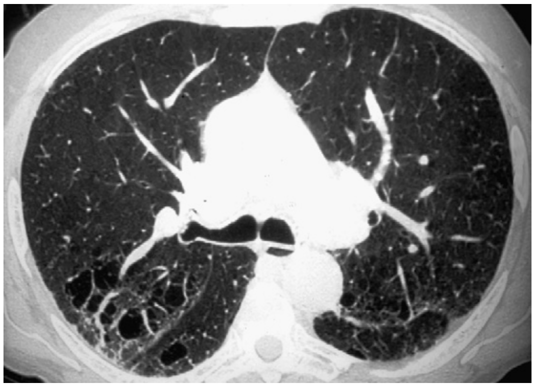

Figure 51-12 Nonbullous emphysema. High-resolution computed tomography scan shows small bullae and low attenuation, without progressive massive fibrosis lesions—an imaging pattern that defines centrilobular or nonparacicatricial emphysema.

than plain radiographs for detection of simple CWP but less obvious benefit with complicated pneumoconiosis. A posterior and right-sided predominance of lesions in the upper zones is evident on these imaging studies.

Nodules usually are observed against a background of parenchymal micronodules and generally are associated with subpleural micronodules. Two categories of lesions can be observed in PMF: lesions with irregular borders that are associated with disruption of the pulmonary parenchyma and lead to typical scar emphysema (Figure 51-10) and lesions with regular borders that are unassociated with scar emphysema. When the lesions are greater than 4 cm in diameter, irregular areas of aseptic necrosis can be observed with or without cavitation (Figure 51-11).

Two major forms of emphysema occurring in coal workers can be detected on the CT scan: bullous changes around PMF lesions, representing *paracicatricial* or *scar emphysema*, and nonbullous lesions, defined as *irregular emphysema* (Figure 51-12). Lesions of diffuse pulmonary fibrosis can be detected on high-resolution CT as honeycombing or areas of ground glass attenuation. Two specific etiopathogenic mechanisms for fibrosis in coal miners should be considered: (1) a direct effect of deposited coal or silica particles and (2) an indirect effect resulting from an association with scleroderma. In addition, determination of the extent of air trapping on expiratory thin-section CT scans may assess obstructive abnormalities.

LUNG FUNCTION

In all studies of lung function in patients with pneumoconiosis, account should be taken of a number of different and confounding influences; in particular, the effects of smoking need to be considered. It can be stated that simple CWP has no important effect on spirometric measures when previous dust exposure is taken into account and when smoking habits also are considered. Similarly, simple silicosis has no appreciable effect on lung function. In more advanced disease, slight reduction in volumes, compliance, and gas transfer can be present; a predominantly restrictive pattern is seen. Slight reduction in arterial oxygen tension on effort may be observed in advanced disease. Oxygen desaturation is not present when measurements are obtained with the patient at rest or on moderate effort in simple CWP. As in the case of radiographic progression, the changes in pulmonary function are more likely to occur in workers who have had intense exposure to dust. In addition, it must be pointed out that miners who did not have CWP on chest radiography exhibited lower values for forced expiratory volume in 1 second than those measured in control subjects, suggesting the frequent presence of coal dust–induced chronic obstructive pulmonary disease. In PMF, lung function depends on the extent of the lesions and extent of emphysematous changes. Studies of lung function in the more advanced stages of PMF have shown an obstructive and restrictive pattern; therefore, diffusing capacity usually is reduced. Compliance also usually is somewhat decreased. Ultimately, hypoxemic respiratory failure may occur.

SEROLOGIC AND IMMUNOLOGIC FEATURES

No specific biologic features of pneumoconiosis have been identified. However, immunologic abnormalities are now well described: positive circulating antinuclear antibodies or rheumatoid factor. Serum immunoglobulins A and G are present at significantly raised levels in miners with pneumoconiosis. Finally, an increased serum angiotensin-converting enzyme level was observed in 45% of pneumoconiotic coal miners, whatever the radiologic classification of pneumoconiosis. More recently, IL-17–producing lymphocytes have been suspected to induce lung inflammation but not fibrosis in a murine model of experimental silicosis.

BRONCHOALVEOLAR LAVAGE

On bronchoalveolar lavage, no change in differential cell count has been noted, in contrast with a number of other interstitial disorders of the lung. Alveolar inflammatory cells from patients with CWP, especially those with PMF, exhibited spontaneous release of superoxide anions, proinflammatory cytokines, and profibrotic mediators in greater amounts than those measured for cells from control subjects.

CLINICAL COURSE, TREATMENT, AND PREVENTION

PROGNOSIS

Simple CWP is not associated with premature death, but approximately 4% of deaths in coal miners are directly due to complicated pneumoconiosis. In workers with categories 1, 2, and 3 of simple CWP and category A of complicated CWP, life expectancy is the same as that for persons without pneumoconiosis in the general population.

The rate of progression to PMF seems to be influenced chiefly by the age at which the miner begins to show radiographic changes of CWP: The earlier the diagnosis, the more likely there is to be progression reflecting individual susceptibility and the level of cumulative exposure.

MANAGEMENT

No specific treatment affects the course of CWP, although treatment options are available for complications such as tuberculosis, pneumothorax, and chronic hypoxemia.

When a miner is found to have CWP, further dust exposure should be excluded. Simple pneumoconiosis does not necessarily imply complete exclusion from mining, whereas when PMF is detected, all further dusty work should be prevented. Additional information can be obtained from pulmonary function tests, because the development of an obstructive ventilatory defect (resulting from dust exposure) may occur in the absence of CWP. For all smoking patients, appropriate advice and support for smoking cessation should be provided.

After a determination of disability from CWP, the physician should be able to direct the patient toward whatever mechanism exists for compensation. As noted earlier, CWP generally is first recognized from the plain chest radiograph, which also is critical in evaluating disease progression. Requirements for the diagnosis include a history of significant exposure, radiographic features consistent with these illnesses, and the absence of conditions that may mimic these diseases (primarily infections with a predominantly miliary radiographic pattern, such as tuberculosis, fungal infections, or sarcoidosis).

PREVENTION

The prevention of pneumoconiosis depends on controlling exposure concentrations of ambient dust to levels known to be associated with minimal and acceptable risk. Dust control is affected primarily by ventilation, although spraying of water at points of dust generation is a useful measure for dust suppression. The effectiveness of such measures should be monitored by regular measurement of dust concentrations and by regular clinical and radiologic surveillance of the persons in the workforce. Surveillance allows early recognition of workers with simple pneumoconiosis, who are likely to be those with greatest susceptibility, so that ongoing exposure can be restricted (perhaps by transfer to jobs with lower exposure) and the risk of future disablement from PMF reduced.

Variability of individual susceptibility is likely to be an important determinant for CWP, as it is for most occupational disorders, and a number of predictive factors may be useful in identifying miners at higher-than-average risk: initial presence of expiratory wheezes, obstructive pattern of lung function, and more micronodules on CT scan. An alternative approach for the future might involve genetic screening evaluating for polymorphisms in the promoter of various mediators. In any event, control of exposure levels alone is likely to prevent most cases of disabling PMF, and it has been predicted that an exposure concentration over 35 working years that does not exceed an average of 4.3 mg/m^3 is associated with a probability for the development of category 2 or more CWP of no more than 3.4%. This represents a dramatic reduction in risk over the last 50 years.

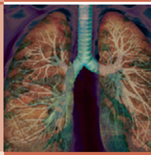
Section 8
PARENCHYMAL LUNG DISEASES



Chapter 52
Asbestosis

Lee S. Newman • Kaylan E. Stinson

Inhalational exposure to asbestos produces both malignant and nonmalignant diseases of the chest. The focus of this chapter is on the two major categories of nonmalignant disease—asbestosis and asbestos-related pleural disorders, listed in Table 52-1. These conditions have received a great deal of attention from the scientific and medical communities because of the ubiquitous use of asbestos in modern society and its diverse and pernicious toxicities. Despite major progress in awareness of the issues and in control of exposure, a large burden of asbestos-related disease will continue to accrue as a consequence of ongoing exposure and the characteristic disease latency.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOPHYSIOLOGY

EPIDEMIOLOGY

The first well-documented cases of asbestosis were reported in the early 1900s among asbestos textile workers. Through the 1920s and 1930s, reports emerged of asbestosis, pleural thickening, pleural calcification, and right ventricular failure in asbestos-exposed workers. Radiographic studies that began in the 1930s documented an asbestosis prevalence of 25% to 55% in these workers, especially among those with greater cumulative exposure. Early evidence from these studies suggested that exposure to higher concentrations of asbestos over longer periods of time resulted in increased risk for development of pulmonary fibrosis.

Asbestos use increased extensively in the early 1940s, and this mineral substance was used widely in the United States for the next 30 years. Asbestos use began to diminish when the Occupational Safety and Health Administration (OSHA) regulated workplace asbestos exposure in 1972. It is estimated that between 1940 and 1979, more than 27 million people had potential exposure in the United States alone. Data from a study of sheet metal workers examined between 1986 and 2004, reported by Welch and colleagues, found that asbestosis is continuing to occur even 50 years after first exposure. The study also found that the strongest predictor of nonmalignant asbestos-related disease in the workers was the cutoff year in which employment commenced: Prevalence was lowest among those who began working in the sheet metal industry after 1970 and highest among those who began work before 1949. With thousands of commercial applications and the mineral's resistance to degradation, asbestos remains ubiquitous. Efforts have been made to limit ongoing exposure through abatement programs of asbestos removal from buildings and/or on-site encapsulation. Nevertheless, asbestos-related disability and mortality will continue well into the next decade.

Although the use of asbestos has been curtailed in many developed nations, in less-developed countries this inexpensive but hazardous material continues to be used widely. Many developed countries are now fast replacing the developed ones in the production and use of asbestos. Currently, Russia is the leading producer of asbestos worldwide, followed by China, Brazil, Kazakhstan, and Canada. More than 85% of the world production of asbestos is used to manufacture products in Asia and Eastern Europe. Although asbestos usage in developing countries is increasing, information about asbestos-related disease remains largely obscure. Epidemiologic questions have not been systematically researched.

In keeping with the long latency required before asbestosis becomes clinically apparent, all past and current asbestos workers must be considered to be at risk for development of this fibrosing lung disorder.

ETIOLOGY AND RISK FACTORS

The minerals referred to herein as "asbestos" are a family of naturally occurring, flexible, fibrous hydrous silicates found in soil worldwide. Mined asbestos fibers are categorized as either long and curly (serpentine) or straight and rodlike (amphibole). The serpentine fiber, chrysotile, accounts for most of the commercially used asbestos, favored for its properties of heat resistance, flexibility, and ease of spinning for textiles. Five categories of amphiboles are recognized: crocidolite, amosite, anthophyllite, tremolite, and actinolite. These more rigid fibers are less commonly used but are still pathogenic. All major commercial forms have been associated with development of nonmalignant respiratory disorders and of lung cancer and mesothelioma, as discussed in Chapters 47, 65, and 70.

Asbestosis is the result of either direct or "bystander" exposure to asbestos-containing materials. Major sources of exposure are summarized in Table 52-2. During the first half of the 20th century, high-level exposures to asbestos dust occurred in the manufacturing of asbestos textiles and construction materials and in the construction and ship-building trades. Potential exposures still occur in the construction trades and in the process of asbestos abatement. Although the use of asbestos has been curtailed in many developed nations since the 1970s, in less developed countries this inexpensive but hazardous material continues to be used widely. High cumulative, occupational exposures in these settings are still commonplace.

Environmental exposure to asbestiform fibers also is well described as the cause of nonmalignant and malignant asbestos-related lung disease in countries including Turkey, Greece, Japan, and China and the territory of New Caledonia. Exposure in these settings usually occurs when villagers in rural areas

Table 52-1 Nonmalignant Asbestos-Related Diseases

Condition	Locus of Pathologic Change	Description
Asbestosis	Parenchyma	Interstitial pulmonary fibrosis
Benign nodules	Parenchyma	Lymphoid or fibrotic nodular scars
Benign pleural effusion	Pleura	Exudative, transient effusion
Pleural plaques	Pleura	Collagenous, hyalinized masses; circumscribed, avascular; usually involving the parietal pleura
Diffuse pleural thickening	Pleura	Collagenous, hyalinized masses; diffuse, avascular; involving the parietal and visceral pleura and interlobular space
Rounded atelectasis	Combined pleura and parenchyma	Scarring of pleura and adjacent lung tissue, resulting in retraction, entrapment, and local partial collapse of lung

disturb natural soil deposits while working in fields or when applying whitewash prepared from these outcrops to their dwellings. In the United States, asbestos-related lung disease caused by nonoccupational exposures is a recently recognized problem, mostly in current and former residents of Libby, Montana. Amphibole asbestos–contaminated vermiculite was mined, milled, and processed near this small town for many years. Personal and commercial use of the contaminated mineral was widespread among residents. During a health screening in 2000 to 2001, nearly 18% of 6668 participants were noted to have pleural thickening on chest radiographs. Less than 1% had findings compatible with asbestosis.

A clear dose-response relationship between asbestos exposure and asbestosis has been recognized, although controversy remains concerning risks at low-level exposure. Risk for asbestosis varies widely among industries, with more disease seen in textile and construction workers than with those in mining. Development of the disease is associated with factors such as respirability of the fiber type, the cumulative dose of exposure, the capacity of the lung to clear the fibers, and the biopersistence of the asbestos. In general, the relative risk for development of asbestosis for asbestos workers increases in proportion to the asbestos exposure levels in the workplace. More severe disease has been associated with higher retention of asbestos fiber in the lungs. Typical asbestos fibers found in the lungs are 20 to 50 µm long and initially are deposited at the bifurcations of conducting airways. Thin fibers, of diameters less than 3 µm,

Table 52-2 Major Asbestos Uses and Sources of Exposure

Environment	Type of Exposure	Source of Exposure
Occupational	Asbestos-cement products	Construction industry (sheeting used in roofing and cladding of structural materials, molded into roof tiles, pipes, gutters; filler for wall cracks, cement, joint compound, adhesive, caulking putty)
	Floor tiling	Filler and reinforcing agent in asphalt flooring, vinyl tile, adhesive
	Insulation, fireproofing	Insulators, pipefitters Construction industry (pipes, boiler covers, ship bulkheads, sprayed on walls and ceilings as fireproofing, soundproofing)
	Textiles	Fireproof textiles used in clothing, blankets
	Paper products	Roofing felt, wall coverings, mill board, insulating paper
	Friction materials	Brake linings
	Rubber, plastic manufacture	Filler in rubber and plastics
	Building trades, secondhand exposure	Building maintenance activities, pipefitting, electrical repair, boiler tending and secondhand exposure repair, boiler tending and repair, power station maintenance Carpenters, plumbers, welders
Domestic	"Fouling the nest"	Carrying home asbestos in hair and clothes of exposed workers results in exposure to family members
	Secondhand exposure	Residential remodeling, removal, handling of frayed, friable asbestos in homes can cause environmental exposure
General	Contaminated buildings	Found in low levels in buildings under normal use Elevated exposures from remodeling, renovation, asbestos removal, disturbance of contaminated materials such as acoustic ceiling tiles, vinyl floor tiles, paints, plaster, pipes, boilers, steel beams
	Geologic exposure	Living near asbestos mines or cement factories, or in geographic areas in which naturally occurring asbestos is found in ambient air
	Urban environment	Ambient air levels slightly higher in cities, perhaps because of asbestos shed from automotive brakes in denser traffic, and high concentration of industry and construction

translocate readily into the alveolar space, interstitium, and pleural space. Thicker fibers tend to be incompletely phagocytosed by alveolar macrophages and are retained in the lung, where they can trigger the inflammatory events that lead to fibrosis, as discussed next.

HISTOPATHOLOGY AND GRADING

Asbestosis is defined histopathologically as bilateral, diffuse interstitial fibrosis of the lungs caused by the inhalation of asbestos fibers (**Figure 52-1**). Gray streaks of fibrosis can be seen in the parenchyma along interlobar and interlobular septa. Later, the pleural surface becomes more nodular in appearance, and the parenchyma loses volume and elasticity and forms more fibrotic scars and honeycombing. The gross pathologic changes are most obvious in the lower lung zones bilaterally, with the worst disease nearest to the pleura.

The College of American Pathologists and Pulmonary Pathology Society has modified a 12-point grading scheme that has been shown to be consistently reproducible. The modified grading scheme, based on histologic criteria presented in the 2010 update on the original diagnostic criteria, consists of the following categories of disease severity:

Grade 0—no appreciable peribronchiolar fibrosis, or fibrosis confined to the bronchiolar walls
Grade 1—fibrosis confined to the walls of respiratory bronchioles and the first tier of adjacent alveoli
Grade 2—extension of fibrosis to involve alveolar ducts and/or two or more tiers of alveoli adjacent to the respiratory bronchiole, with sparing of at least some alveoli between adjacent bronchioles
Grade 3—fibrotic thickening of the walls of all alveoli between two or more adjacent respiratory bronchioles
Grade 4—honeycombing changes

Although histologic evidence of pulmonary fibrosis may occasionally be obtained in the course of clinical evaluation, routine lung biopsy and lavage are not recommended, and microscopic evidence is rarely required to diagnose asbestosis.

Occasionally, the determination of asbestos fibers in lung tissue, bronchoalveolar lavage, or sputum may be used to document past exposure, although these measurements are neither usually relied on nor required for the clinical diagnosis of asbestosis. Under light microscopy or by use of transmission electron microscopy, uncoated fibers or fibers coated with proteinaceous material may be detected. These coated fibers—so-called asbestos bodies or ferruginous bodies—are nonspecific, because they can be found in occupationally unexposed people, in occupationally exposed people who have no asbestos-related lung disease, and in workers who have asbestosis. Generally, the most exposed and most severely affected people have higher asbestos fiber counts, but a significant interlaboratory variability is found in these measures.

PATHOGENESIS

Some of the major events thought to be involved in the pathogenesis of asbestosis are summarized in **Figure 52-2**. Within minutes after asbestos fibers have been inhaled, a local tissue response is initiated at the bifurcations of terminal bronchioles and alveolar ducts. The first changes occur in epithelial cells and then in alveolar macrophages as they attempt to engulf and are pierced by the fibers. In addition to cell death, which leads to the release of macrophage contents, asbestos-activated macrophages release reactive oxygen species that directly damage the tissue through peroxidation and direct cytotoxicity. Asbestos also can induce toxicity by mechanisms independent of its ability to promote formation of reactive oxygen species.

Increasing numbers of alveolar macrophages accumulate within 48 hours of first exposure. With chronic inhalation, a localized fibrosing alveolitis in the peribronchiolar region develops, followed by diffuse fibrotic scarring. Increasing the dose of asbestos increases the cellular response. A cascade of events ensues in which the macrophages and neutrophils release various cytokines (such as interleukin-8 and interferon-γ), chemokines, oxidants, and growth factors (such as fibronectin, platelet-derived growth factor, insulin-like growth factor, transforming growth factor-β, tumor necrosis factor-α, and fibroblast growth factor). These attract and alter the function of other inflammatory cells and resident cells, thereby promoting inflammation and fibrosis. The response of fibroblasts to these signals is to proliferate and produce the constituents of extracellular matrix (e.g., collagen, proteoglycans) in the pulmonary interstitium. Resident cells themselves are both targets and perpetrators of the fibrotic response. The pathogenesis of the chronic fibrotic response is complex and remains to be fully elucidated. It is clear, however, that this chronic response is progressive and that, apart from macrophage, neutrophil, and

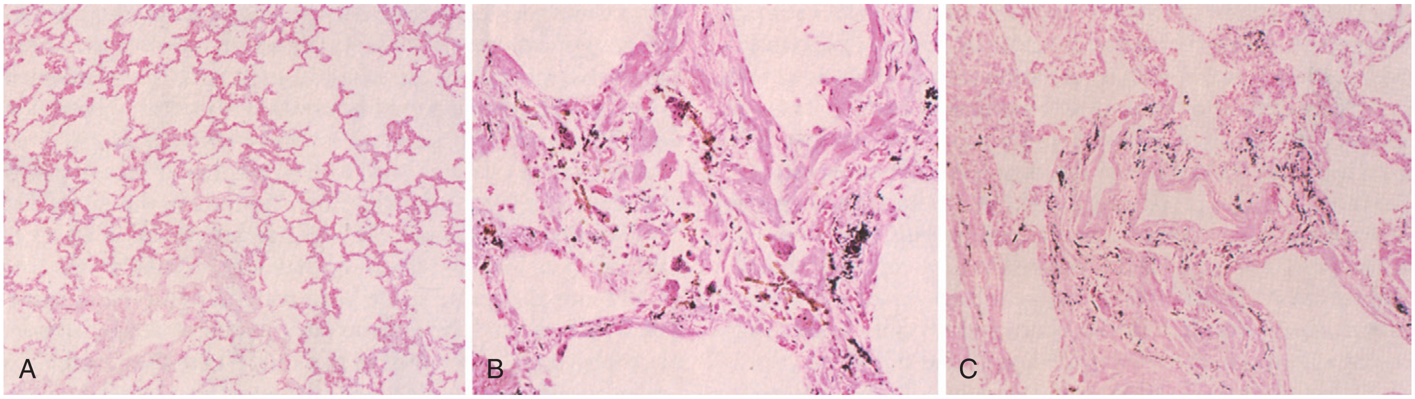


Figure 52-1 Histopathologic features of asbestosis. Disease severity is classified according to a modified grading scheme from the College of American Pathologists, as described in the text. **A,** In this grade 1 lesion, fibrosis is limited to the peribronchiolar tissue and the walls of the respiratory bronchioles. **B,** Enlargement of a grade 1 lesion illustrates presence of asbestos bodies. **C,** In this grade 3 lesion, fibrosis extends into the interstitial space between the respiratory units and into the alveolar ducts. (**A** to **C,** Hematoxylin and eosin stain.) *(Courtesy Dr. Val Vallythan, National Institute for Occupational Safety and Health, Morgantown, West Virginia.)*

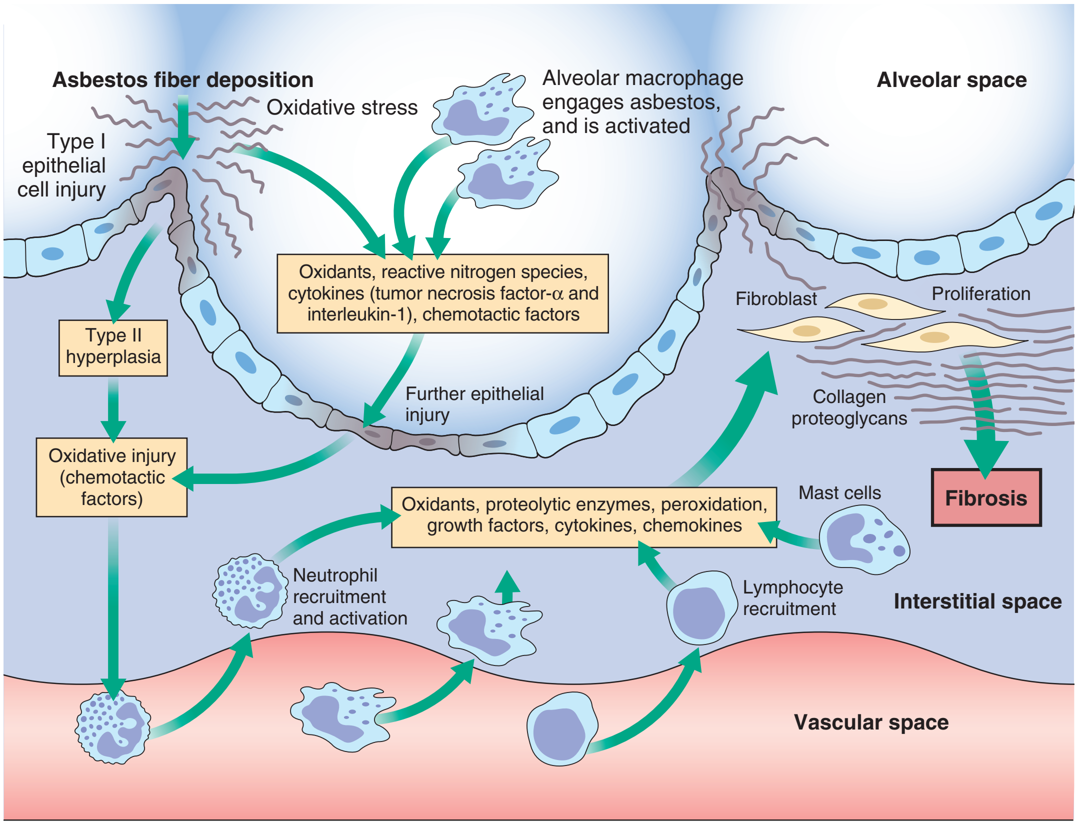

Asbestos fiber deposition
Oxidative stress
Type I epithelial cell injury
Alveolar macrophage engages asbestos, and is activated
Alveolar space
Oxidants, reactive nitrogen species, cytokines (tumor necrosis factor-α and interleukin-1), chemotactic factors
Type II hyperplasia
Fibroblast
Proliferation
Further epithelial injury
Collagen proteoglycans
Oxidative injury (chemotactic factors)
Mast cells
Fibrosis
Oxidants, proteolytic enzymes, peroxidation, growth factors, cytokines, chemokines
Neutrophil recruitment and activation
Lymphocyte recruitment
Interstitial space
Vascular space

Figure 52-2 Proposed pathogenesis of asbestosis. Asbestos fibers deposit at branch points in the distal airways and alveolar ducts, which prompts an inflammatory cascade characterized by cellular activation, recruitment, and injury. The result is fibroblast proliferation and extracellular matrix deposition in the interstitial space.

epithelial cells, a number of other cell types, such as lymphocytes and mast cells, contribute to the cycle of lung remodeling and fibrosis. Multiple, functionally overlapping, redundant inflammatory events occur in the lung simultaneously during the period of fibrogenesis. The consequence is an irreversible alteration in the structure and function of the lung.

GENETICS

Asbestos exposure is the principal risk factor for the development of nonmalignant asbestos-related disorders. The genetic contribution to this risk is uncertain. A small number of cross-sectional, candidate gene studies have examined the possible contribution of genetic determinants of susceptibility to asbestosis. The glutathione *S*-transferases (GSTs) and *N*-acetyltransferases (NATs) are enzymes that aid in the detoxification of hazardous agents. Several small studies examined GST-null (deletion) polymorphisms and NAT2 slow acetylator genotype in workers with and without asbestosis. Results from these studies, although somewhat inconsistent suggest that people who have a constitutional, homozygous deletion in the *GSTM1* gene that codes for GST class mu, as well as those who are NAT2 slow acetylators, may be at higher risk for asbestosis if exposed to sufficiently high levels of asbestos. On the basis of the premise that asbestos causes DNA damage and alters DNA repair, Zhao and colleagues demonstrated an association between polymorphisms of the DNA repair gene *XRCC1* and the in vitro extent of asbestos-induced DNA damage in Chinese asbestosis cases versus that in nonasbestosis cases. In Spain, patients with asbestosis were more likely than exposed control subjects to be heterozygous for the α_1-antitrypsin polymorphism Pi*Z.

CLINICAL FEATURES

Asbestosis is the pulmonary fibrotic disease that results from asbestos exposure. It affects the lungs symmetrically and typically is diagnosed on the basis of a consistent occupational or environmental history of asbestos exposure plus evidence of pulmonary fibrosis, usually obtained by chest radiography. The latency period from first exposure to clinical disease is 10 to 20 years but can be up to 40 years or more, with shorter latency and more severe disease seen in those workers with the highest inhalational exposures. In some situations, the exposure history may be difficult to document. If needed, further evidence of occupational exposure can be verified by identifying high numbers of asbestos bodies in bronchoalveolar lavage fluid, sputum, or lung tissue, as discussed previously. Evidence of bilateral pleural plaques is pathognomonic for previous asbestos exposure. The radiographic finding of bilateral interstitial markings in the lower lung zone is sufficient radiographic evidence of asbestosis, although (as discussed in the following section) other tools such as computed tomography (CT) and measures of lung physiology also aid diagnosis.

The most common signs and symptoms of asbestosis are the insidious onset of dyspnea on exertion (and eventually at rest), dry cough that can be paroxysmal, and fatigue. Hemoptysis, chest pain, and weight loss are not common and should raise suspicion for asbestos-related malignancy. Although physical abnormalities are uncommon at the early stages of asbestosis,

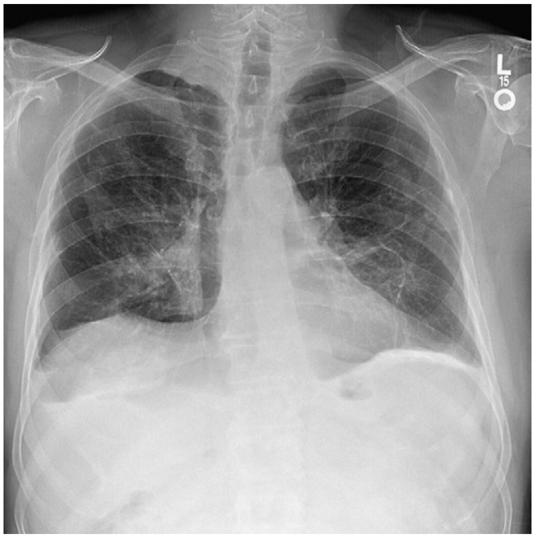

Figure 52-3 Chest radiograph illustrating parenchymal abnormalities in asbestosis. Descriptive designations are from the International Labour Organization (ILO) classification for the radiographic appearance of pneumoconioses (see Chapter 51, Table 51-2). In this case, fine linear opacities of profusion category 1/0 can be seen in the middle and lower lung zones. Calcified pleural plaques are seen along the diaphragm bilaterally.

patients may exhibit such signs later in the clinical course, such as dry, bilateral basilar rales evident on end inspiration, digital clubbing, cyanosis, and signs of cor pulmonale.

RADIOLOGIC FINDINGS

Radiographically, asbestosis typically manifests in the lower lobes with irregular “reticular” markings toward the lung periphery and costophrenic angles (**Figure 52-3**). Linear opacities that resemble extensions of vascular markings may assume a netlike appearance. In early or less severe disease, the middle and upper lung zones may appear relatively spared. With progression, the linear and irregular opacities thicken and spread to the midlung zones, but rarely to the apex. The International Labour Organization (ILO) International Classification of Radiographs of Pneumoconioses characterizes each type of irregular opacity on the basis of increasing size and thickness as either *s*, *t*, or *u*, and on a scale of profusion (number) of opacities from normal profusion (0/–, 0/0, 0/1) to severe (3/2, 3/3, 3/+) (see Chapter 51, Table 51-2, for classification details). When irregular opacities are seen on the chest radiograph in conjunction with pleural thickening, the radiograph can be considered virtually pathognomonic for asbestosis. However, the chest radiograph lacks sensitivity, because 15% to 18% of symptomatic, biopsy-proven asbestosis cases are associated with a normal appearance on chest radiographs. Focal masses are uncommon except for those caused by rounded atelectasis.

COMPUTED TOMOGRAPHY

Conventional CT and high-resolution CT (HRCT) are more sensitive and specific than radiography for the diagnosis of pleural disease related to asbestos. HRCT, with use of 1- to 3-mm slices, is superior in sensitivity to plain chest radiography for detection of the fine reticular opacities in this disease. Of asbestos-exposed workers who have normal-appearing chest radiographs, 10% to 30% have HRCT scans suggestive of underlying interstitial disease. Thus, the HRCT scan can prove useful when the clinical index of suspicion for asbestosis is high but the chest radiograph appears normal. The most common HRCT findings in asbestosis are short, peripheral septal lines; subpleural curvilinear lines; ground glass attenuation; peripheral cystic lesions (honeycombing); parenchymal bands adjacent to areas of pleural thickening; and bronchiolar thickening (**Figure 52-4**). The density of interstitial abnormalities found on HRCT has been shown to correlate with the symptoms and with physiologic and inflammatory indicators of asbestosis, although in general, findings on both the chest radiograph and the HRCT scan demonstrate only a limited correlation with disease severity measured by assessment of lung physiology.

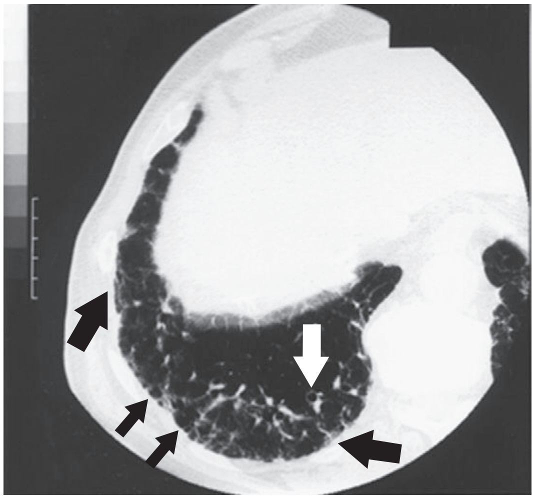

Figure 52-4 Asbestosis. This high-resolution computed tomography (CT) scan of the thorax was obtained in an asbestos-exposed worker with asbestosis and mild pleural thickening. Patchy subpleural accentuation of interstitial markings (*thick arrows*) with honeycombing (*thin arrows*) and traction bronchiectasis (*white arrow*) are classic for the CT appearance in advanced asbestosis.

PULMONARY PHYSIOLOGY ASSESSMENT

The earliest pathophysiologic changes include small airway dysfunction (e.g., decreased forced expiratory flow). As the disease progresses, restriction, evidenced by diminished total lung capacity and forced vital capacity, is observed, as is worsening gas exchange as measured by diffusing capacity and by arterial blood gas partial pressures determined under conditions of exercise and rest. These different parameters do not necessarily show the same degree of abnormality. Measures of gas exchange generally are more sensitive than measures of lung volumes in this disorder. Isolated, severe, obstructive airway disease usually is not attributable to asbestosis alone, although airflow obstruction may be present with or without restriction and occurs even in asbestos-exposed workers who were nonsmokers.

DIAGNOSIS

The long latency between asbestos exposure and development of asbestosis and the gradually progressive nature of the symptoms mean that this disease has a tendency to remain undetected until fairly late in its course. Efforts to conduct workplace surveillance by use of the chest radiograph and ILO readings of these films have improved disease detection. The diagnosis is based on a consistent history of exposure to asbestos, with sufficient duration of latency, and evidence of interstitial fibrosis. A careful work and environmental history holds the key to determining that past exposure has occurred. As discussed previously, the presence of bilateral pleural plaques or demonstration of asbestos bodies in lavage or on biopsy also can aid in the assessment of exposure. Although most algorithms for diagnosis of asbestosis suggest that the combination of histologic analysis plus mineralogic assessment is the most sensitive and specific method of diagnosis, frequently the required biopsy material is unavailable, and such studies are unnecessary in making a probable determination of disease. Even the lung pathophysiologic findings should be considered in context with clinical data. The main considerations in the histologic differential diagnosis include the other pneumoconioses and other causes and agents of pulmonary fibrosis such as pharmaceutical drugs, metal dusts, infectious agents, autoimmune disorders, and idiopathic pulmonary fibrosis.

In the absence of lung histologic and mineralogic analysis, the clinical diagnosis of asbestosis can be made with reasonable confidence on the basis of the following criteria:

- History of significant asbestos exposure
- Appropriate time interval between exposure and disease detection (latency)
- Radiographic evidence of bilateral lung fibrosis by chest radiograph or HRCT (especially with coexisting pleural plaques)

Helpful, but less essential criteria include evidence of restrictive impairment of lung function, abnormalities of gas exchange, bilateral inspiratory crackles (rales), and digital clubbing.

TREATMENT

At present, no cure exists for asbestosis, and no benefit from the use of corticosteroids or other immunosuppressive therapy has been documented. After exposure and early disease have occurred, no prophylactic measures are available.

Medical management in cases of asbestosis focuses on the following interventions:

- Supplemental oxygen therapy in the face of hypoxemia or pulmonary hypertension
- Treatment of intercurrent infections
- Treatment of right ventricular failure in advanced disease
- Immunization for influenza virus and pneumococcal infections
- Appropriate medical documentation of the degree of physical impairment and support and referral of the patient to relevant agencies to apply for workers' compensation benefits if exposure was occupational
- Education on the signs and symptoms of lung cancer and mesothelioma
- Assistance in smoking cessation for current smokers who have asbestosis, to help reduce the risk of lung cancer
- Cessation of ongoing asbestos exposure—always advisable, because it may slow disease progression, as indicated by experimental evidence

In the United States, patients with a diagnosis of asbestosis and occupational exposure to asbestos may apply for workers' compensation benefits. Compensation may be granted on appropriate medical documentation of the degree of physical impairment in combination with employment and exposure requirements. Workers who have evidence of pleural plaques, also referred to as pleural asbestosis, also may be eligible for compensation in some programs, with or without evidence of coexisting pulmonary asbestosis.

CLINICAL COURSE

The prognosis for patients with asbestosis varies widely. It is dependent in part on the magnitude of exposure. In 1906, the disease was almost uniformly fatal by the third decade of life. Today, however, with fewer exposures and shorter exposure times, and with superior detection and supportive care, few patients demonstrate such severe progression of their disease. After removal from exposure, progression usually is slow and occurs in 5% to 40% of patients over approximately a decade of follow-up. Thus, if clinical deterioration occurs over a period of days or weeks, the clinician must look first for other explanations, such as infection or malignancy. Many patients may remain mildly symptomatic for many years and show little or no objective signs of disease progression, whereas others show steady, inexorable decline in lung function, gas exchange, worsening symptoms, development of end-stage respiratory insufficiency, and cor pulmonale with right ventricular failure.

Patients with asbestosis are at increased risk for intercurrent lung infections and lung cancer. The best prognosis is found in those workers who have the lowest ILO profusion scores (i.e., chest radiographs that show the fewest irregular opacities) at the time of termination of exposure. Multiple studies demonstrate that those with the greatest average and cumulative dust exposures tend to have higher initial profusions of small opacities on chest radiographs and more rapid disease progression.

Tobacco smoking also contributes to radiographic evidence of disease severity. Tobacco smoking has been shown to increase risk for development of asbestos-related fibrosis and asbestos-induced lung cancer. Several studies have proposed that smoking enhances the development of interstitial fibrosis in workers exposed to asbestos.

On the basis of National Center for Health Statistics data through 2005, for U.S. residents the age-adjusted mortality rate attributable to asbestosis began to plateau after 2000, but only after having risen from an age-adjusted mortality rate of 0.54 per 1 million population in 1968 to 6.03 per 1 million in 2005. Mortality rates are much higher among men than among women, and the age at which people die of asbestosis has risen from a median of 60 years in 1968 to approximately 79 years in 2005. In 2005, asbestosis resulted in more than 14,000 years of potential lives lost due to reduced life expectancy. Lung cancer is a significant contributing cause of increased mortality rates among patients with asbestosis.

ASBESTOS-RELATED, NONMALIGNANT PLEURAL DISORDERS

The most common pleural changes caused by asbestos are pleural plaques, with or without pleural calcification and diffuse pleural thickening. Presence of pleural thickening is a marker of exposure. Pleural changes are now known to contribute to the lung function abnormalities seen in asbestos-exposed workers. Both types of pleural alteration contribute independently to restrictive lung physiology (reduced vital capacity), reduced lung compliance, and diminished diffusing capacity. Of asbestos-exposed construction workers, 20% to 60% demonstrate chest radiographic evidence of pleural disease, which is remarkable in light of the insensitivity of the radiograph.

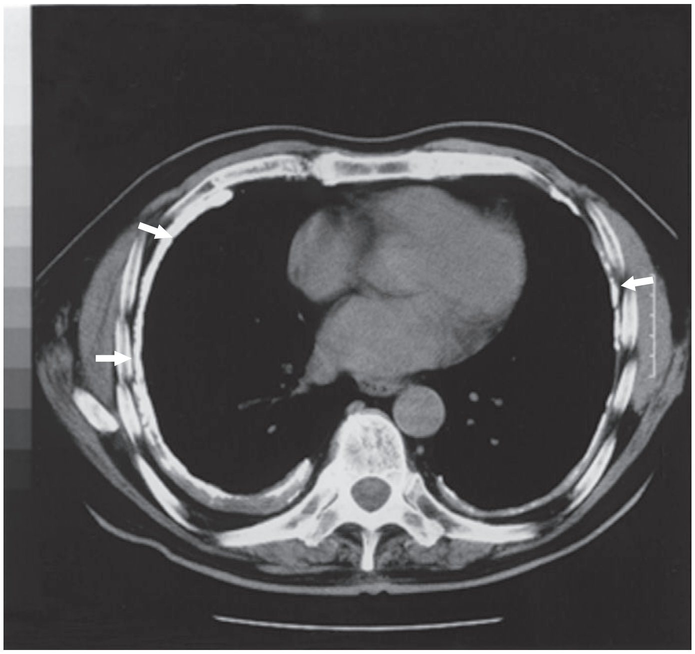

Figure 52-5 Pleural plaque. This conventional computed tomography scan of the thorax, obtained in an asbestos worker, shows extensive bilateral pleural calcifications (*arrows*).

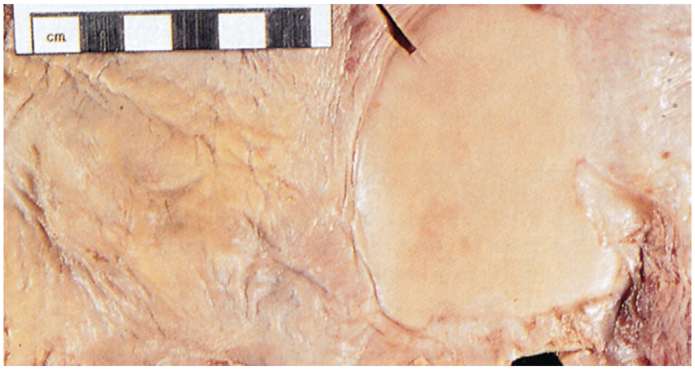

Figure 52-6 The gross pathologic appearance of a pleural plaque adjacent to the diaphragm in a specimen from a construction worker. The benign pleural plaques that form as a consequence of asbestos inhalation have a smooth, shiny appearance and usually are well circumscribed.

Circumscribed pleural plaques that involve the parietal pleura usually are symmetric and bilateral, most commonly between the fifth and eighth ribs toward the posterolateral aspects of the thorax (Figure 52-5); they also frequently involve the diaphragmatic pleura (Figure 52-6). These lesions remain discrete. Thus, if radiographic evidence of more diffuse thickening is found, either mesothelioma or diffuse pleural thickening must be considered. On histologic examination, pleural plaques are seen to be hyalinized, acellular, avascular masses, and they rarely contain asbestos bodies. They have a tendency to calcify, which can be mistaken for nodular infiltrates on the chest radiograph. Although the ILO classification system has an elaborate section devoted to characterization of pleural abnormalities on the chest radiograph, interreader agreement is relatively low. Because HRCT is more sensitive than chest radiography in the detection of pleural plaques, it helps to determine past asbestos inhalation, because these plaques are pathognomonic for that exposure. Also, HRCT helps to differentiate plaques from extrapleural fat pads. Asbestosis can occur in the absence of pleural disease, and inversely, pleural disease can occur without underlying pulmonary fibrosis, although autopsy studies suggest that when pleural changes are seen, histopathologic features of asbestosis often are evident even if the radiograph is normal in appearance. Pleural plaques rarely, if ever, undergo malignant transformation.

Diffuse pleural thickening involves both parietal and visceral pleura and is strongly associated with previous, benign asbestos-related pleural effusions. It also may develop when subpleural parenchymal fibrosis extends to the visceral pleura. Diffuse pleural thickening most commonly is located in the lower thorax, can blunt the costophrenic angles, and may be either unilateral or bilateral. Because it is so diffuse, this form of pleural thickening can produce dyspnea on exertion and dry cough, as well as loss of lung function. Other conditions that can induce similar diffuse thickening include past tuberculosis, thoracic surgery, chest trauma with hemorrhage, adverse drug reactions, and infection.

After direct contact of asbestos fibers pleura, an inflammatory, exudative, and often hemorrhagic effusion can develop. It is asymptomatic in two thirds of cases but can be associated with acute chest pain, with or without fever. It can occur in the presence or absence of asbestosis. Its incidence in asbestos-exposed workers has been estimated to be less than 5%. Although it can be the first manifestation of asbestos-related disease, the mean latency period for benign, asbestos-related pleural effusions is 30 years. These effusions often resolve spontaneously but recur in approximately one third of cases. The regression may be associated with pain. The consequences include not only diffuse pleural thickening but also the formation of adhesive fibrothorax. Benign pleural effusion is considered a diagnosis of exclusion.

Rounded atelectasis, although uncommon, is important to recognize because of its tendency to mimic lung tumors. It is thought to occur when visceral pleural thickening invaginates and folds on the lung parenchyma, resulting in atelectasis; CT is the preferred method of detecting its typical cicatricial pattern. Malignancy has only rarely been described in areas of rounded atelectasis. A positron emission tomography scan usually shows no abnormality in rounded atelectasis and may help differentiate the lesion from a lung cancer.

CONTROVERSIES AND PITFALLS

The threshold of asbestos exposure below which asbestosis will not occur is unclear, so any asbestos exposure carries some potential risk of asbestos-related disease. Prevention is superior to treatment of disease, because there is no cure. The best preventive measure is to eliminate inhalational exposure by the following measures or precautions:

- Not working with asbestos
- Not disturbing asbestos in buildings or other locations in which it has been used in the past
- Encapsulating exposed areas of friable asbestos
- Having asbestos removed by personnel experienced in asbestos abatement technologies

Substituting materials that have less toxicity must be considered in industrial applications. When asbestos substitutes are not available, appropriately designed and maintained engineering controls, such as local exhaust ventilation systems, must be in place. Personal respiratory protection is appropriate for short periods of exposure or when other controls are not feasible. Such respirators must be appropriately fitted to the person and tested for the degree of protection they afford the worker by quantitative fit testing. Showering and changing of work clothes at the end of work shifts will help to eliminate take-home exposures. Workers must be educated about the combined risks of asbestos exposure and smoking for lung cancer and must be counseled to avoid future asbestos exposure. Companies that use asbestos must maintain strict compliance with government regulations on permissible exposure limits and appropriate medical surveillance of workers.

Section 8
PARENCHYMAL LUNG DISEASES

Chapter 53
Connective Tissue Diseases

J.C. Grutters • J.-W.J. Lammers

Connective tissue diseases (CTDs) are generally referred to as a group of systemic disorders with abnormalities in the tissues containing collagen and elastin. Usually, CTDs are characterized by overactivity of the immune system from unknown causes resulting in production of autoantibodies. Pathologic changes are often seen in the lungs of these patients and may be the site of initial manifestation of the systemic disease. All compartments of the respiratory system can be involved, from pleura, airways, and alveolar parenchyma through the pulmonary vasculature. These anatomic regions can be affected either in isolation or in combination, producing a variety of clinical presentations. Furthermore, the pulmonary manifestations of CTDs need to be separated from the effects of therapy (drug reactions, opportunistic infections).

EPIDEMIOLOGY

Specific CTDs include the following:

- *Rheumatoid arthritis* (RA) is the most common CTD and occurs worldwide in approximately 1% of the adult population.
- *Systemic sclerosis* (SSc) has a prevalence of approximately 10 in 100,000 population, with a female/male ratio of 4:1 to 9:1.
- *Polymyositis/dermatomyositis* (PM/DM) is relatively rare, affecting 2 to 10 per 1 million people; has a bimodal age distribution, with an early peak at 5 to 15 years and a later peak at 50 to 60; and occurs three to four times more often in women.
- *Mixed connective tissue disease* (MCTD) has a prevalence that has not been precisely defined but probably approximates 1 in 10,000 people. Mixed disease is more common in women, and most patients present in the second or third decade of life.
- *Systemic lupus erythematosus* (SLE) occurs in up to 1 in 2000 individuals, with a female/male ratio of 10:1.
- *Sjögren syndrome* (SS) has a prevalence of 0.5% to 1% in the general population for primary SS and of 10% to 30% in patients with other autoimmune disorders (secondary SS). SS predominantly affects middle-aged women.

Other CTDs include relapsing polychondritis and ankylosing spondylitis.

PULMONARY INVOLVEMENT

Estimates of the prevalence of pulmonary involvement in CTDs vary widely, depending on the investigated cohort and the methods used to detect lung abnormality. For parenchymal disease, the highest prevalence is seen in histologic or autopsy studies and high-resolution computed tomography (HRCT), which often demonstrates abnormalities not seen on chest radiography.

Systemic sclerosis shows the highest prevalence of *interstitial pneumonia* (IP) (±80% nonspecific) and vascular disease among the CTDs. Autopsy studies indicate that at least some degree of pulmonary fibrosis is present in up to 75% of SSc patients, and vascular disease occurs in approximately 30%. RA and PM/DM also show relatively high prevalence of certain degrees of lung fibrosis, but clinically overt disease occurs less often and is similar to SSc (~5%). Compared with SSc patients, those with RA or PM/DM complicated by lung fibrosis show higher frequency of *usual interstitial pneumonia* (UIP) and *organizing pneumonia* (OP). Of all pulmonary manifestations in CTDs, pleural disease is probably the most common, especially in RA and SLE. Table 53-1 summarizes the relative frequencies of the major respiratory complications, including IP subtypes, across the various CTDs.

GENETICS

There is increasing evidence of a genetic predisposition for CTDs. For example, RA is strongly associated with the major histocompatibility complex (MHC) Class II gene product HLA-DR4; up to 70% of patients with definite RA express HLA-DR4 versus 28% of control subjects. Evidence for genetic factors in SSc is supported by familial clustering, increased prevalence in twin studies, the high frequency of autoimmune disorders and autoantibodies in family members of SSc patients, and differences in prevalence and clinical manifestations among different ethnic groups. Strong genetic associations have been found between HLA-DRB1*11 and HLA-DPB1*1301 and diffuse SSc, and some evidence suggests an amino acid motif shared by the different MHC Class II susceptibility alleles that may be pivotal in predisposing to autoantibody formation.

GENETIC RISK FACTORS FOR PULMONARY COMPLICATIONS

In SSc and RA in particular, several genetic factors are specifically associated with pulmonary complications. In SSc, carriage of HLA-DRB1*11(04) and DPB1*1301 alleles is associated with lung fibrosis and DRB1*04 and DRB1*08 with pulmonary hypertension, related to the presence of anticentromere autoantibodies (ACAs). ACA positivity has also been shown to associate with carriage of a functional tumor necrosis factor promoter variant (TNF-863A). This and other genetic findings

Table 53-1 Relative Frequencies of Pulmonary Manifestations in Connective Tissue Diseases

Pulmonary Manifestation	RA	SSc	PM/DM	MCTD	SLE	SS
Interstitial pneumonias	++	+++	++	++	+	+
Usual interstitial pneumonia	++	+	+	+	+	+
Nonspecific interstitial pneumonia	+	+++	++	+	+	+
Organizing pneumonia (COP)	+	±	++	+	+	+
Diffuse alveolar damage (AIP)	±		±	±	+	
Lymphocytic interstitial pneumonia	+				±	++
Follicular bronchiolitis	±					+
Constrictive bronchiolitis	+		±	±	±	
Bronchiectasis	++				±	±
Pleural involvement	+++			++	+++	±
Pulmonary hypertension		+++	+	++	++	±
Alveolar hemorrhage	±				+	
Respiratory muscle weakness		±	++		++	

AIP, Acute interstitial pneumonia; *COP*, cryptogenic organizing pneumonia; *MCTD*, mixed connective tissue disease; *PM/DM*, polymyositis/dermatomyositis; *RA*, rheumatoid arthritis; *SSc*, systemic sclerosis; *SLE*, systemic lupus erythematosus; *SS*, Sjögren syndrome.
+++, Common; ++, fairly frequent; +, occasional; ±, rare or very rare.

as yet have no clinical implication, although in the case of TNF-α, they suggest a different pathogenetic role of this cytokine across different SSc subsets. In RA, there is an association between obliterative bronchiolitis (OB) and the expression of histocompatibility antigens HLA-B40 and DR1, which implicates a genetic risk factor.

PATHOGENESIS

INTERSTITIAL FIBROSIS

In CTDs the current concept is that interstitial fibrosis occurs in response to a persistent inflammatory stimulus, causing extended or repetitive tissue damage, and that fibrosis can be considered as an inappropriate response to injury or excessive wound healing. Activation and interaction of both the innate and the adaptive immune system and interaction with extravascular tissue promote the production and secretion of inflammatory mediators, including free radicals, cytokines, and chemokines. Along with growth factors and proteolytic enzymes, together these mediators modulate mesenchymal cell phenotypes and induce synthesis, deposition, and accumulation of extracellular matrix components within the affected tissues. As part of the regulatory process, there is often an upregulation of connective tissue matrix protein breakdown enzymes (e.g., collagenase) and other metalloproteinases and serine proteases (e.g., elastase), which can cause damage to the original architecture. Over time, these processes cause extensive tissue remodeling, with scar tissue substituting for normal tissue architecture and structures.

Numerous lines of evidence suggest that autoimmune antibodies play a key role in the inflammatory process that precedes the development of fibrosis. Reactivity to the nuclear autoantigen topoisomerase I (Scl70) is rarely seen other than with SSc and is strongly associated with lung fibrosis. Recently, the serum of SSc patients was found to contain stimulatory antibodies to the platelet-derived growth factor receptor, which can selectively induce intracellular transcription factors and reactive oxygen species and stimulate type I collagen-gene expression and myofibroblast phenotype conversion in normal human fibroblasts.

VASCULAR DISEASE

Pulmonary vessels may be involved by inflammation *(vasculitis)* or by concentric fibrosis formation. Vasculitis can affect all levels of the pulmonary circulation. Pulmonary capillaritis usually manifests as diffuse alveolar hemorrhage. The exact pathogenesis of vasculitis is not known, but in some syndromes such as SLE, it is thought to result from immune complex deposition.

Concentric fibrosis of small arterioles will give rise to pulmonary artery hypertension. The pathogenesis of pulmonary hypertension in CTDs is complex, with no single unifying hypothesis at present. Potential etiologies are autoimmune antibodies (e.g., antifibrillarin, antiendothelial, or anticentromere antibodies) and enhanced vasoreactivity. Several reports suggest that dysregulation of the pulmonary vascular tone may contribute to CTD-related pulmonary hypertension ("pulmonary Raynaud's hypothesis"). The observation of decreased nitric oxide (NO) production in the lungs of patients with SSc and pulmonary hypertension supports that endothelial dysfunction contributes to altered regulation of pulmonary vascular tone and development of pulmonary hypertension. Other etiologies might be involved as well, including increased endothelin-1 (ET-1), platelet activation, and oxidant stress.

LUNG PATHOLOGY

AIRWAY PATHOLOGY

The CTDs may affect all parts of the airways. Usually, the pathology is characterized by diffuse inflammatory infiltrates in and around the walls of the larger and smaller airways and sometimes in their lumina. It is usually chronic in nature but may be a mixture of acute and chronic. Persistent inflammatory activity can cause damage to normal airway structures, which may induce wound-healing responses that lead to the accumulation of scar tissue in and around airways. In some conditions, such as relapsing polychondritis, specific anatomic structures may be involved.

Chronic Bronchitis/Bronchiolitis

Chronic bronchitis or bronchiolitis refers to a variable, intense, nonspecific chronic inflammatory cell infiltrate within the bronchial or bronchiolar walls. In SS the infiltrate tends to involve the seromucinous glands, leading to glandular atrophy and a "dry" trachea.

Follicular Bronchitis/Bronchiolitis

Follicular bronchitis or bronchiolitis (FB) is characterized by prominent peribronchial or peribronchiolar lymphoid follicles, with a minor interstitial inflammatory component. Compression of the airway lumina can lead to obstruction and intraluminal acute inflammatory cell infiltrate, plus pneumonia in some cases. FB is part of the spectrum of pulmonary lymphoid hyperplasia, with FB peribronchiolar in localization at one end and *lymphocytic interstitial pneumonia* (LIP) showing interstitial predominance at the other end. Both FB and LIP are rarely found in an idiopathic setting, and their recognition should always prompt investigation for an underlying CTD.

Obliterative Bronchiolitis

Obliterative bronchiolitis (OB) is thought to begin with damage of the respiratory epithelium of terminal bronchioles, leading to the formation of chronic inflammatory granulation tissue, often laid down in a circumferential pattern causing narrowing of the airways. Disease progression leads to obliteration of terminal bronchioles by dense fibrous tissue, with sparing of the respiratory bronchioles and alveoli (Figure 53-1).

Organizing pneumonia (OP) is one of the seven entities that constitute IP and has been confused with OB because of the previous term "bronchiolitis obliterans organizing pneumonia" (BOOP). In cryptogenic OP, patchy filling of alveoli with buds of granulation tissue may extend into respiratory bronchioles, but not terminal bronchioles.

Bronchiectasis

Bronchiectasis is defined as permanent abnormal dilation of the airways, usually associated with an inflammatory cell infiltrate. It has many causes, including most CTDs.

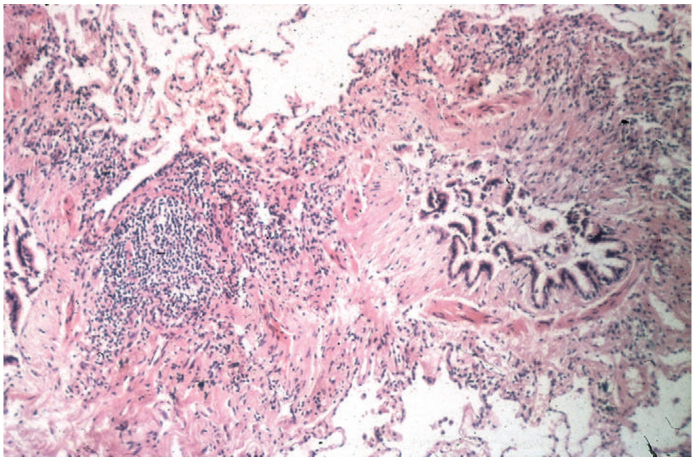

Figure 53-1 Lung biopsy of patient with rheumatoid arthritis (RA), showing constrictive bronchiolitis.

PARENCHYMAL PATHOLOGY

Alveolar parenchymal disease in CTDs usually involves the IPs and sometimes other rare conditions such as alveolar hemorrhage and amyloidosis.

Interstitial Pneumonias

Interstitial pneumonia is now used as a term to indicate the presence of diffuse inflammatory and/or fibrosing lung disease, either idiopathic or in the context of CTDs. In the past the term "fibrosing alveolitis" was often used for this condition. The past decade has seen considerable refinement in the recognition of pathologic IP patterns. For idiopathic IPs, there are presently seven histologic patterns: usual interstitial pneumonia (UIP), nonspecific interstitial pneumonia (NSIP; with a cellular and fibrotic subgroup), cryptogenic organizing pneumonia (COP), acute interstitial pneumonia (AIP; with diffuse alveolar damage [DAD]), lymphocytic interstitial pneumonia (LIP), desquamative interstitial pneumonia (DIP), and respiratory bronchiolitis interstitial lung disease (RBILD). Use of this classification seems consistent and reliable and provides prognostic information for idiopathic disease.

In patients with UIP on lung biopsy and HRCT characteristics compatible with UIP, and with no known cause or association, the diagnosis of idiopathic UIP, *idiopathic pulmonary fibrosis*, is justified and carries a poor prognosis, especially compared with idiopathic NSIP. However, this prognostic difference between idiopathic UIP and NSIP is not necessarily the case in patients with CTD. Those with a UIP pattern on biopsy have a better chance of response to treatment and better prognosis than their counterparts with idiopathic disease.

Both DIP and RBILD are strongly associated with smoking and might not belong in the "idiopathic" IP classification system. Moreover, only small numbers of patients with histologic patterns of DIP and RBILD have been reported in series relating to CTDs, and many of these were smokers. Therefore, these two IP entities are unlikely to be causally related to CTD. Table 53-2 summarizes the histopathologic characteristics of the IPs typically seen in CTDs.

Other Parenchymal Disorders

Other parenchymal disorders that can sometimes be found in CTDs include diffuse alveolar hemorrhage, amyloidosis, eosinophilic pneumonia, and alveolar proteinosis. In *alveolar hemorrhage*, biopsy shows a combination of intraalveolar hemorrhage and hemosiderosis. The hemosiderin, which provides evidence of previous bleeding, is largely contained within alveolar macrophages but may also impregnate elastin in a blood vessel. Alveolar hemorrhage is usually caused by small-vessel vasculitis of the lung, which is a rare pulmonary manifestation of CTDs, especially in SLE.

Amyloidosis is characterized by extracellular deposition of a proteinaceous substance that can be visualized under polarized light after Congo red staining. Amyloidosis is seen most often in relation to SS, with lymphoid hyperplasia and causing cystic changes.

Eosinophilic pneumonia is characterized by the expansion of alveoli by eosinophils, macrophages, and fibrinous debris, often with eosinophils involving the interstitium, as well as focal intraalveolar organization. This condition is often related to drug exposure in patients with CTD, but has also been attributed to RA itself.

Alveolar proteinosis is marked by accumulation of acellular, finely granular lipoproteinaceous material in alveolar spaces. It has been described in dermatomyositis.

Table 53-2 Interstitial Pneumonias in Connective Tissue Disease: Major Histopathologic Characteristics

Type	Histopathologic Characteristics
Usual interstitial pneumonia (UIP)	Fibrosis with honeycombing, fibroblast foci; anatomic destruction; little inflammatory cell infiltrate; normal/near-normal intervening lung parenchyma (temporal heterogeneity)
Nonspecific interstitial pneumonia (NSIP)	Variable interstitial inflammation and fibrosis; fibroblastic foci absent or scarce; uniformity of changes within biopsy specimen
Organizing pneumonia (OP; or cryptogenic OP)	Patchy filling of alveoli by buds of granulation tissue that may extend into bronchioles (Masson bodies); preservation of lung architecture
Lymphocytic interstitial pneumonia (LIP)	Extensive lymphocytic infiltration in the interstitium often associated with peribronchiolar lymphoid follicles (follicular bronchiolitis)
Diffuse alveolar damage (DAD)*	Diffuse alveolar septal thickening by inflammatory cell infiltrate, hyperplastic pneumocytes, hyaline membranes, air space organization

*In acute interstitial pneumonia (AIP).

PULMONARY HYPERTENSION

The histologic features in CTD-associated pulmonary hypertension vary in relation to the degree of raised pulmonary artery pressure. In mild pulmonary hypertension, the histologic features are typically those of medial hypertrophy. With progression of the disease, marked intimal fibrous thickening and eventually plexiform lesions can be found. These histologic changes are essentially the same as those in idiopathic pulmonary hypertension. Early changes need to be distinguished from secondary changes related to an associated IP.

PULMONARY MALIGNANCY

There is an increased risk for lung cancer in CTDs, especially in patients with lung fibrosis who also smoke. The most common neoplasm in SSc is *adenocarcinoma*, in some cases with a bronchoalveolar pattern. Patients with Sjögren syndrome have an increased risk of pulmonary lymphoma. This is usually a marginal zone, non-Hodgkin lymphoma of mucosa-associated lymphoid tissue (MALT). Preexisting follicular bronchiolitis or LIP is a risk factor (±5% may develop lymphoma).

CLINICAL FEATURES

RHEUMATOID ARTHRITIS

The clinical hallmark of RA is an inflammatory erosive arthritis of small and large joints. Although rheumatoid factor (RF) has a reasonable sensitivity (60%), its specificity is often low (90%). Recently, anticyclic citrullinated peptide (CCP) antibodies have been identified that combine a high sensitivity (75%) with an excellent specificity (97%) for the diagnosis of RA. Extraarticular manifestations of RA are associated with RF, but interestingly not with anti-CCP antibodies. RA can involve any part of the respiratory tract, including the cricoarytenoid joint, airways, parenchyma, and pleura. Usually, only one of these disorders is predominant in a single individual, although parenchymal changes are often associated with airway disease (on HRCT).

Pleural Disease

Rheumatoid arthritis–associated pleural disease can be asymptomatic, although presenting symptoms and signs can include fever, pleuritic chest pain, and shortness of breath. Pleural effusions are generally small and unilateral, but rarely may occur in large volume or bilaterally. The fluid is exudative, with high protein and lactate dehydrogenase levels and low glucose concentration. Rheumatoid effusions usually have a low pH (<7.2) and are often paucicellular (<10,000/mL), with lymphocytic or polymorphonuclear predominance. Cytologic examination may reveal lipid droplets in the cytoplasm of neutrophils, similar to the phagocytes seen in the joint fluid of arthritic patients and known as RA cells, but these may occur in other conditions. Immunocytochemistry may reveal IgM (RF) and phagocytosed immune complexes in granulocytes and histiocytes. Thoracoscopy may reveal a fine granular appearance to the pleural wall. Histopathologic examination of these micronodules may show a linear granulomatous reaction with the mesothelium replaced by palisading histiocytes. Histologic examination can also show fibrosis with often prominent chronic inflammation, including hyperplastic lymphoid follicles. In general, however, pleural biopsy is especially helpful for exclusion of other causes of pleural disease.

Airways Disease

Bronchiectasis is a frequent finding on HRCT in patients with RA (up to 70%), but in most patients, it is asymptomatic.

Obliterative bronchiolitis is a serious complication of RA, and seems to be more common in women. OB usually occurs in patients who are RF positive and have well-established joint disease. In the past, penicillamine, which is rarely used now, was associated with development of OB in patients with RA. Also, a relationship with gold therapy has been suggested. Patients most often are initially seen with dyspnea and a nonproductive cough, which can worsen rapidly. The chest radiograph is usually normal but may show signs of hyperinflation (Figure 53-2) and in later stages fibrobullous degeneration (Figure 53-3). The diagnosis of OB should be considered in any patient with RA with progressive dyspnea and cough who has rapidly progressive airflow obstruction. Characteristic HRCT findings of OB consist of areas of decreased attenuation and vascularity with blood flow redistribution, resulting in areas of increased lung attenuation and vascularity ("mosaic perfusion" pattern), which is accentuated on expiratory scans (Figure 53-4). The prognosis is poor in RA patients with OB.

Interstitial Pneumonias

The prevalence of clinically significant IP in patients with RA is estimated at 5%. IP is seen more often in men than in women, especially in the context of a high RF titer and severe articular disease. The pathologic patterns are diverse, but in contrast to other CTDs, a UIP pattern is relatively common (Figure 53-5). Symptoms are nonspecific and include progressive dyspnea and nonproductive cough. Dyspnea may appear late because of physical inactivity secondary to polyarthritis. Most patients have fine bibasilar crackles, but digital clubbing is less common than in patients with idiopathic pulmonary fibrosis (IPF). Lung function tests usually reveal a restrictive defect with normal airflow and reduced diffusion capacity (DLCO). HRCT is the

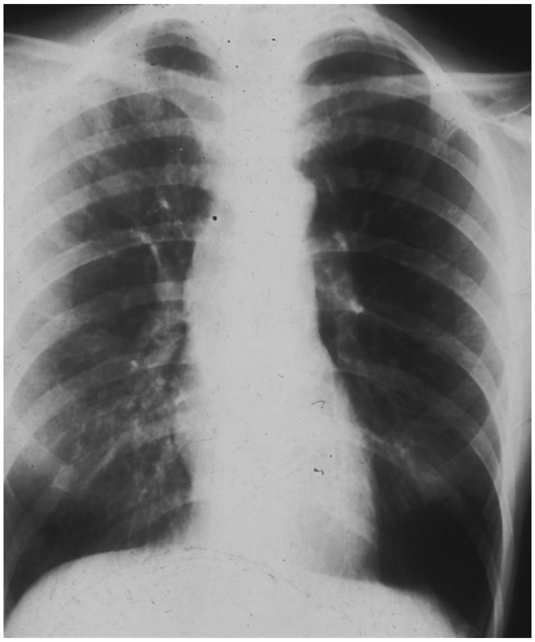

Figure 53-2 Chest radiograph of patient with rheumatoid arthritis showing hyperinflation caused by constrictive bronchiolitis.

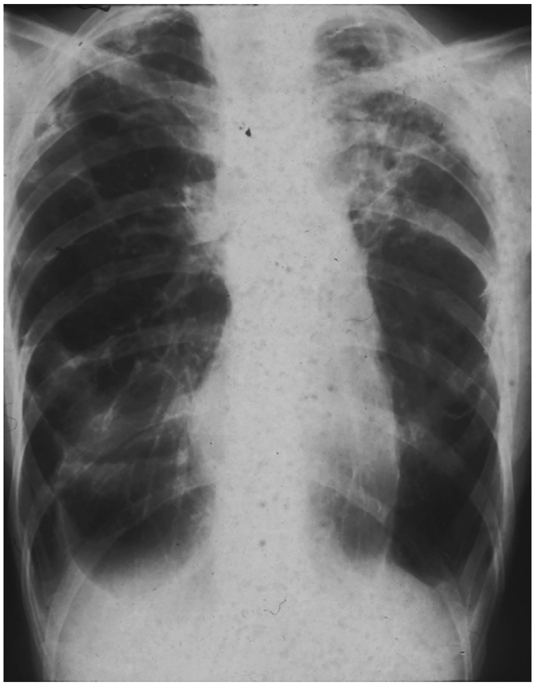

Figure 53-3 Chest radiograph of same patient as in Figure 53-2 a few years later, showing evolution toward fibrosis and bullous degeneration.

most appropriate investigation to detect IP and is also useful in follow-up. UIP patterns on HRCT appear similar in RA and IPF, but coexisting pleural effusion or (necrobiotic) nodules may help in the differential diagnosis. In general, UIP associated with RA tends to follow a more benign course than the idiopathic form, but patients may develop end-stage respiratory failure (**Figure 53-6**).

Pulmonary Nodules

Pulmonary nodules are an uncommon manifestation in RA. Their occurrence is strongly associated with positive RF and presence of extrapulmonary (i.e., subcutaneous) rheumatoid nodules. In some cases the nodules may antedate clinical arthritis. Their radiologic appearance is not specific and may mimic malignancy, especially if the lesion is solitary. Nodules may vary in size from millimeters to 7 cm. The nodules are most often

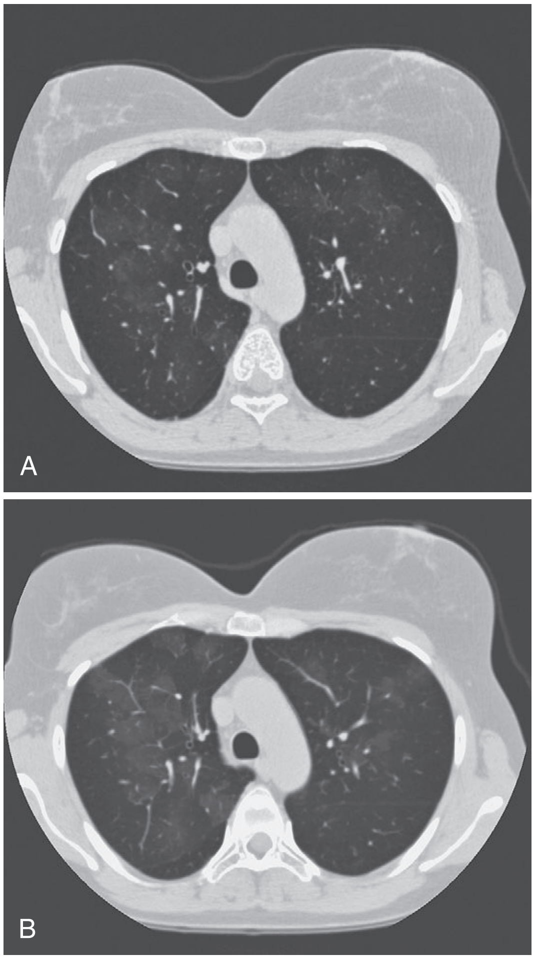

Figure 53-4 Characteristic findings on high-resolution computed tomography (HRCT) in 36-year-old woman with rheumatoid arthritis and severe constrictive bronchiolitis (FEV$_1$ of 35% predicted). **A,** Inspiratory HRCT scan shows geographic pattern, with areas of increased (normal) and decreased (air trapping) attenuation. **B,** This pattern is accentuated on the expiratory scan.

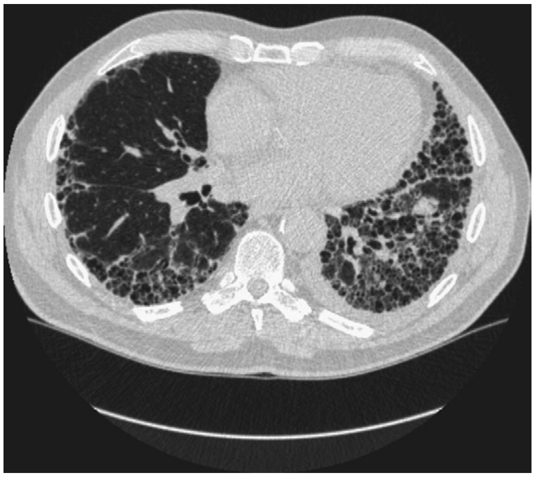

Figure 53-5 Chest CT scan (April 2005) in patient with seropositive rheumatoid arthritis, showing usual interstitial pneumonia (UIP) pattern.

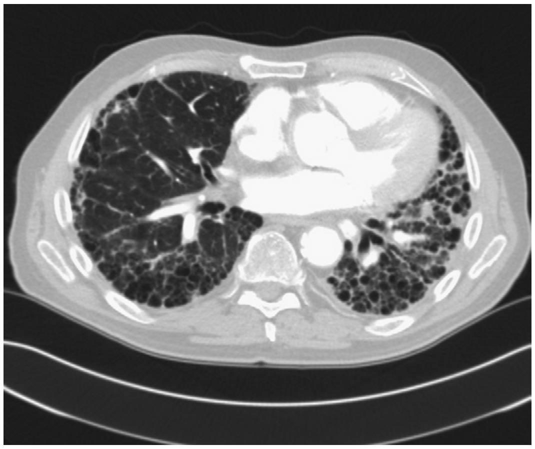

Figure 53-6 Stable lung fibrosis on follow-up chest CT scan (September 2009) of same patient as in Figure 53-5, illustrating a more benign course of usual interstitial pneumonia in rheumatoid arthritis than usually seen in the idiopathic form.

found in the subpleural regions of the upper lung zones but may also be found in other parts of the lung. Histologically, pulmonary nodules show a central zone of fibrinoid necrosis surrounded by a palisading rim of epithelioid histiocytes, together with lymphocytes and plasma cells (*necrobiotic* nodule). Cavitation may occur and can lead to complications such as hemoptysis, secondary infections, and pneumothorax in the case of perforation to the pleura. During follow-up, uncomplicated pulmonary nodules may spontaneously resolve and recur, often in association with the size of extrapulmonary nodules and depending on disease activity status.

Caplan syndrome (rheumatoid pneumoconiosis) is the coexistence of RA with pneumoconiosis, typically coal worker's pneumoconiosis or silicosis. The associated nodules differ from rheumatoid nodules by their large size and the presence of circumferential bands or "arcs of dust" within the necrotic centers of the lesions.

Lymphoid Hyperplasia

Hyperplasia of lymphatic tissue is frequently seen in RA. In particular, lymph nodes, spleen, and bronchus-associated lymphatic tissue (BALT) may be hyperplastic (**Figure 53-7**).

SYSTEMIC SCLEROSIS

Systemic sclerosis can be classified according to American Rheumatism Association criteria. One major criterion and two or more minor criteria (e.g., bibasilar pulmonary fibrosis) are necessary to establish a diagnosis of SSc. A subclassification can be made in *limited* (cutaneous) SSc (lSSc) and *diffuse* (cutaneous) SSc (dSSc). Limited SSc is characterized by skin involvement limited to hands, feet, face, and forearms; presence of anticentromere autoantibodies (ACAs; 60%-70%); Raynaud's phenomenon for years; and a significant incidence of pulmonary hypertension. The acronym CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) fits into this subclassification. Diffuse SSc is characterized by skin involvement on the upper arms and trunk, presence of antitopoisomerase antibodies (Scl70; 40%), and a high incidence of interstitial lung disease (ILD). Furthermore, dSSc is associated with hypertensive crises and renal failure, diffuse gastrointestinal disease, and myocardial involvement.

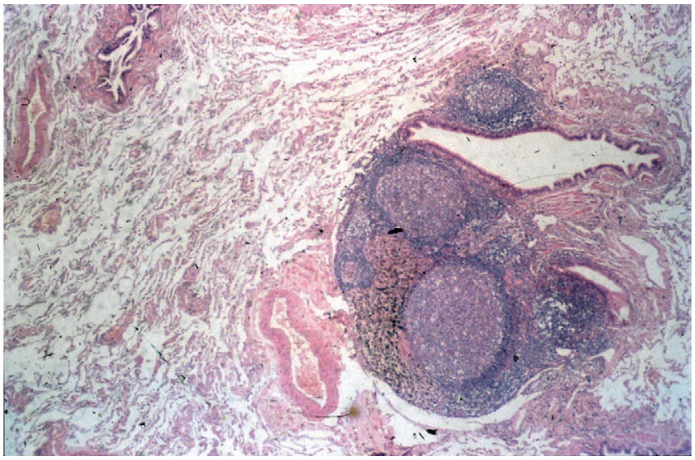

Figure 53-7 Lung biopsy showing hyperplasia of bronchus-associated lymphoid tissue (BALT) in patient with rheumatoid arthritis.

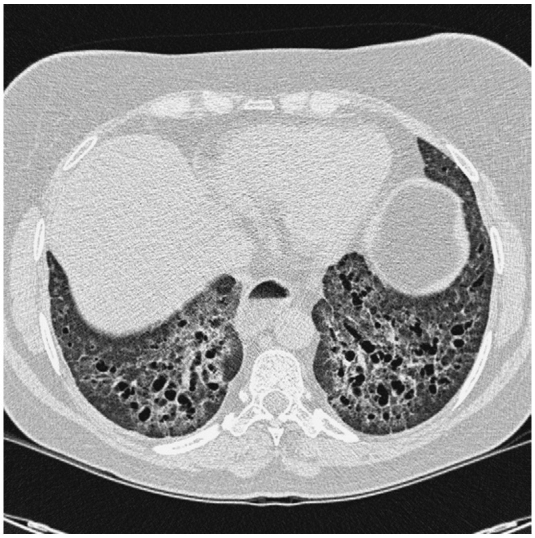

Figure 53-8 Chest high-resolution CT image in patient with systemic sclerosis, showing extensive interstitial fibrosis with traction bronchiectasis (fibrotic nonspecific interstitial pneumonia, fibrotic nonspecific interstitial pneumonia pattern) and ectatic (dilated) esophagus.

Interstitial Pneumonias

Most patients with SSc develop pulmonary manifestations. Patients with diffuse scleroderma and antitopoisomerase-I autoantibodies especially are at high risk for interstitial lung fibrosis. However, the clinical course of it may vary considerably. Although some patients have stable lung function parameters for years, others may have incapacitating or even fatal pulmonary fibrosis.

Lung fibrosis associated with SSc used to be expressed as fibrosing alveolitis (FA) SSc. It was believed that FASSc was indistinguishable from cryptogenic fibrosing alveolitis (CFA) or idiopathic pulmonary fibrosis. The histopathologic substrate of IPF is UIP. Various studies over the past decade, however, clearly demonstrate that histologic and HRCT features of lung fibrosis in SSc are more similar to those found in idiopathic NSIP (**Figure 53-8**).

The most common type of lung fibrosis in SSc is NSIP, with incidence ranging from 55% to 77% of cases. In NSIP, fibrosis and inflammation are more diffuse in involved areas and of the same age throughout the affected lung. On HRCT, fibrotic changes are less coarse, and the proportion of ground-glass opacification is greater than in UIP. A UIP pattern, characterized by honeycomb changes and negligible ground-glass opacity, can also be found in SSc. In contrast to their idiopathic equivalents, SSc patients with UIP or NSIP do not seem to differ in response to immunosuppressive therapy or prognosis, but further studies are needed.

The course of pulmonary fibrosis in SSc is variable and can range from indolent to rapidly progressive. Careful monitoring of longitudinal change of lung function is still regarded as the best means of evaluating disease behavior. Bronchoalveolar lavage (BAL) eosinophilia has also been linked to the progressiveness of lung fibrosis in SSc. The prognosis further depends on the severity of disease at presentation; patients with greater impairment in lung function and more extensive disease on HRCT have higher mortality.

Pulmonary Hypertension

Pulmonary hypertension is typically seen in patients with CREST syndrome. It is usually caused by a precapillary disease process leading to pulmonary artery hypertension. In some patients, pulmonary hypertension is caused by venoocclusive disease or related to severe interstitial fibrosis with hypoxemia. In addition, diastolic dysfunction of the left ventricle, possibly because of cardiac fibrosis, may lead to pulmonary hypertension, defined as mean pulmonary artery pressure higher than 25 mm Hg at rest or higher than 30 mm Hg during exercise in the absence of left-sided heart disease (pulmonary wedge pressure >15 mm Hg). Pulmonary hypertension, both isolated and in association with ILD, occurs in approximately 30% of patients with dSSc and in up to 60% of patients with lSSc (CREST syndrome). In both cases, the presence of pulmonary hypertension significantly worsens the prognosis. Reported survival in patients with SSc and pulmonary hypertension is similar to patients with primary pulmonary hypertension: 2-year survival of approximately 50%.

Other Thoracic Diseases in Sclerosis

In addition to lung fibrosis and pulmonary vascular disease, SSc can be complicated by aspiration pneumonia because of regurgitation of pooled contents from a fibrotic, ectatic esophagus (see Figure 53-8). Aspiration-related infection can be worsened by immunosuppressive therapy, architectural distortion, and traction bronchiectasis caused by fibrotic lung disease, which impairs normal protective clearance mechanisms and increases bacterial colonization of the airways.

Rarely, basal pleural thickening is found, but pleural effusions are unusual.

DERMATOMYOSITIS/POLYMYOSITIS

Polymyositis and dermatomyositis (PM/DM) are rare inflammatory myopathies. Major criteria include symmetric muscle weakness; a muscle biopsy showing inflammatory cell infiltrates and necrosis; elevated muscle enzymes; and a characteristic electromyogram (EMG). The most common pulmonary complications derive indirectly from neuromuscular weakness and directly from diffuse inflammatory manifestations of PM/DM in the lung parenchyma. Furthermore, it may be complicated by pulmonary or extrapulmonary malignancies (PM relative risk, 1.7; DM relative risk, 3.8). Of note, PM/DM may also present as a paraneoplastic syndrome (up to 20% of cases), so it may be difficult to determine which condition arose first.

As in other CTDs, autoantibodies are frequently found in patients with PM/DM. Autoantibodies to a group of cellular enzymes, transfer ribonucleic acid (tRNA) synthetases (anti-Jo1, anti-PL7, anti-PL12) are present in about 30% of patients with PM/DM and are rarely present in other CTDs. Presence of anti-tRNA synthetase antibodies is strongly associated with the occurrence of IPs.

Pulmonary Complications of Muscular Weakness

Muscular weakness can give rise to aspiration pneumonia (as a result of discoordinated swallowing) or respiratory insufficiency (reflecting respiratory muscle dysfunction). Airway protection is critical in patients with PM/DM and severe dysphagia; in severe cases, tracheotomy may be necessary while awaiting the impact of treatment for the underlying myopathy. Clinically significant respiratory muscle weakness has been cited in 7% to 22% of patients with PM/DM, sometimes leading to respiratory insufficiency requiring mechanical ventilatory support or to death. Rarely, bilateral diaphragmatic paralysis has been reported. Respiratory muscle weakness may be the initial presentation of PM/DM, but this is rare. Serial measurements of forced vital capacity (FVC), and maximal static inspiratory and expiratory pressures (PI_{max} and PE_{max}) are useful to diagnose respiratory muscle weakness and monitor the course of the disease.

Interstitial Pneumonias

The most common forms of interstitial lung disease in PM/DM are NSIP and OP. Rarely, other types of IP are found. IP can occur at any point in the disease course. IP onset precedes PM/DM in approximately 20% of cases, but this may be higher, because treatment with immunosuppressive drugs may mask the myopathy, delaying the diagnosis for weeks or even years. Rarely, patients present more acutely, with fevers, dyspnea, and cough evolving over a few days or weeks. In this context, progression to acute respiratory failure may occur. This syndrome resembles idiopathic acute interstitial pneumonia (AIP) and is associated with a histopathologic pattern of DAD (Figure 53-9).

In PM/DM, the occurrence of IP is strongly associated with the presence of circulating antisynthetase antibodies (50%-100% of cases). In contrast, antisynthetase antibodies are

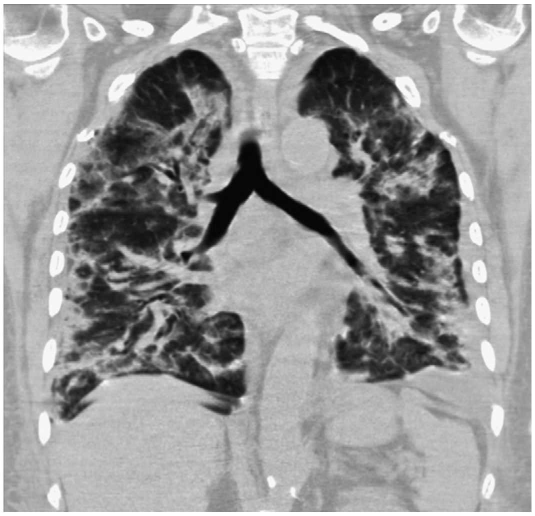

Figure 53-9 High-resolution CT section (coronal plane) of 73-year-old woman presenting with diffuse alveolar damage and organizing pneumonia (proven by video-assisted thoracic surgery lung biopsy) as first manifestation of antisynthetase syndrome (Jo1).

found in less than 5% of patients without diffuse lung disease. This clinical combination, which also includes arthritis, is known as the *antisynthetase syndrome.*

MIXED CONNECTIVE TISSUE DISEASE

Mixed CTD is characterized by the presence of overlapping features of more than one CTD (e.g., Raynaud's phenomenon, synovitis, and/or myositis) and the presence of high titers (>1 : 1600) of circulating autoantibodies to a nuclear ribonucleoprotein antigen (anti-U1-RNP). Currently, different classification systems are in use for the diagnosis of MCTD, causing difficulty in comparing populations and standardizing clinical evaluation. This is further complicated by the term "overlap syndrome," which is often used for the presence of features of more than one CTD not in the context of high anti-U1-RNP titers, and because some patients have only a few features that defy categorization into one of the major CTDs, but progress to exhibit typical findings of SSc, DM/PM, or SS over time.

Pulmonary complications and their pathologic features resemble those seen in other CTDs. The three most frequent are pleural effusion, interstitial pneumonia, and pulmonary hypertension. Pleural disease in MCTD occurs most frequently in patients with SLE-like clinical features; the pleura are seldom involved in SSc or PM/DM. Interstitial fibrosis most closely resembles interstitial lung involvement in SSc (i.e., showing a histologic pattern of NSIP). OP seems to be relatively infrequent in MCTD, despite a high prevalence in PM/DM. The most serious complication is progressive pulmonary hypertension and cor pulmonale; rapid deterioration and death can occur despite intensive medical intervention. Other causes of pulmonary hypertension include pulmonary vasculitis and pulmonary thromboembolism, especially in MCTD with SLE-like features and circulating antiphospholipid antibodies.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus is characterized by polyclonal B cell activation and the production of autoantibodies directed against nuclear targets (i.e., double-stranded DNA and anti-Sm antibodies). In contrast, T-cell functions are impaired, resulting in a greater susceptibility to infectious complications.

Pleural disease with or without effusion is the most common pulmonary manifestation of SLE. Diaphragmatic dysfunction or "shrinking lung syndrome" is a rare disorder characterized by reduced lung volumes and normal parenchyma, probably caused by progressive pleural fibrosis or respiratory muscle weakness. Infection is the most common cause of parenchymal disease. Clinically significant IP is a relatively rare complication in patients with SLE (±5%), and usually the course is slowly progressive with stabilization over time. Although difficult to demonstrate, immunohistochemistry may reveal characteristic granular patterns of IgG and complement at the alveolocapillary membrane (Figure 53-10). SLE-associated pulmonary hypertension should not be overlooked, especially in the presence of antiphospholipid antibodies, and has been reported in 4% to 14% of patients with SLE, with an overall mortality rate of 25% to 50% at 2 years from the time of diagnosis of pulmonary hypertension. In SLE patients the pulmonary vasculature may be directly involved, or pulmonary hypertension may be related to ILD, diffuse alveolar hemorrhage, airways disease, or thromboembolic disease. Acute lupus pneumonitis/alveolar hemorrhage is a rare pulmonary manifestation in SLE.

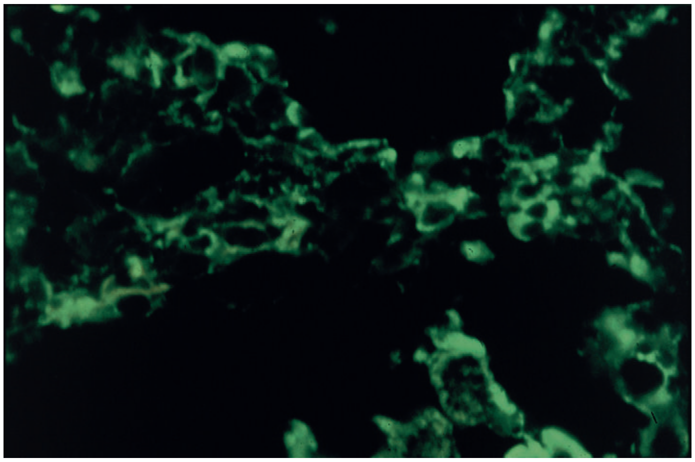

Figure 53-10 Immunohistochemical analysis of lung tissue of patient with systemic lupus erythematosus complicated by interstitial pneumonia, showing characteristic granular patterns of IgG and complement at alveolocapillary membrane.

Antiphospholipid Syndrome

The antiphospholipid syndrome (APS) is a systemic autoimmune disorder characterized by arterial and/or venous thrombosis, recurrent fetal loss (often accompanied by mild to moderate thrombocytopenia), and elevated levels of antiphospholipid antibodies, namely the lupus anticoagulant and/or anticardiolipin antibodies, and/or antibodies to β_2-glycoprotein 1. The APS may be divided into two categories. *Primary* APS occurs in patients without and *secondary* APS occurs in patients with clinical evidence of a major autoimmune disorder (i.e., mainly SLE). Pulmonary manifestations associated with APS include pulmonary embolism and infarction, primary thrombosis of large and small lung vessels, pulmonary capillaritis, pulmonary hypertension, and adult respiratory distress syndrome (ARDS). Also, fibrosing alveolitis has been associated with APS. When multiple organs, systems, and tissues are involved and manifestations develop simultaneously or in less than 1 week, this is known as *catastrophic* APS, which has a mortality greater than 50% despite treatment with full anticoagulation, high-dose corticosteroids and immunosuppressives, and intravenous immune globulin (IVIG). Some evidence suggests therapeutic plasma exchange might improve survival for patients with catastrophic APS.

SJÖGREN SYNDROME

Sjögren syndrome is a slowly progressive autoimmune inflammatory disease affecting the exocrine glands and epithelia in multiple sites, leading to diminished or absent glandular secretions and to a more or less generalized mucosal dryness. SS presents with a wide spectrum, from lacrimal and salivary exocrinopathy to systemic disease, including lung manifestations, and sometimes an associated B cell lymphoma (±5%). The disease can occur alone (primary SS) or in association with almost all of the other CTDs (secondary SS). Pulmonary manifestations have been reported in both the primary and the secondary form. In secondary SS the coexisting CTD influences the pattern of pulmonary expression. Box 53-1 summarizes the pulmonary manifestations of SS. Figure 53-11 shows chest HRCT scan consistent with follicular bronchiolitis in a patient with primary SS.

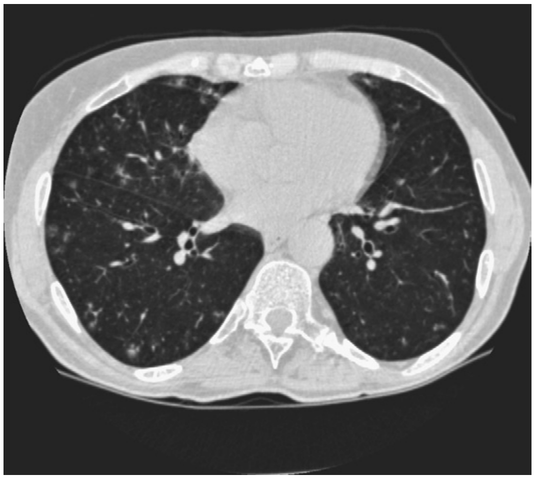

Figure 53-11 Chest high-resolution CT image in patient with primary Sjögren syndrome (SS) and chronic cough, showing pattern consistent with follicular bronchiolitis. Bronchoalveolar lavage (BAL) fluid demonstrated a 57% increase in lymphocytes, and other causes of BAL lymphocytosis were excluded.

Box 53-1 Pulmonary Manifestations in Sjögren Syndrome (SS)

- Upper airways disease
  - Nasal mucosa infiltration and dryness ("rhina sicca")
  - Oral cavity salivary gland involvement (xerostomia)
- Lymphocytic infiltration of tracheobronchial submucosal glands (xerotrachea)
- Subepithelial bronchial and bronchiolar lymphocytic infiltration (lymphocytic bronchitis/bronchiolitis)
- Lymphoproliferative disorders
  - Diffuse lymphoid hyperplasia of lungs (follicular bronchiolitis [FB]/lymphoid interstitial pneumonia [LIP])
  - Pseudolymphoma
  - Lymphomatoid granulomatosis
  - Malignant B cell non-Hodgkin lymphoma
- Other diffuse interstitial pneumonias
  - Usual interstitial pneumonia (UIP)
  - Nonspecific interstitial pneumonia (NSIP)
  - Organizing pneumonia (OP; or cryptogenic OP)
- Multiple lung cysts (often in association with LIP)
- Vasculitis and pulmonary hypertension
- Pulmonary amyloidosis
- Pleural disease (mainly in secondary SS)

RELAPSING POLYCHONDRITIS

Box 53-2 Clinical Criteria for Diagnosis of Relapsing Polychondritis*

- Bilateral auricular chondritis
- Nonerosive, seronegative inflammatory polyarthritis
- Nasal chondritis
- Ocular inflammation
- Respiratory tract involvement (upper/lower)
- Cochlear with/without vestibular abnormality

*The presence of three or more criteria is required.

Relapsing polychondritis is a rare (<5 : 1 million) multisystem disease in which recurrent progressive inflammation of cartilaginous structures results in widespread degenerative change. It is considered an autoimmune process, and autoantibodies directed against cartilage and type II collagen have been found. The condition may affect all parts of the body containing cartilage (e.g., nose, ears, joints, ribs). Involvement of the tracheobronchial tree may be found in up to 50% of cases. The diagnosis is generally clinical; Box 53-2 summarizes the most widely applied diagnostic criteria for relapsing polychondritis. CT may disclose smooth thickening of airway walls, as well as increased airway wall attenuation, with or without calcification. Airway collapse and lobar air trapping can be found in half of patients examined with expiratory CT. Biopsy of affected cartilage is not generally required for a diagnosis but may be pivotal in atypical cases; auricular biopsy is the most frequent procedure, but rarely biopsy of the tracheal rings may be indicated. Measurement of anti–type II collagen antibody may also be helpful, because it is fairly specific, although only positive in one third of patients with relapsing polychondritis.

Inflammation and destruction of the respiratory cartilage may lead to destruction and obstruction of the glottis, trachea, and bronchi, causing inspiratory and expiratory flow rate limitations, atelectasis, and secondary infections. Pulmonary parenchymal disease is rare, with the exception of vasculitis, which may be present but is often subclinical.

Treatment depends on disease severity. Mild cases may be controlled with nonsteroidal antiinflammatory drugs, whereas relapses may require short-term, high-dose corticosteroids. In life-threatening disease, steroid-resistant disease, and the case of repeated relapses, corticosteroid therapy in combination with an immunosuppressive such as cyclophosphamide should be considered. Tracheostomy may be required for severe glottic or subglottic obstruction, and stenting is occasionally indicated for airway collapse or refractory airway stenosis in the patient with relapsing polychondritis.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is a chronic seronegative spondyloarthritis strongly associated with the MHC antigen HLA-B27, present in 7% of whites and 95% of AS patients. AS is a disease of white males with a prevalence of 0.15%. AS is primarily a chronic inflammatory disease of the vertebral column, but involvement of other parts of the body is common. Nongranulomatous anterior uveitis occurs in up to 25% of patients, and asymptomatic inflammation of the thoracic aorta is present in 20% to 30%. In 10% of patients with AS, clinically important aortic incompetence or dilation of the ascending aorta develops. Pulmonary complications take the form of extrapulmonary restriction or parenchymal disease. Apical fibrobullous disease, with or without cavitation and hilar distortion, is found in some patients, almost exclusively in males. However, AS should always be considered in patients seen with upper lobe fibrosis, present in more than 20% of cases. Of note, a variety of other nonapical parenchymal diseases (e.g., NSIP) may be found in AS patients.

There is no effective treatment against development of apical fibrosis; resistance to corticosteroids is usually seen. In most patients, careful observation without treatment is appropriate, with specific antimicrobial therapy when infectious complications occur. One of the greatest therapeutic dilemmas is the patient with major hemoptysis caused by aspergilloma development in a cavity. First-line treatments include administration of antifungal agents and bronchial artery embolization. When uncontrollable, there may be no option but to proceed to surgical resection of the cavity, usually by lobectomy. However, this surgery carries a high risk of postoperative bronchopleural fistula or empyema and may lead to a fatal outcome.

MARFAN SYNDROME

Marfan syndrome is an inheritable disorder of connective tissue. The condition affects all races and both genders equally, with estimated prevalence of 1 in 5000 (0.02% of population). The mode of inheritance is autosomal dominant with variable penetrance, and 15% to 30% of all cases are caused by de novo mutations. The disorder has been linked to a defect in the *FBN1* gene on chromosome 15, which encodes the glycoprotein fibrillin-1. Fibrillin is essential for the formation of the elastic fibers found in connective tissue, because it provides the scaffolding for tropoelastin.

Patients with Marfan syndrome often have long limbs (arm span/height ratio >1.05) and involvement of the ocular system (e.g., ectopia lentis), cardiovascular (e.g., dilation or dissection of ascending aorta), and skeletal system involvement (e.g., pectus carinatum/excavatum, scoliosis, spondylolisthesis). Pulmonary involvement occurs in approximately 10% of patients and involves apical emphysematous and cystic changes; bullous degeneration may lead to spontaneous pneumothorax. In some cases, upper lobe fibrosis has been described.

BEHÇET SYNDROME

Behçet syndrome is an inflammatory disorder of unknown etiology affecting blood vessels of almost all sizes and types, ranging from small arteries to large vessels and involving veins and arteries. Disease prevalence varies from 1 in 10,000 to 1 in 300,000 worldwide, and it is most common in eastern Mediterranean countries and the Far East. It occurs mainly in young adults with the mean age of onset between 25 and 30 years and is associated with HLA-B51.

Because of the diversity of blood vessels that can be affected, manifestations of Behçet syndrome may occur at many sites throughout the body. Mucocutaneous ulceration is the clinical hallmark, with aphthous oral and genital ulceration seen in almost all patients. Besides ocular lesions (anterior or posterior uveitis or retinal vasculitis) and skin lesions (e.g., erythema nodosum) pseudofolliculitis and papulopustular lesions often occur. Other features include marked arthralgias with synovitis, a predilection to thrombosis, and central nervous system involvement (headaches, meningoencephalitis, cranial nerve palsies, seizures).

Pulmonary involvement is seen in less than 10% of patients with Behçet syndrome. Symptoms include dyspnea, chest pain, and recurrent hemoptysis that can be life threatening. Pathology typically involves aneurysms of the pulmonary artery because of outpouchings of the blood vessel wall caused by inflammation (Figure 53-12). Also, arterial and venous thrombosis with pulmonary thromboembolism, pulmonary infarcts, and pleural effusions (in some patients) may occur. In patients with hemoptysis, it is very important to distinguish between aneurysms of the pulmonary artery (with pulmonary-bronchial fistula formation) and pulmonary thromboembolism, because catastrophic pulmonary hemorrhage can occur if the wrong patients are anticoagulated.

Glucocorticoids and other immunosuppressive agents such as cyclophosphamide and azathioprine are the mainstay of therapy to control the vasculitis. In life-threatening situations, lobectomy or pneumonectomy might be considered.

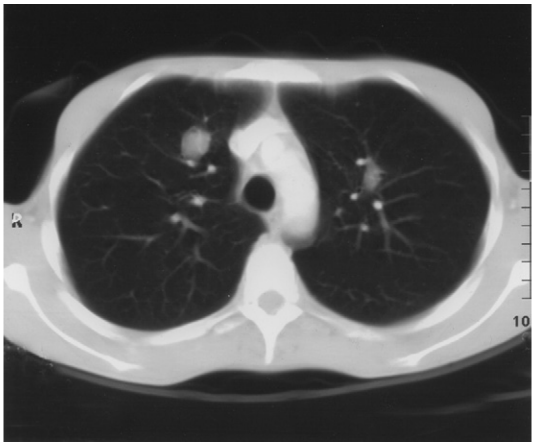

Figure 53-12 CT scan of 27-year-old Moroccan man with Behçet's syndrome initially seen with hemoptysis. The multiple coin-sized consolidations close to central vessels of lung hili proved to be aneurysms on angiography of pulmonary artery.

A forme fruste of Behçet syndrome is known as *Hughes-Stovin syndrome*, defined as the presence of pulmonary artery aneurysm in the setting of systemic thrombosis without extrapulmonary features consistent with Behçet syndrome.

DIAGNOSTIC TESTING

Pulmonary Function Tests

Pulmonary function tests (PFTs) are extremely useful in the identification of clinically relevant parenchymal manifestations of CTDs. Pulmonary fibrosis leads to restrictive lung disease and interferes with gas exchange, resulting in decreased total lung capacity (TLC), vital capacity (VC), and DLCO, but often no decreased flow rates. Follow-up of lung function during the first 6 years of scleroderma symptoms seems helpful for the evaluation of disease progressiveness. The mean percent loss of VC over three 2-year periods in patients with initial PFTs performed during the first 5 years of SSc were 32%, 12%, and 3%, respectively. Thus, careful monitoring of lung function early in the disease, when the greatest loss of lung function occurs, may help identify patients likely to respond to new therapy.

The PFT data also provide important prognostic information. SSc patients with FVC less than 50% predicted have the worst prognosis, with a cumulative 10-year survival close to 50%. Furthermore, DLCO less than 70% predicted in combination with proteinuria and elevated erythrocyte sedimentation rate (ESR) has accurately predicted mortality over 5 years in patients newly presenting with scleroderma.

A reduction in DLCO does not necessarily indicate underlying ILD and can also be a manifestation of pulmonary vascular disease or a combination of both. The VC/ DLCO% predicted ratio might be helpful: in pure fibrotic disease, approximately 1; in isolated pulmonary arterial hypertension, usually greater than 1.8; and with a mixture of fibrosis and vasculopathy, VC is moderately decreased but DLCO is even lower, also resulting in an elevated ratio.

Chest Radiography

Chest radiography should be performed in every patient with CTD, regardless of whether they have pulmonary complaints or findings. The pattern of abnormalities might help in the

Table 53-3 **Interstitial Pneumonias in Connective Tissue Disease: Major High-Resolution Computed Tomography (HRCT) Imaging Characteristics**

Type	HRCT Characteristics
Usual interstitial pneumonia (UIP)	Peripheral, subpleural, and basal distribution; irregular reticular changes with honeycombing; traction bronchiectasis and architectural distortion; minimal ground-glass changes (focal)
Nonspecific interstitial pneumonia (NSIP)	Symmetric, peripheral distribution; basal predominance; more ground-glass attenuation; reticular changes and traction bronchiectasis; honeycombing is not dominant.
Organizing pneumonia (OP; or cryptogenic OP)	Patchy consolidations and/or nodules and/or perilobular opacities; may have a ground-glass component
Lymphocytic interstitial pneumonia (LIP)	Diffuse ground-glass attenuation; centrilobular nodules; septal and bronchovascular thickening; thin-walled cysts
Diffuse alveolar damage (DAD)	Gravity-dependent consolidation; ground-glass opacification, often with lobular sparing; traction bronchiectasis occurs later.

differential diagnosis of some of the CTDs. If any parenchymal abnormality is seen, HRCT should be performed.

High-Resolution Computed Tomography

Currently, HRCT is the imaging method of choice in evaluating patients with CTD with ILD. It identifies more disease than the chest radiograph, is more specific, and has a greater ability to demonstrate coexisting pleural disease, small airways disease, bronchiectasis, and pulmonary nodules, while also providing diagnostic clues such as esophageal dilation. In addition, HRCT can also be helpful in choosing the best site for open or thoracoscopic lung biopsy. HRCT has revolutionized the subcategorization of IPs in terms of histopathologic-radiologic patterns, especially in idiopathic disease. Similar patterns can be found in CTDs. Recently, 16-slice CT technologies have enabled post-processing strategies (minimal intensity projection, minIP) that may further improve the evaluation of parenchymal disease patterns. Table 53-3 summarizes the major characteristics of the different types of IPs, and Figures 53-13 to 53-16 illustrate HRCT patterns of UIP, NSIP, OP, and LIP.

High-resolution CT also offers particular benefit in the assessment of the severity of diffuse lung and airway diseases. In addition, the pattern of abnormality may frequently be informative in terms of likelihood of response to treatment. A ground-glass pattern denotes predominantly inflammatory disease and is generally associated with improvement. A reticular pattern, particularly honeycombing, correlates well with the presence of established fibrosis.

Bronchoalveolar Lavage

Bronchoalveolar lavage is a valuable diagnostic tool to rule out infection and confirm the presence of (fibrosing) alveolitis, and it can provide a specific diagnosis, as in cases of diffuse alveolar hemorrhage (Figure 53-17). Also, BAL fluid can be particularly helpful in the differentiation of follicular bronchiolitis (see Figure 53-11).

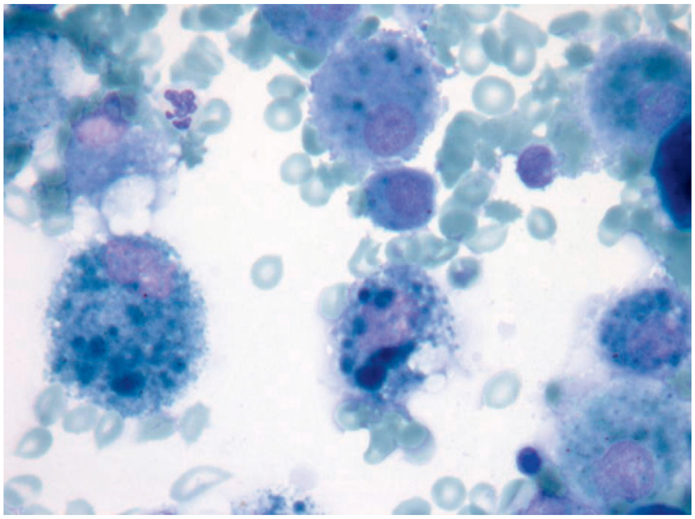

Figure 53-17 May-Grünwald-Giemsa staining of bronchoalveolar lavage fluid in patient with alveolar hemorrhage caused by autoimmune capillaritis. The large cells are hemosiderin-laden alveolar macrophages; the small cells are erythrocytes.

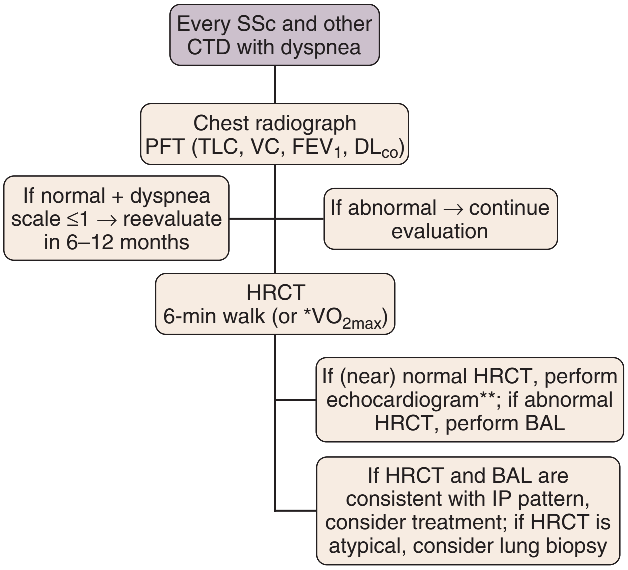
In SSc, differential cell count of BAL is also a valuable prognostic test. In one study of 49 SSc patients with fibrosing alveolitis followed for 2 years, only those with BAL granulocytosis (>3% neutrophils and/or >0.5% eosinophils) at baseline showed a significant disease progression with a marked reduction of DLco, whereas almost all patients with normal BAL findings or BAL lymphocytosis had stable lung function parameters during the study period.

Lung Biopsy

An important clinical question is when to biopsy for IPs in CTD. If patients are known to have a CTD and have respiratory symptoms, HRCT and lung function testing are most appropriate to detect or exclude with reasonable confidence diffuse ILD. BAL might provide further clues for specific diagnosis and is especially helpful for exclusion of other diagnoses such as infections. In many cases, HRCT findings will also allow, with reasonable confidence, the diagnosis of one of the IP subsets. If this is not the case or HRCT findings are atypical beforehand, a surgical lung biopsy should be considered. However, prognostic data in biopsy specimens from patients with CTD-associated IP are relatively lacking. Therefore, the decision to biopsy should be primarily reserved for cases with an atypical presentation and when a diagnosis other than IP is being considered (e.g., amyloidosis). Patients may also be taking immunosuppressive drugs, and histopathologic examination may be necessary to distinguish parenchymal manifestations of CTD from drug-induced lung disease or opportunistic infections. Lastly, biopsies may be undertaken to investigate for associated malignancies, especially in LIP.



Every SSc and other CTD with dyspnea
Chest radiograph PFT (TLC, VC, FEV$_1$, DL$_{co}$)
If normal + dyspnea scale ≤1 → reevaluate in 6–12 months
If abnormal → continue evaluation
HRCT 6-min walk (or *VO$_{2max}$)
If (near) normal HRCT, perform echocardiogram**; if abnormal HRCT, perform BAL
If HRCT and BAL are consistent with IP pattern, consider treatment; if HRCT is atypical, consider lung biopsy

Figure 53-18 Diagnostic flowchart for evaluation of pulmonary manifestations in connective tissue disease *(CTD)*. All patients with systemic sclerosis *(SSc)* and patients with other CTDs and respiratory symptoms can be evaluated for pulmonary complications according to this flowchart. Dyspnea scale is proposed by American Thoracic Society/European Respiratory Society: *0*, no breathlessness except with strenuous exercise; *I*, shortness of breath when hurrying or walking up a gradually sloping hill; *II*, walking slower than people of the same age because of breathlessness, or stopping for breath when walking at a normal pace on a level surface; *III*, stopping for breath after walking approximately 100 meters, or after a few minutes on a level surface; *IV*, being too breathless to leave the house, or breathless when dressing or undressing. *PFT*, Pulmonary function testing; *HRCT*, high-resolution computed tomography; *BAL*, bronchoalveolar lavage; *IP*, interstitial pneumonia.
*VO$_{2max}$ is recommended, because it provides more objective determination of functional capacity and impairment. It identifies factors limiting exercise capacity.
**Routine echocardiography is recommended in SSc because of high risk of cardiac involvement and pulmonary hypertension.

DIAGNOSTIC FLOWCHART

On the basis of the relatively high prevalence of parenchymal and vascular complications in patients with SSc, routine screening is advisable for these complications at presentation of disease. In other CTDs, evaluation of pulmonary manifestations will usually take place in patients who are symptomatic (Figure 53-18).

TREATMENT

Treatment of pulmonary complications in CTDs is primarily based on the type of lung disease and not on the specific type of CTD. In most cases, no controlled data are available for evidence-based decision making. Because CTDs are autoimmune-based inflammatory diseases and these drugs exert a broad range of immunosuppressive actions, corticosteroids

remain the mainstay of therapy despite many potential side effects. Other well-known drugs are cyclophosphamide, azathioprine, and methotrexate (MTX). These drugs have immunocytotoxic properties but are also associated with more serious side effects. In particular, MTX has a small (±3%) risk of pulmonary toxicity. Furthermore, cyclosporine A and tacrolimus are of therapeutic value because they can provide strong and specific T cell suppression, but careful monitoring of blood levels is needed to minimize side effects.

DIFFUSE LUNG DISEASE

Corticosteroids are widely used in the treatment of IPs associated with CTDs, although randomized controlled trials (RCTs) offer scant data showing they prevent progression of IPs or reverse fibrosis. Despite this lack of evidence, corticosteroids again remain the mainstay of therapy, with usual doses of prednisone between 0.5 and 1.0 mg/kg in nonacute situations. However, medium-dose corticosteroid therapy (15 mg/day prednisone or equivalent) is associated with the development of *scleroderma renal crisis,* which may lead to irreversible renal failure.

Of the other immunosuppressive drugs, RCTs data are now available in scleroderma diffuse lung disease only for cyclophosphamide. The North American Scleroderma Lung Study investigated the effects of 12 months of 2 mg/kg oral cyclophosphamide versus placebo in patients with signs of interstitial lung fibrosis. Lung function was significantly preserved in the active treatment arm, although absolute changes were small. Interestingly, the skin score improved as well. The cyclophosphamide group had a greater frequency of leukopenia and neutropenia, but the difference between the two groups in the number of serious adverse events was not significant. Open studies have recently reported mycophenolate mofetil as an alternative to cyclophosphamide.

VASCULAR DISEASE

Treatment options for patients with CTD-associated pulmonary hypertension are similar to those for idiopathic pulmonary hypertension (Figure 53-19). Although patients with CTD may not respond as well to therapy as patients with primary pulmonary hypertension, aggressive therapy may improve functional status and quality of life.

Immunomodulatory therapy (corticosteroids with or without cyclophosphamide), long-term plasma exchange, and autologous stem cell transplantation have also been reported to improve or stabilize pulmonary hypertension in patients with CTDs. However, these represent case reports or retrospective case studies, and no prospective study of immunosuppressive therapy has yet been completed.

LUNG TRANSPLANTATION

Lung transplantation is now considered an accepted treatment in patients with end-stage pulmonary or cardiopulmonary disease, although chronic rejection still remains a key problem that precludes long-term survival. According to the recent International Society of Heart Lung Transplantation registry, pulmonary fibrosis caused by systemic diseases, such as scleroderma, sarcoidosis, histiocytosis X, and lymphangioleiomyomatosis (LAM; see Chapter 54), make up approximately 5% of all cases of lung transplantation. Provided that patients with systemic disease have no active disease in other organs, and other organ functions are preserved, the results after transplantation are similar to other diseases (e.g., IPF, emphysema).

CLINICAL COURSE AND PREVENTION

Can early treatment of systemic disease prevent irreversible lung scarring or development of pulmonary hypertension? The widespread use of HRCT has led to increased detection of early lung disease in patients with CTDs. It is unclear what management strategy can be best applied in these patients, who are often asymptomatic and have normal or near-normal pulmonary function. In theory, they might benefit from early introduction of treatment to prevent further irreversible damage. However, most of these cases of subtle disease might never show progression. At present, these patients can only be considered "at risk" for intrinsically progressive disease and should be monitored carefully, especially in the first years after presentation.

Does the clinical course of IPs in the context of CTDs differ from their idiopathic counterparts? Currently, it is not clear that histologic distinctions between IP patterns are as important in CTD as in idiopathic IPs. In limited systemic sclerosis, however, there might be a difference in outcome between UIP and NSIP, justifying lung biopsy in carefully selected cases where HRCT cannot make this distinction, and the patient might benefit from timely referral for lung transplantation.

CONTROVERSIES AND PITFALLS

ACTIVITY VERSUS SEVERITY

In the context of CTDs and lung complications, *disease activity* means "the underlying pathophysiologic process in the pulmonary tissue is still going on and has not (yet) come to a rest (i.e., complete remission)." Complete remission, however, is not synonymous with resolution of disease, because it may have caused severe damage to the tissue leaving scars (i.e., irreversible fibrosis).

Disease severity can best be defined in terms of symptoms and functional limitations of the patient. Pulmonary complications in CTDs may be severe because of direct danger to life, such as diffuse alveolar hemorrhage.

In IPs, treatment decisions are primarily guided by severity of disease. In most of these processes, lung function impairment is the result of the ongoing interstitial inflammatory process and irreversible fibrosis. In some patients, however, the inflammatory phase of disease might have burnt out, leaving only extensive scar tissue. The proportion of active disease will likely determine success of immunosuppressive therapy. At present, however, no validated biomarkers or imaging technologies can be used to dissect reversible inflammatory disease from irreversible fibrosis. Watchful follow-up of disease evolution is still considered the most important strategy to overcome these limitations.

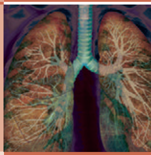
Section 8

PARENCHYMAL LUNG DISEASES



Chapter 54

Rare Diffuse Interstitial Lung Diseases

Simon R. Johnson • William Y.C. Chang

More than 7000 rare conditions exist, and although individually uncommon, together these diseases affect about 11% of all populations. Most rare diseases are chronic, often progressive, and can therefore form a significant portion of the workload for physicians. The term *orphan disease* is frequently applied to rare conditions and was originally used to suggest a lack of knowledge, research, or specific therapy. In many cases, however, significant progress in understanding the molecular basis of these diseases has resulted in biologically targeted treatments, making a definitive diagnosis especially important for these patients. This chapter describes select rare diffuse lung diseases, either primary or occurring in the context of systemic disease (secondary), likely to be encountered by most physicians, and particularly those for which a firm diagnosis can benefit patient management.

RARE CYSTIC LUNG DISEASES

LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis (LAM) is a cystic lung disease that affects almost exclusively women and has a prevalence of approximately 5 women per 1 million of most populations. LAM may occur sporadically or as part of the autosomal dominant genetic disorder, *tuberous sclerosis complex* (TSC). In both forms the lungs and lymphatics are infiltrated by LAM cells, an abnormal cell clone harboring biallelic inactivating mutations in the genes associated with TSC, either TSC-1 or more often TSC-2. LAM cells accumulate and cause progressive cystic destruction of the lungs, probably by the elaboration of proteolytic enzymes (Figure 54-1). LAM cells form small nodular clumps associated with lymphatic endothelial cells, which in turn form lymphatic channels that allow LAM cells to disseminate throughout the body. LAM cells also infiltrate the axial lymphatics and form the smooth muscle elements of *angiomyolipoma*, a rare tumor of the perivascular epithelioid cell family, present in up to 40% of women with sporadic LAM and almost all patients with TSC-LAM.

Other, extrapulmonary manifestations are related to lymphatic obstruction and include *lymphadenopathy* in up to 30% of patients and *lymphangioleiomyomas*, cystic lymphatic swellings usually in the abdomen, pelvis, or retroperitoneum occurring in up to 20% of patients (Figure 54-2). Thoracic and abdominal chylous collections are present in up to 10% of patients. LAM is also associated with a higher prevalence of *meningioma* than the general population. Cystic lung destruction results in recurrent pneumothorax and progressive airflow obstruction, with an average decline in forced expiratory volume in 1 second (FEV_1) of 120 mL per year (normal, ~27 mL/yr). However, the clinical course of patients with LAM varies, with some remaining stable for many years. At present, no features definitively predict which patients will develop progressive disease; however, onset at a younger age, presentation with breathlessness, and poor lung function at presentation suggest more aggressive disease.

Patients with LAM most frequently present with breathlessness or pneumothorax, although chylous pleural effusions, complications of angiomyolipoma, or weight loss can also be the presenting feature. Recurrent pneumothorax or airflow obstruction in younger women, particularly nonsmokers, should raise the possibility of LAM. In most cases the computed tomography (CT) findings of multiple round thin-walled cysts with no zonal predominance suggest the diagnosis. Increasingly, patients are being identified with LAM after investigations for other problems where cystic lung disease is observed on high-resolution CT (HRCT) scanning. In addition, screening for LAM at 18 years of age by CT is recommended for women with TSC; many of these patients have evidence of LAM on CT, but only a minority have respiratory symptoms.

With diagnostic criteria recently formulated by the European Respiratory Society (ERS), a definite diagnosis of LAM can be made based on a characteristic HRCT scan with a renal angiomyolipoma, histologic evidence of LAM cells at other sites (e.g., lymphangioleiomyomas, chylous collections in abdomen or thorax), or the presence of TSC. If TSC or extrapulmonary manifestations are not present, lung biopsy is required for a definitive diagnosis. Transbronchial biopsy can occasionally be helpful, although in most patients, video-assisted thorascopic surgery (VATS) is preferred. LAM cells characteristically stain with the monoclonal antibody HMB-45 and also express α–smooth muscle actin, estrogen, and progesterone receptors. The use of these immunohistochemical markers improves identification of LAM cells in lung tissue, including smaller transbronchial biopsies. The recent observation that vascular endothelial growth factor type D (VEGF-D) serum level is increased in about two thirds of patients with LAM has led to its use as a diagnostic marker for LAM. Importantly, a serum VEGF-D level greater than 800 ng/mL can differentiate LAM from other cystic lung diseases, including Langerhans cell histiocytosis, Birt-Hogg-Dube disease, and emphysema.

Patients with sporadic LAM should undergo clinical examination and where necessary, formal screening to exclude tuberous sclerosis complex. Only one third of patients with TSC have the classical triad of epilepsy, learning difficulties, and facial angiofibromas. Many patients with TSC-LAM have normal intelligence and mild skin changes that may be overlooked. Almost all patients with TSC-LAM have renal

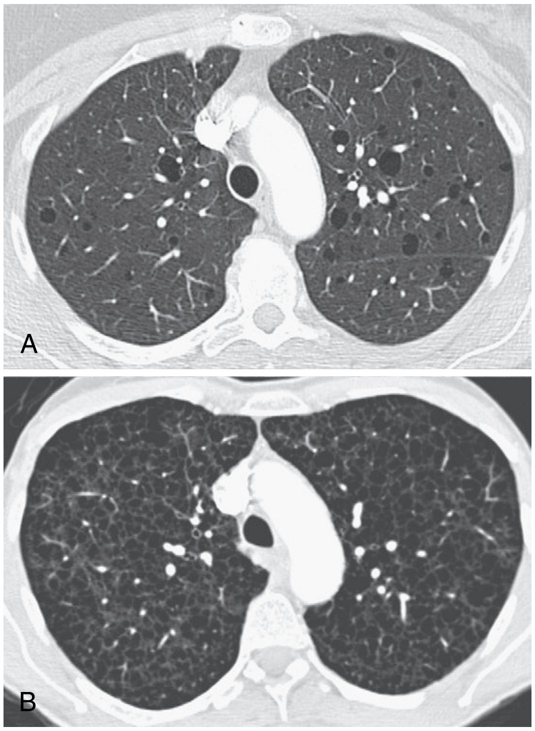


Figure 54-1 High-resolution computed tomography (HRCT) scans showing characteristic radiologic features of patients with lymphangioleiomyomatosis. **A,** HRCT in patient with asymptomatic disease and normal lung function. **B,** Image shows extensive cystic change in patient being considered for lung transplantation.

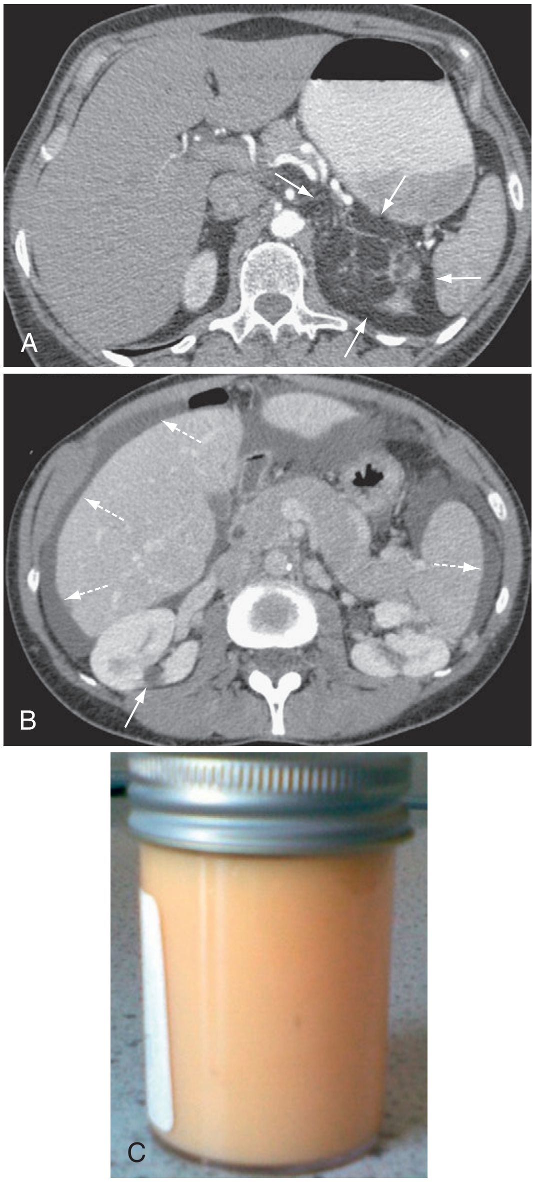

Figure 54-2 **A,** CT image shows a large, left renal angiomyolipoma with areas of fat density *(white arrows).* **B,** CT scan shows chylous ascites and a small, right renal angiomyolipoma *(white arrows).* **C,** Chylous fluid aspirated from pleural collection of patient with lymphangioleiomyomatosis.

angiomyolipomas, which tend to be larger and more frequently multiple and bilateral than in those with sporadic LAM. Making the diagnosis of TSC is important for the management of other aspects of TSC and for the patient's offspring.

To confirm LAM in the presence of cystic lung disease or to evaluate patients for renal angiomyolipoma, a CT scan of the abdomen and pelvis should be performed. Angiomyolipomas greater than 4 cm are prone to growth, rupture, and hemorrhage and should be treated prophylactically when large or in the presence of symptoms.

General management of LAM includes avoidance of estrogen supplementation, including oral contraceptives and hormone replacement therapy. Prophylactic vaccination, pulmonary rehabilitation, and oxygen should be given when appropriate. Bronchodilators are helpful for those with airflow obstruction. Patients with LAM are prone to *pneumothorax*, which occurs in more than 70% of patients and is recurrent in the majority, and early surgical intervention is recommended. Patients considering pregnancy should be warned that the disease may be more active in pregnancy, particularly an increase in pneumothorax. Those with TSC should receive genetic counseling. For patients with severe disease, including those with TSC, lung transplantation can be performed.

Previously, hormone treatment with progesterone or other antiestrogen therapies have been used for these patients, but no evidence indicates there is a benefit for most patients. Studies show that *rapamycin*, an inhibitor of mTOR pathway, is effective in reducing the rate of decline of FEV_1 in patients with impaired lung function. In those with renal angiomyolipoma, including those with TSC, a reduction in tumor volume is seen in those treated with rapamycin. On cessation of therapy, decline in lung function resumes and angiomyolipoma volume increases, and these patients may need long-term therapy. ERS recommends that mTOR inhibitors for LAM not be used routinely but likely have a role in patients with progressive disease.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH) is a bronchocentric disease categorized by a clonal proliferation of Langerhans cells in the lungs with focal granuloma and small airways destruction resulting in nodules and cystic change. LCH is part of a spectrum of diseases characterized by activated Langerhans cells, including Letterer-Siwe disease (acute disseminated LCH) and Hand-Schüller-Christian disease (chronic idiopathic xanthomatosis). The latter two entities are systemic cancerlike diseases of childhood and are not discussed further here. Adult LCH is generally restricted to the lung, although up to 30% of patients have extrapulmonary features; most often diabetes insipidus

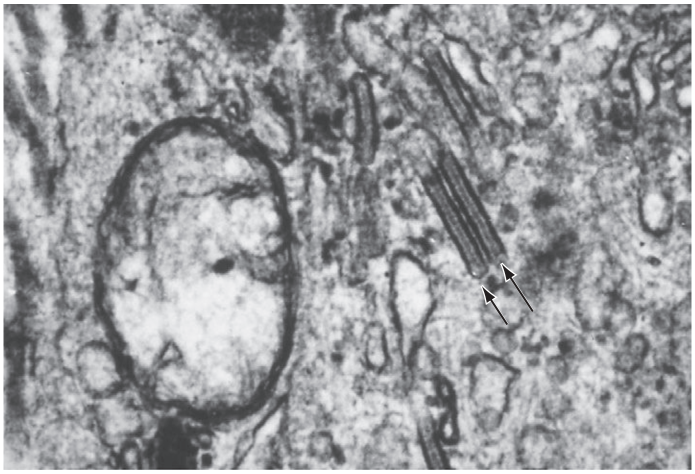

Figure 54-3 Langerhans cell histiocytosis. Electron micrograph showing Birbeck granules (*arrows*).

caused by pituitary involvement, skin lesions, or bone lesions causing pain and rarely, central nervous system lesions.

Langerhans cell histiocytosis typically affects individuals between 20 and 40 years of age, almost all of whom are current or recent smokers. The infiltrating Langerhans cell clone expresses the surface protein CD1a and has a characteristic appearance on electron microscopy with Birbeck inclusion granules (Figure 54-3). LCH may coexist with areas of *desquamative interstitial pneumonitis*, another smoking-related entity characterized by activation of macrophages. Similar to LAM, LCH is of variable severity, with approximately one quarter of LCH patients detected by imaging being asymptomatic. Pneumothorax is the presenting feature in about 20% of patients; the rest present with cough, dyspnea, or weight loss. The chest x-ray film is abnormal in most patients, showing reticular shadowing with midzone and upper-zone predominance (Figure 54-4). The CT scan shows a mixture of nodules, cavitating nodules, and cysts, often with thick, irregular walls forming bizarre shapes (Figure 54-5); characteristically, the bases of the lungs are relatively spared. As the disease progresses, the cysts tend to amalgamate, and nodules become less common. The diagnosis is usually suspected by the combination of these imaging appearances in younger smokers. Absolute confirmation often requires a surgical biopsy (Figure 54-6). However, bronchoalveolar lavage (BAL) fluid with greater than 5% Langerhans cells identified by CD1a positivity, often with increased macrophages and eosinophils, is supportive and can be diagnostic in the correct clinical context.

Lung function is normal in about 15% of LCH patients, although most have airflow obstruction with impaired gas transfer or a mixture of obstructive and restrictive changes. The course of LCH is variable, with spontaneous remission and even resolution in some patients; up to half of patients improve by CT criteria. However, some develop progressive respiratory failure, and a poor outcome is predicted by older age at onset, persistent constitutional symptoms, extrapulmonary involvement, and the presence of pulmonary hypertension. The overall survival for LCH patients is approximately 70% after 10 years, although some will require evaluation for pulmonary transplantation.

Management of LCH is generally supportive. Stopping smoking is the most important intervention and may significantly increase the chance of spontaneous resolution. As a particular feature of LCH, pulmonary hypertension should be screened for in those with active disease and may require specific treatment. In addition, many reports suggest an increased prevalence of lymphoma and lung cancer in patients with LCH. Persisting constitutional symptoms, hemoptysis, or other unexplained features should be thoroughly evaluated before being attributed to LCH alone. For those with active disease, steroids are frequently used, although no evidence supports this. More recently, in individual series, patients with active disease have been treated with 2-chlorodeoxyadenosine (Cladribine), a purine nucleoside analogue with activity

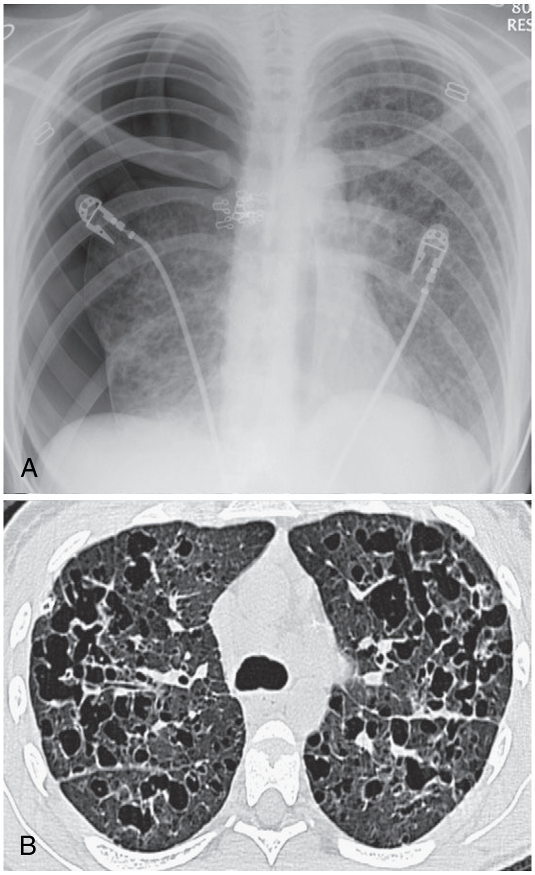

Figure 54-4 **A,** Chest radiograph of patient with Langerhans cell histiocytosis presenting with a pneumothorax. **B,** CT image from same patient shows multiple irregular cyst and nodules. A chest drain is present in the right hemithorax.

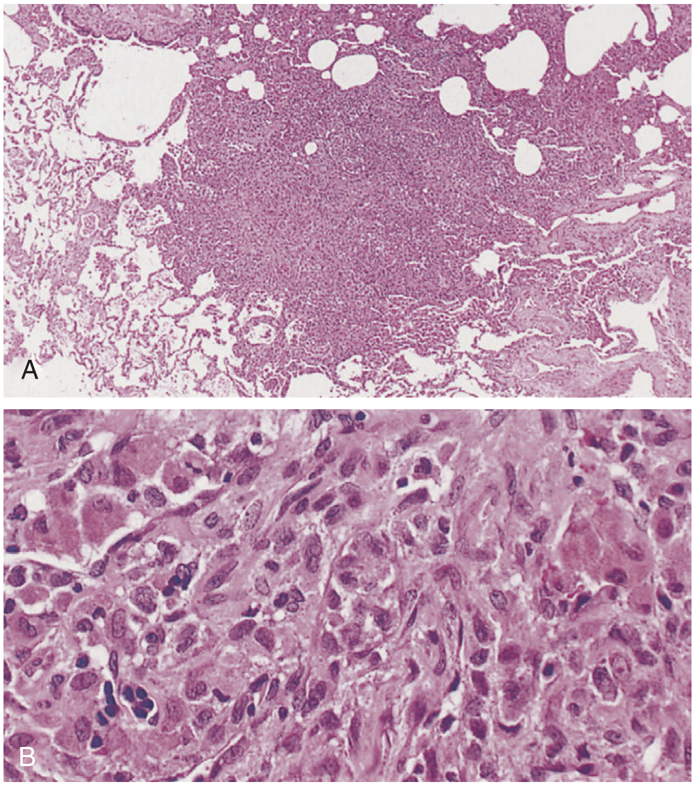

Figure 54-6 Histopathology of pulmonary Langerhans cell histiocytosis (PLCH). **A,** Low-magnification photomicrograph showing stellate, bronchocentric nodule in PLCH. **B,** High-magnification photomicrograph showing polymorphic, interstitial infiltrate in PLCH. The cellular infiltrate includes a mixture of mononuclear cells and eosinophils. Langerhans cells predominate and are differentiated by highly convoluted nuclei with nuclear grooves, which result in nuclear configurations that resemble crumpled paper or coffee beans.

against lymphocytes and monocytes, with evidence of response in many patients.

BIRT-HOGG-DUBE SYNDROME

Birt-Hogg-Dube (BHD) syndrome was first described as the association of fibrofolliculomas, acrocordons, and trichodiscomas; benign skin-colored papules and skin tags of adult onset; presence of lung cysts; and a predisposition to renal cancer. It is now realized that BHD syndrome may be entirely restricted to the lungs, without cutaneous manifestations, and is caused by either germline or somatic mutations in the folliculin *(FLCN)* gene, a tumor suppressor of unknown function. Patients with pulmonary disease develop lung cysts predominantly in the central and lower zones of the lungs, characteristically around the heart (Figure 54-7). The cysts are 0.2 to 7 cm in size, have thin walls, are often ovoid in shape, and occasionally are multiseptated. The cyst walls have disrupted elastic fibers and are infiltrated by macrophages.

Diagnostic markers of BHD syndrome include a family history of pneumothorax, skin lesions, and early renal cancer. However, less than half of patients will have the triad of skin, renal, and lung features. The main respiratory manifestation is recurrent pneumothorax, generally occurring in adult life. Symptomatic disease is possibly more common in women and those harboring germline rather than somatic mutations. Diagnosis of BHD syndrome is usually made on clinical criteria and the presence of more than five fibrofolliculomas or trichodiscomas of adult onset or an *FLCN* mutation. Minor criteria are renal cancer before age 50, multiple lung cysts, or a first-degree relative with a germline *FLCN* mutation. In practical terms, particularly with isolated lung disease, diagnosis is best made by screening the patient's blood for *FLCN* mutations in the correct clinical context.

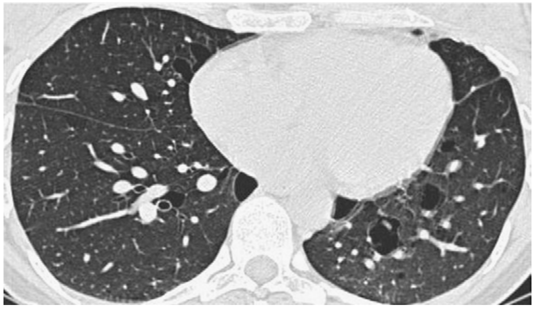

Figure 54-7 High-resolution CT image of patient with Birt-Hogg-Dube syndrome. Cysts are characteristically in a pericardiac distribution.

Patients with BHD syndrome tend *not* to develop progressive respiratory failure. The important management is prevention of recurrent pneumothorax; screening for renal cancer, probably best done by yearly magnetic resonance imaging (MRI); and when necessary, cosmetic treatment of dermatologic manifestations.

PULMONARY LIGHT CHAIN DEPOSITION DISEASE

The classic form of light chain deposition disease (LCDD) is caused by a light chain–producing B cell clone, resulting in monoclonal gammopathy, renal deposits, and occasionally, heart and liver nonamyloid light chain deposits; it may be associated with pulmonary nodules. A cystic lung disease caused by a variant LCDD was recently reported. Patients with pulmonary cystic LCDD have no evidence of systemic light chain deposition but develop an aggressive cystic lung disease, resulting in respiratory failure over 3 to 10 years. CT scan initially shows diffuse round cysts that may be associated with micronodules and linear densities, which may enlarge and coalesce over time. The lungs are infiltrated by small CD20-positive B lymphocytes suggestive of an antigen-driven process. Diagnosis is generally made by lung biopsy showing amorphous eosinophilic material in the alveolar walls, small airways, and blood vessels, sometimes associated with reactive giant cells. Congo red staining shows no birefringence, and immunofluorescence is positive for kappa light chains, which are also detectable in serum. Although a rare disorder, most reported patients develop progressive disease that may require pulmonary transplantation. Interestingly, LCDD does not recur in the transplanted lungs, and lung transplantation is associated with a normalization of the serum κ/λ light chain ratio suggesting the disease is located exclusively in the lungs.

EVALUATION OF PATIENTS WITH CYSTIC LUNG DISEASES

In addition to the entities previously described, lung cysts are also seen in *multiple cystic mesenchymal hamartoma*, an entity categorized by a small number of larger, thick-walled cystic lesions prone to hemorrhage. Metastatic endometrial stromal sarcoma can present as lung cysts and can run a deceptively indolent course, in one case diagnosed only after lung transplantation for suspected LAM. Lung cysts are also seen in

Table 54-1 **Cystic Lung Diseases: CT Appearance and Clinical Characteristics**

	CT Appearance of Cysts		
Disease	**Features**	**Distribution**	**Associated Features**
Lymphangio-leiomyomatosis	Round, thin walls	All zones	Exclusively women Angiomyolipoma Lymphatic abnormalities and chylous collections Tuberous sclerosis
Langerhans cell histiocytosis	Irregular shapes, thicker walled	Predominantly in middle and upper zones	Positive smoking history Nodules and/or cavitating nodules
LIP/Sjögren syndrome	Round, thin walls, sparse	All zones	Systemic features Interstitial shadowing Serum autoantibodies
Birt-Hogg-Dube syndrome	Ovoid, thin walls	Middle and lower zones; pericardiac	Renal cancer, skin hamartomas *FLCN* mutation
Light chain deposition disease	Mostly round		Nodules and lines serum κ light chains
Cavitating tumors	Round, thicker walls	All zones	History or evidence of primary tumor
Emphysema	Absent walls	Variable pattern	Smoking; inhalational exposure

CT, computed tomography; *LIP*, lymphoid interstitial pneumonia.

lymphocytic interstitial pneumonia (LIP) and patients with acquired immunodeficiency syndrome (AIDS). In these entities, cysts are generally less profuse and associated with interstitial changes.

Diagnosis in patients with cystic lung disease can be difficult. Although imaging and associated features usually suggest the most likely diagnosis, imaging alone is not generally diagnostic (Table 54-1). Suspicion of LAM should be followed by abdominal CT, which will show extrapulmonary manifestations in two thirds of patients; LCH by BAL and CD1a staining, and BHD by *FLCN* mutation analysis and renal/skin evaluation. Nonspecific or mixed appearances can be evaluated by autoantibody screening, serum κ/λ light chain ratio and human immunodeficiency virus (HIV) serology. Surgical biopsy may be required but can be avoided in many cases. Because many of these diseases have genetic implications for the patient and family, and specific treatments and clinical trials are available, a definitive diagnosis is often necessary.

OTHER RARE DIFFUSE LUNG DISEASES

PULMONARY ALVEOLAR PROTEINOSIS

Also known as alveolar lipoproteinosis, alveolar phospholipidosis, and pulmonary alveolar phospholipoproteinosis, pulmonary alveolar proteinosis (PAP) is a disease caused by a failure of granulocyte-macrophage colony-stimulating factor (GM-CSF) signaling, which results in a failure of surfactant protein clearance by alveolar macrophages and the accumulation of lipoproteinaceous material in the alveolar spaces. Three categories of PAP have been described: idiopathic, secondary, and congenital.

Idiopathic PAP results from GM-CSF neutralizing autoantibodies and accounts for approximately 90% of cases, with overall prevalence or 4 to 40 per 1 million, dependent on the population studied. It is two to three times more common in men and smokers and has been putatively linked to exposure to flour, cement, wood, chlorine gas, gasoline, and plastics, but a causal link has not been established. Heavy silica dust exposure was known to cause *silicoproteinosis*, a similar condition, but this is now rarely seen as a result of reduced workplace exposure. Idiopathic PAP usually presents in adulthood, with a mean age at diagnosis of 39 years. Presentation is nonspecific, the most common symptoms being dyspnea, cough, chest pain, hemoptysis, and constitutional upset. Superimposed infection may also be the presenting feature. Examination can be normal, but lung crackles and finger clubbing may be present.

Secondary PAP is not related to GM-CSF autoantibodies but occurs in a small fraction of patients with hematologic disorders (e.g., chronic myelogenous leukemia, myelodysplastic syndromes), immunodeficiency (e.g., HIV, hypogammaglobulinemia, thymic aplasia, IgA deficiency) and *lysinuric protein intolerance*, a genetic disorder caused by an amino acid transporter mutation. *Congenital* PAP is a group of autosomal recessive disorders caused by a variety of GM-CSF receptor and surfactant protein mutations and is invariably fatal in childhood without transplantation.

Chest radiography demonstrates consolidation with thickened intralobular septae (Figure 54-8). In a third of cases the changes are asymmetric or unilateral. The pattern is variable and in 50% of PAP patients may be perihilar, resembling the "bat wing" appearance seen in pulmonary edema. The CT appearance of air space shadowing in a geographic pattern with interlobular septal thickening is described as a "crazy paving" pattern (Figure 54-9). This appearance is not specific for PAP and may also be seen in cardiogenic pulmonary edema, bronchoalveolar cell carcinoma, *Pneumocystis jirovecii* pneumonia, alveolar hemorrhage, sarcoidosis, cryptogenic organizing pneumonia, nonspecific organizing pneumonia, exogenous lipoid pneumonia, and drug-induced lung diseases. Diagnosis is usually made on the basis of a compatible clinical history and typical radiology and a milky appearance on BAL fluid containing periodic acid–Schiff–positive granular material (Figure 54-10). Open-lung biopsy, although rarely essential, shows accumulation of lipoprotein in the alveolar spaces (Figure 54-11). Nonspecific increase in serum lactate dehydrogenase (LDH) may also be seen. Lung function is generally restrictive with decreased gas transfer. Anti-GM-CSF antibody

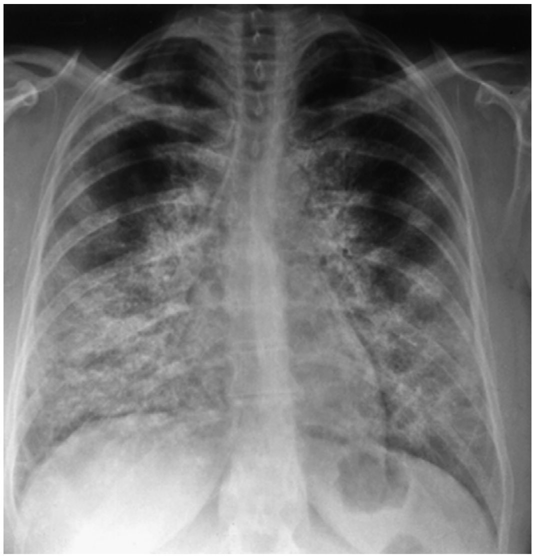

Figure 54-8 Chest radiograph in patient with diffuse bilateral air space shadowing caused by pulmonary alveolar proteinosis (PAP).

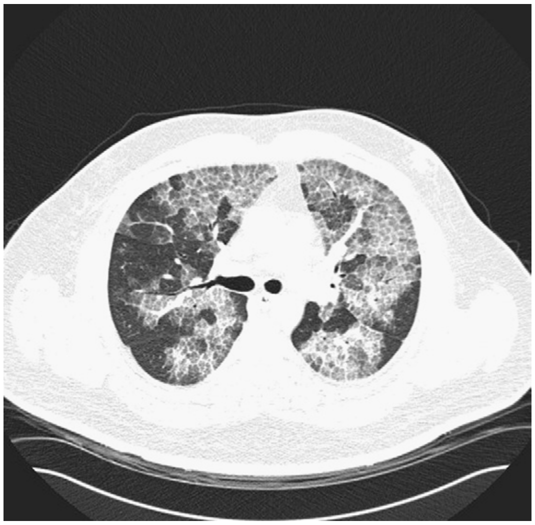

Figure 54-9 High-resolution CT image showing typical "crazy paving" appearance of pulmonary alveolar proteinosis, representing alveolar filling and thickening of secondary pulmonary lobules.

titers also show promise as a diagnostic test in both serum and BAL fluid.

Opportunistic infections can complicate PAP because of impaired macrophage function and host defense. Common organisms include *Nocardia* species, fungi, and mycobacteria. Pulmonary fibrosis has been documented to occur in PAP, but this is rare, and it is unclear as to whether this process is progressive. The treatment of choice for idiopathic PAP is *whole-lung lavage* (WLL) with warmed 0.9% saline performed at specialist centers under general anesthesia using double-lumen endotracheal tube. Lavage is continued until fluid runs clear, typically taking 10 to 12 L of saline per lung. Chest percussion is also sometimes employed to aid clearance of lipoproteinaceous material. Both multisession WLL and single-session, sequential bilateral WLL are performed. In PAP patients with severe hypoxia, WLL has been performed with extracorporeal membrane oxygenation and in hyperbaric chambers. Complications of WLL include barotrauma and saline thorax. Although there are no randomized controlled trials (RCTs) of WLL, case series report 85% of patients treated have some improvement in symptoms, lung function, radiology, and survival. The median duration of clinical benefit is 15 months and 60% to 70% will require a repeat lavage. WLL may still be required for secondary PAP, but the mainstay of therapy is to treat the underlying condition. Congenital PAP does not appear to respond well to WLL.

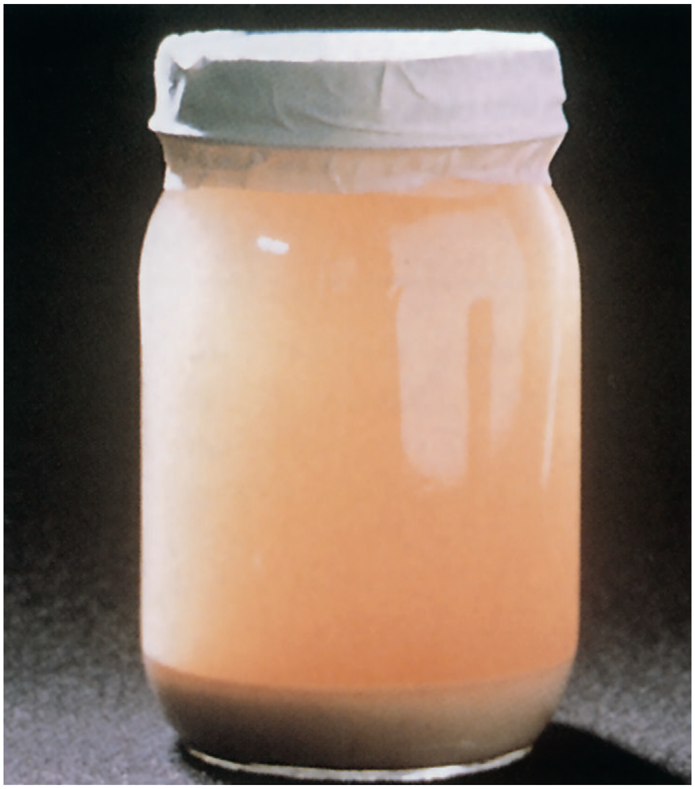

Figure 54-10 Bronchoalveolar lavage (BAL) fluid with classic milky appearance from patient with pulmonary alveolar proteinosis.

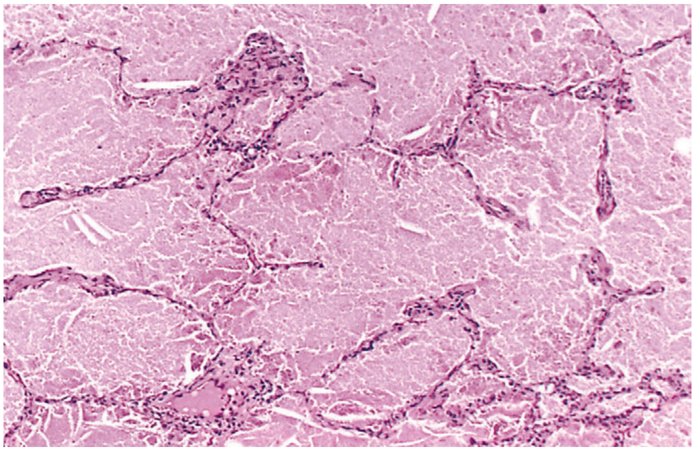

Figure 54-11 Surgical biopsy of patient with pulmonary alveolar proteinosis showing accumulation of lipoprotein in alveoli.

Several small, nonrandomized studies of subcutaneous GM-CSF for idiopathic PAP show an improvement in up to 50% of patients. Inhaled GM-CSF has also undergone trials, but further studies are needed.

In the adult forms of PAP, estimated 5-year and 10-year survival are 75% and 68%, respectively. Approximately one third of cases resolve spontaneously over months to years, one third of patients have stable disease, and another third have progressive disease, with lung transplantation as an option. The overall risk of respiratory death is 10% to 15%. The prognosis is much worse in those under age 5 years with congenital PAP, with 5-year survival of about 14%.

AMYLOIDOSIS

The term *amyloidosis* encompasses a complex group of multisystem conditions that result in the extracellular deposition of *insoluble amyloid*, abnormally folded low-molecular-weight protein molecules, resulting in progressive organ damage. It may be acquired or inherited and present with multisystem or focal disease. Amyloidosis may present to respiratory physicians in a variety of ways. Chronic pulmonary conditions such as bronchiectasis may give rise to systemic AA amyloidosis; systemic amyloidosis itself may result in respiratory symptoms and referral; and localized respiratory tract amyloid deposits may either present with respiratory symptoms or may be found incidentally on chest radiography.

The two most common forms of amyloid to affect the respiratory system are *AL light chain* (AL) amyloidosis, which occurs as a result of deposition of excess immunoglobulin light chain fragments, usually secondary to a plasma cell dyscrasia, or reactive *systemic AA* amyloidosis caused by accumulation of the acute-phase reactant, serum amyloid A, secondary to a variety of other chronic inflammatory conditions. Almost all clinically significant respiratory tract disease is related to AL amyloid. The diagnosis of amyloidosis should be considered with unusual upper airways symptoms in patients with parenchymal changes, unexplained congestive cardiac failure, or nephrotic syndrome suggesting a multisystem disease.

Laryngeal amyloid represents 0.5% to 1% of benign laryngeal disease and may present as discrete nodules or diffuse infiltration; it is often localized and usually relatively benign. Laryngeal amyloid usually affects the supraglottic larynx, and patients present with hoarse voice or stridor, although choking or exertional dyspnea also occur. *Tracheobronchial amyloid* is uncommon, and presenting symptoms include dyspnea, persistent cough, and hemoptysis. Airway narrowing can also cause wheeze, distal atelectasis, recurrent pneumonia, or lobar collapse, and solitary nodules have been mistaken for neoplasia. Amyloidosis can also present with mediastinal and hilar lymphadenopathy although *parenchymal amyloidosis* presenting as either solitary or multiple nodules or a diffuse alveolar-septal pattern is the most frequently detected respiratory manifestation.

The "gold standard" for diagnosis remains biopsy demonstrating apple-green birefringence with polarized microscopy after staining with Congo red. In some centers, radiolabeled serum amyloid P (SAP) has been used to identify distribution and burden of disease, particularly for solid-organ involvement. With pulmonary involvement, lung function tests may show a restrictive pattern with reduced transfer factor, and in the case of tracheobronchial disease, large airways obstruction may be detected by flow-volume loop. Routine workup excludes an underlying blood cell dyscrasia (e.g., myeloma) and looks for other organ involvement.

Studies on management of respiratory tract amyloid are limited, and management decisions are often made empirically based on symptom management. No treatment may be needed, but local measures such as laser therapy, stenting, and surgical resection have been used for endobronchial and tracheobronchial disease. No evidence shows that steroids have any effect on laryngeal amyloid, and it is thought that repeated endoscopic procedures are safer than repeated open surgery. Many modalities used for myeloma, including chemotherapeutic agents (e.g., melphalan, thalidomide) and autologous bone marrow transplantation, are being tried in systemic AL amyloid, but there have been limited clinical trials.

PULMONARY ALVEOLAR MICROLITHIASIS

Pulmonary alveolar microlithiasis (PAM), first described in 1957, is characterized by the extensive accumulation of intraalveolar calcium phosphate deposits, or "microliths." PAM is an autosomal recessive disease and, although reported worldwide, is most common in Japan, Turkey, and Italy. Presentation is most common in the mid-30s with dyspnea, cough, and chest pain. However, half of patients are asymptomatic, and PAM is detected as an incidental finding on chest radiography or by family screening.

Diagnosis is usually made on the basis of a distinctive calcified micronodular "sandstorm" appearance seen on chest radiography with mid/lower-zone predominance, often obliterating the mediastinal and diaphragmatic contour (Figure 54-12). CT scanning, particularly in advanced disease, demonstrates calcified interlobular septa, pleura, and bronchovascular bundles;

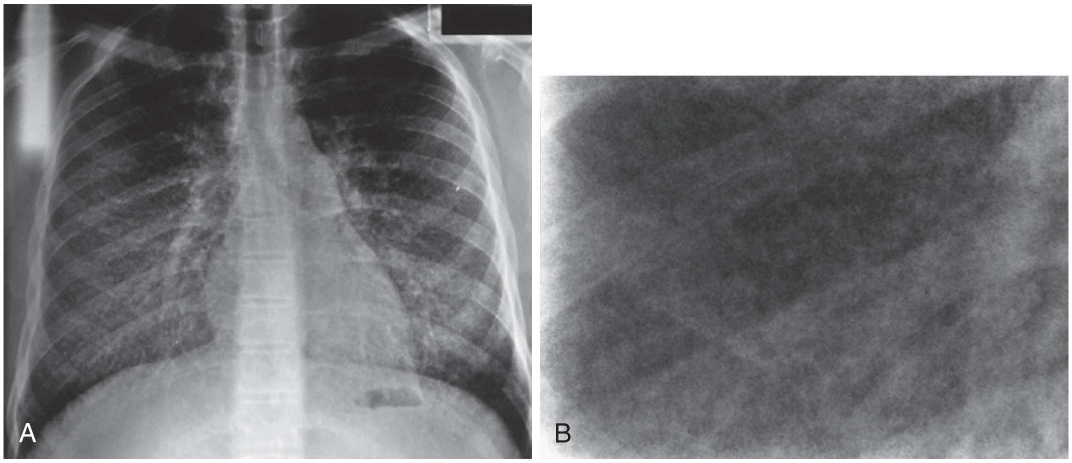

Figure 54-12 Chest x-ray films of patient with pulmonary alveolar microlithiasis. **A,** Numerous tiny opacities are present throughout both lungs. **B,** Magnified view of lower right lung showing numerous opacities (<1 mm in size).

perilobular microliths; and often ground-glass attenuation, areas of consolidation, and subpleural cysts. Lung biopsy reveals characteristic lamellar intraalveolar microliths. Mutations in *SLC34A2*, a gene encoding a sodium-dependent phosphate transporter, highly expressed by alveolar type II cells have been identified in most patients, possibly leading to the aberrant accumulation of calcium phosphate in alveolar spaces.

Longer-term prognosis in patients with PAM is poor, with a mean age of death from respiratory failure of 46 years. Treatment is supportive, including oxygen when required and lung transplantation. Bisphosphonates have been used in children with PAM with some evidence of short-term radiologic and clinical improvement.

PULMONARY MANIFESTATIONS OF RARE SYSTEMIC DISEASES

A number of rare systemic diseases associated with pulmonary manifestations may be encountered by respiratory physicians, including Hermansky-Pudlak syndrome, Erdheim-Chester disease, lysosomal storage disorders (e.g., Gaucher, Niemann-Pick, Fabry), and mucopolysaccharidoses.

HERMANSKY-PUDLAK SYNDROME

Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder that results in impaired trafficking of the membrane-bound organelles, melanosomes, platelet-dense bodies, and lysosomes. HPS is most prevalent in Puerto Ricans, in whom it is one of the most common single-gene disorders. The disease segregates to at least seven genes, each with a slightly different phenotype. Clinically, HPS is characterized by the triad of oculocutaneous albinism, platelet aggregation defects causing a bleeding diathesis, and visceral deposition of the fatlike substance ceroid, resulting in pulmonary fibrosis, also involving the gastrointestinal tract, heart, and kidneys. HPS-1 is the most common subtype, with 80% of these patients developing pulmonary fibrosis. Pulmonary fibrosis is more frequent in women, typically presents in the third decade of life, and results in premature death in about half of patients.

No treatment is of proven efficacy, although pirfenidone reduced rate of lung function decline in one small study of patients with HPS-1. Experience with lung transplantation in HPS is limited but can be considered for patients with end-stage disease.

ERDHEIM-CHESTER DISEASE

Erdheim-Chester disease (ECD) is a rare, systemic, non–Langerhans cell histiocytosis of unknown etiology. It occurs predominantly in middle-aged and older adults, most often presenting with bone pain. ECD is characterized clinically and radiologically by bilateral, symmetric osteosclerotic lesions involving the metaphyses and diaphyses of long bones. Approximately half of patients have extraosseous disease, with the lungs affected in 20% to 35% of these. Pulmonary symptoms include cough and progressive dyspnea. The chest x-ray film generally shows diffuse interstitial infiltrates with pleural and interlobular septal thickening; pleural effusions may be present. CT findings include interlobular septal and visceral pleural thickening, patchy reticular and centrilobular opacities, ground-glass changes, and pleural effusions. Diagnosis is generally by biopsy demonstrating CD1a-negative histiocytes around lymphatics and absence of Birbeck granules, although a typical CT scan in combination with the radiologic skeletal findings are highly suggestive of ECD.

Various combinations of treatment have been tried, with the most successful anecdotal cases using a combination of chemotherapeutic agents and steroids. The overall prognosis is poor; one third of ECD patients with pulmonary involvement die within 6 months and about 60% within 3 years.

LYSOSOMAL STORAGE DISORDERS

Lysosomal storage disorders (LSDs) are a group of approximately 50 inherited conditions characterized by a defect in the functional expression of any of the lysosomal enzymes, resulting in the accumulation of their substrates both intracellularly and extracellularly and loss of function in a variety of organ systems, including the lungs. The clinical features depend greatly on the rate and magnitude of accumulation, with a wide spectrum of phenotypes observed, the vast majority presenting in childhood.

Gaucher disease (GD), the most prevalent LSD, is inherited in an autosomal dominant manner and results from a deficiency of glucocerebrosidase activity causing glucocerebroside to accumulate in phagocytic reticuloendothelial cells, called Gaucher cells. Pulmonary involvement is most common in the infantile form (type 2) although adult onset (type 1) is sometimes associated with an interstitial lung disease resulting from accumulation of Gaucher cells in the alveolar spaces and septa. Pulmonary hypertension and hepatopulmonary syndrome are also occasionally seen. Pulmonary involvement is more common in those with severe disease, particularly with neuropathic involvement. Enzyme replacement therapy is currently the mainstay of treatment, but respiratory involvement may not respond well to this.

Niemann-Pick disease is an autosomal recessive disorder characterized by the accumulation of lipid-laden macrophages (Niemann-Pick cells). Lung involvement is relatively frequent in infantile forms but less common in adult forms. The radiologic appearance is typically of reticular or reticulonodular infiltrates. Treatment by WLL may be of some benefit, and bone marrow transplantation has been attempted in some patients.

Fabry disease is an X-linked metabolic disease caused by the absence of α-galactosidase A, resulting in the accumulation of glycosphingolipids. Patients can present with a variety of pulmonary symptoms, including dyspnea, airway obstruction, wheeze, pneumothorax, and hemoptysis. The chest radiograph may be normal, but chest CT may show ground-glass change. Diagnosis is made by bronchial biopsy, bushings, or lavage. Enzyme replacement therapy has been shown to alleviate pulmonary dysfunction in some patients.

MUCOPOLYSACCHARIDOSES

The mucopolysaccharidoses, including *Hurler disease* and *Hunter syndrome*, are a group of inherited multisystem conditions caused by an accumulation of mucopolysaccharides (glycosaminoglycans). Deposition in the upper airway can result in symptoms of sleep apnea as a result of upper airways obstruction, and a number of patients will require nocturnal continuous positive airway pressure (CPAP) support. Deposition in the lungs may result in chronic interstitial changes. Respiratory function may be further compromised by other disease features, such as abnormalities in the shape and structure of the ribs, short neck and immobile jaw, and abdominal organomegaly.

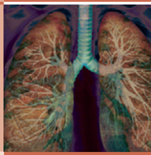
Section 8

PARENCHYMAL LUNG DISEASES



Chapter 55

Extrinsic Allergic Alveolitis

Kelsey Gray • Cecile Rose

One of the first written descriptions of hypersensitivity pneumonitis (HP), or extrinsic allergic alveolitis (EAA), was in 1713 by Ramazzini, who observed that “minute worms” contained in grain cause a syndrome of dyspnea and cachexia associated with a shortened life span. In 1932, Campbell reported five farmers who developed acute systemic and respiratory symptoms after exposure to moldy hay. In 1944, Pickels named this syndrome “farmer’s lung.” Farmer’s lung and pigeon breeder’s disease are the most well studied forms of EAA. Each year, however, new exposure settings and types are added to the list of antigens implicated in the development of EAA.

A heterogeneous disease, EAA has varying clinical presentations associated with the inhalation of antigens, leading primarily to a diffuse mononuclear cell inflammation of the small airways and lung parenchyma. Classifying etiologic antigens into three broad categories is clinically helpful: microbial agents, animal proteins, and low-molecular-weight chemicals (Table 55-1). Most particulate antigens are of respirable size, less than 3 to 5 μm in diameter, and deposit in the alveoli. However, some antigens are deposited in airways and then become soluble, as occurs with *Alternaria* spores.

Estimating the true incidence of disease can be challenging, because EAA may be misdiagnosed as an interstitial pneumonia or other pulmonary disorder or may not come to medical attention in individuals with mild disease. Moreover, genetics, coexisting exposures such as smoking, work environments, climates, altitude, and endemic disease (i.e., other granulomatous disorders such as sarcoidosis) vary from country to country, making comparisons of prevalence and incidence challenging. A longitudinal primary care database estimate of the incidence of EAA in the general population was 1 per 100,000 person-years in the United Kingdom. Incidence rates in specific populations with antigen exposure have also been reported. A study in Finnish farmers found 5 cases of EAA per 10,000 farmers who required hospital admission over a 1-year period. A study in Swedish farmers estimated an annual rate of 2 to 3 per 10,000 farmers. Prevalence of EAA among pigeon breeders is estimated at 0.1% to more than 10%, depending on antigen exposure.

RISK FACTORS

It is unclear why some individuals exposed to an antigen develop EAA and others residing or working in the same environment do not. Because only 1% to 15% of persons exposed to etiologic antigens develop EAA, a combination of antigen dose, host-specific factors, and underlying genetics likely contributes to the development of EAA.

Intensity, frequency, and duration of exposure; particle size; antigen solubility; climate; work practices; and use of respiratory protection combine to alter the risk of disease. *Farmer’s lung* is associated with exposure to moldy hay, which is more common in harsh winter environments with heavy rainfall, where damp hay is fed to livestock in indoor barns with poor ventilation. *Summer-type EAA*, the most prevalent form of EAA in Japan, occurs in the wet summer months when indoor microbial contamination is at its height. Moreover, EAA associated with bird exposure occurs more frequently during the sporting (bird-hunting) season.

As with other granulomatous disorders, EAA occurs more often in individuals who do not smoke. However, when the disease occurs in smokers, they typically have a more severe course with increased mortality compared to nonsmokers. Concurrent high exposures to carbamate and organochlorine pesticides are associated with a higher risk of developing EAA in at-risk farmers. Pesticide exposure has been shown to activate the immune system, with increased inflammatory cytokine production and differential functional effects on macrophages, which may serve to enhance the inflammatory response to antigen.

There is also evidence that viral infections may be associated with disease development. Dakhama et al. found viral nucleic acids in more than half of the bronchoalveolar lavage (BAL) specimens and alveolar macrophages in subjects with acute EAA; influenza A was isolated in the majority of subjects. Infection with respiratory syncytial virus (RSV) and Sendai virus in mouse models of EAA are associated with a more robust inflammatory response to the inhaled antigens that cause farmer’s lung. Fetal microchimerism (fetal cells in maternal tissues) may also be an important mechanism to help explain the observation that EAA is more common in antigen-exposed women who have had children.

Several genetic studies suggest that individuals with certain major histocompatibility complex (MHC) class II haplotypes and alleles as well as tumor necrosis factor alpha (TNF-α) promoter polymorphisms are at increased risk of developing EAA. Specific single nucleotide polymorphisms (SNPs) in the transporter associated with antigen processing (TAP-1) and proteasome subunit beta type 8 (PSMB8) genes, involved in antigen processing and presentation by MHC classes I and II, may have affected disease susceptibility in a population of Mexican patients with EAA. Interestingly, two studies in different populations showed that allelic variants in the promoter region of tissue inhibitor of metalloproteinase 3 (TIMP-3), which inhibits the proteolytic activity of matrix metalloproteinases and thus extracellular matrix turnover, are protective against the development of EAA.

Table 55-1 Three Major Categories of Antigens Causing Extrinsic Allergic Alveolitis (EAA)

Antigen	Exposure	Syndrome
Microbial Agents		
Bacteria		
Thermophilic	Organic dust	Farmer's lung, bagassosis, mushroom worker's lung
Nonthermophilic	Water, hot tubs	Humidifier lung, hot tub lung
Fungi		
Aspergillus spp.	Moldy hay and moldy water Animal bedding Esparto grass	Farmer's lung, ventilation pneumonitis Doghouse disease Espartosis
Trichosporon cutaneum (T. biegelii)	Damp wood and mats	Japanese summer-type EAA
Alternaria spp.	Wood pulp	Wood pulp worker's lung
Cryptostroma corticale	Wood bark	Maple bark stripper's lung
Animal and Plant Proteins		
Animal proteins		
Avian proteins	Bird droppings, feathers (bloom)	Bird fancier's lung, pigeon breeder's lung
Urine, serum, pelts	Rats, gerbils	Animal handler's lung
Plants		
Coffee	Coffee bean dust	Coffee worker's lung
Low Molecular Weight Chemicals		
Toluene diisocyanate (TDI)	Paints, resins, polyurethane foams	Isocyanate (TDI) EAA
Drugs	Amiodarone, gold, procarbazine	Drug-induced EAA
Methylmethacrylate	Dental laboratories	

CLINICAL FEATURES

The clinical presentation of patients with EAA can vary depending on the duration and intensity of exposure. Presentation does not seem to change with the type of antigen (organic vs. inorganic). Traditionally, the clinical presentation of EAA has been classified according to Richerson's scheme, which describes acute, subacute, and chronic forms. Symptoms of *acute* EAA generally occur within 4 to 12 hours of antigen exposure. Flulike symptoms predominate, including fever, cough, dyspnea, chills, malaise, chest tightness, and myalgias. Physical examination frequently reveals fever, tachypnea, tachycardia, and rales. With *subacute* and *chronic* forms, the temporal relationship between antigen exposure and symptom onset is more difficult to assess. Typically, these patients report more insidious onset of progressive dyspnea on exertion, dry or minimally productive cough, fatigue, malaise, anorexia, and weight loss. The physical examination may reveal bibasilar rales; right-sided heart failure and digital clubbing may be present in patients with advanced fibrosis.

Notably, Richerson's classification system was described before the use of computed tomography (CT) and does not correlate well with lung pathology. Lacasse et al., using data from the hypersensitivity pneumonitis (HP) study, used a cluster analysis (e.g., symptomatology, physiology, imaging, BAL data) and found that subacute EAA is likely an attenuated form of acute EAA. Thus, they proposed a binary scheme in which patients are classified according to disease activity, whether active or sequelae. This classification scheme, however, needs further validation before it is integrated into clinical practice.

Table 55-2 Clinical Prediction Rule for Diagnosis of Extrinsic Allergic Alveolitis

Variable	Odds Ratio (95% CI)
Exposure to known antigen	38.8 (11.6-129.6)
Positive precipitating antibodies	5.3 (2.7-10.4)
Recurrent episodes of symptoms	3.3 (1.5-7.5)
Inspiratory crackles	4.5 (1.8-11.7)
Symptoms 4-8 hours after exposure	7.2 (1.8-28.6)
Weight loss	2.0 (1.0-3.9)

From Lacasse Y et al: *Am J Respir Crit Care Med* 168:952-958, 2003.

Several diagnostic criteria have been proposed to differentiate EAA from other interstitial lung diseases (ILDs). A prospective multicenter cohort study of patients who had a pulmonary syndrome with EAA in the differential diagnosis adopted a "clinical prediction rule" for the diagnosis of active EAA (Table 55-2). Significant predictors in the final model included exposure to a known offending antigen, positive precipitating antibodies, recurrent episodes of symptoms, inspiratory crackles, symptoms 4 to 8 hours after exposure, and weight loss. These criteria are helpful when combined with BAL and high-resolution CT in determining the likelihood of EAA.

IMAGING

The chest radiograph is often normal in patients with EAA, with an estimated sensitivity of only 10%. In acute

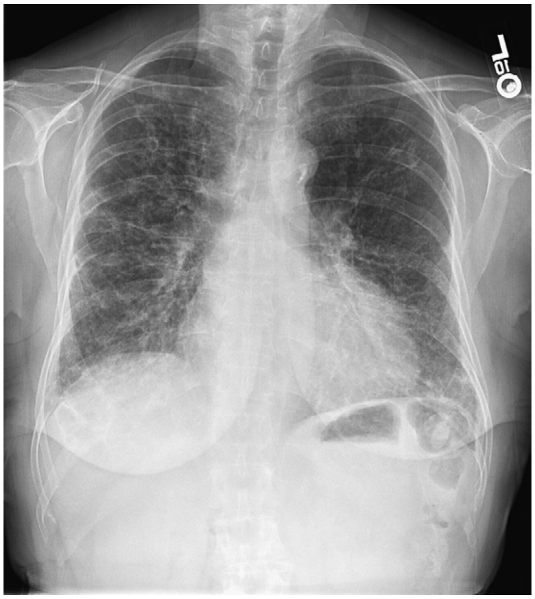


Figure 55-1 Chest radiograph of patient with hot tub lung, showing extensive reticular changes and fibrosis indicative of chronic hypersensitivity pneumonitis, or extrinsic allergic alveolitis (EAA).

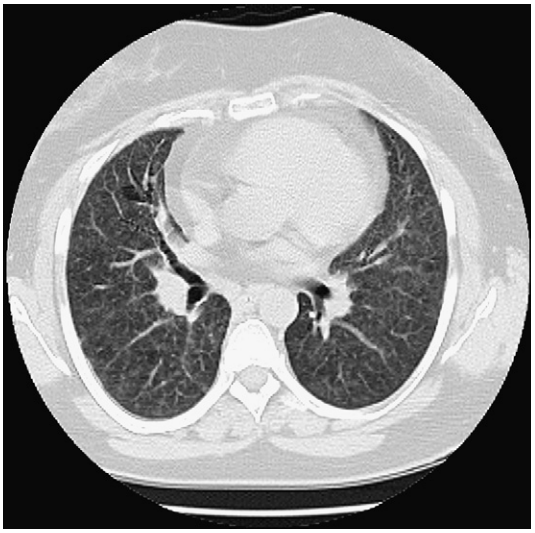

Figure 55-2 Classic high-resolution computed tomography (HRCT) appearance of extrinsic allergic alveolitis, revealing centrilobular nodularity and ground-glass opacities.

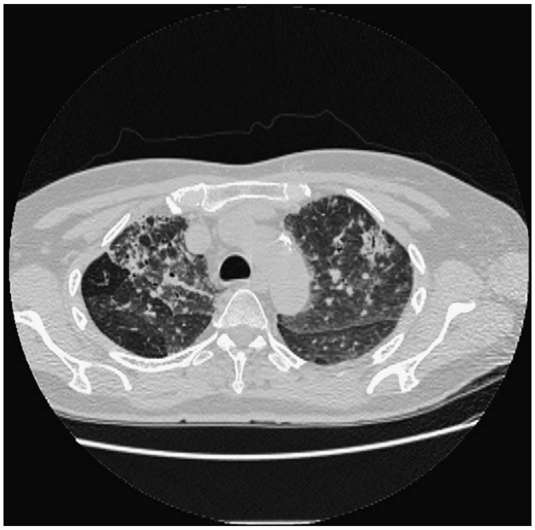

Figure 55-3 High-resolution CT scan of patient with chronic fibrotic extrinsic allergic alveolitis, showing upper-zone fibrosis with mosaic attenuation.

EAA, radiographs may show diffuse ground-glass or air space consolidation. Patients with subacute EAA may have a combination of nodular or reticulonodular opacities with ground-glass attenuation. Chronic fibrotic EAA usually has the appearance of reticular opacities with honeycombing on chest radiographs (Figure 55-1).

High-resolution computed tomography (HRCT) of the chest is the most sensitive imaging study for the detection of subtle changes associated with EAA (Figures 55-2 and 55-3). Multiple HRCT abnormalities are seen in patients with EAA that are loosely correlated with histologic and pulmonary function abnormalities (Table 55-3). Up to 50% of patients will have mediastinal lymphadenopathy; the nodes are usually smaller than 20 mm and are not detectable on the chest radiograph.

Table 55-3 Radiologic Abnormalities in EAA with Physiologic/Histologic Association

HRCT Abnormality	Physiologic Correlate	Histologic Correlate
Centrilobular nodules	None	Cellular bronchiolitis, alveolitis
Ground-glass opacities	Restriction, decreased diffusion capacity	Alveolitis, fine fibrosis, granulomas in alveolar septa
Mosaic attenuation	Obstruction	Bronchiolitis
Emphysema	Obstruction, decreased diffusion capacity	Emphysema, bronchiolar inflammation
Reticulation, honeycomb	Restriction, decreased diffusion capacity	Fibrotic change Traction bronchiectasis

EAA, extrinsic allergic alveolitis; *HRCT*, high-resolution computed tomography.

Centrilobular nodules are the most frequent HRCT finding in EAA. The nodules are poorly defined, round, and less than 5 mm in diameter. Nodules predominate in the middle and lower lung zones, although this is not the rule, and are generally of ground-glass attenuation. Histologically, nodules correlate with polypoid intraluminal granulation tissue within the bronchioles (obliterative bronchiolitis [OB], or bronchiolitis obliterans) and reflect an active alveolitis. Centrilobular nodules do not correlate well with pulmonary function abnormalities.

Hazy opacity without obscuration of the underlying bronchovascular margins is most common in acute EAA but may also be seen in the subacute and chronic forms, especially with ongoing antigen exposure. *Ground-glass opacities* typically accompany other CT abnormalities such as centrilobular nodules and air trapping. Histologically, ground-glass opacities correlate with the presence of small granulomas within the alveolar septa, alveolitis, or fine fibrosis. Pulmonary function tests (PFTs) often reveals restrictive physiology with decreased diffusing capacity.

Mosaicism represents a patchwork of regions of differing attenuation caused by ground-glass opacities or air trapping, and often a combination of both in EAA. *Air trapping* reflects a failure of an area to increase in attenuation on expiratory imaging and suggests histologic bronchiolitis. It may also represent the presence of pulmonary hypertension in advanced cases. Obstructive physiology is often present on PFTs when mosaicism is apparent on imaging.

Multiple studies have shown that *emphysema* is more common than fibrosis in chronic farmer's lung, even after adjusting for smoking status. The pattern of emphysema is similar to that caused by tobacco smoke and may be secondary to bronchiolar inflammation and obstruction.

In chronic EAA, the HRCT scan may show patterns typical for nonspecific interstitial pneumonitis (NSIP) or usual interstitial pneumonitis (UIP). Fibrotic EAA is associated with a reticular pattern, honeycombing, and traction bronchiectasis. Honeycomb change is seen in up to 50% of patients with chronic bird fancier's lung and is less common in other forms of EAA. Fibrosis may predominate in the midlung, although a more diffuse distribution has been observed. Imaging features that favor a diagnosis of EAA over idiopathic pulmonary fibrosis (IPF) are upper-zone or midzone predominance, presence of ground-glass opacities, and less honeycomb change. Not surprisingly, the presence of fibrosis on HRCT is correlated with a poor prognosis.

Air space consolidation is rarely seen in EAA patients. Thin-walled cysts, resembling those in lymphocytic interstitial pneumonia, are found in up to 13% of patients with subacute EAA and have an uncertain pathogenesis.

OTHER DIAGNOSTIC TESTING

Laboratory Studies

There are no specific laboratory tests for EAA. Occasionally, nonspecific serum markers of inflammation are elevated, including C-reactive protein, erythrocyte sedimentation rate, rheumatoid factor, and lactate dehydrogenase (LDH). LDH levels are higher in patients with cryptogenic fibrosing alveolitis and EAA than in those with sarcoidosis and correlated with treatment response, as reflected in improving pulmonary physiology. Elevated angiotensin-converting enzyme (ACE) levels have also been correlated with acute symptoms. A neutrophilic leukocytosis with relative lymphopenia may be present in those with acute EAA, whereas leukocyte counts are usually normal in chronic disease. Elevated serum immunoglobulins (IgG and IgM) have also been described.

Serum Precipitins

Serum precipitins are neither specific nor sensitive for EAA. In fact, 10% of asymptomatic farmers and 40% of asymptomatic pigeon breeders have positive precipitating antibodies to causative antigens, but no clinical evidence of disease. In the HP study group's evaluation of diagnostic criteria, 78% of patients with EAA had positive precipitating antibodies. In a patient with a clinical presentation, imaging, physiology, and histology consistent with EAA, the presence of precipitating antibodies can help confirm the diagnosis. Most centers have the ability to test for antigens implicated in pigeon breeder's disease, bird fancier's lung, farmer's lung, and humidifier lung, which include pigeon and parakeet sera, dove feather antigen, *Aspergillus* spp., *Penicillium*, *Saccharopolyspora rectivirgula*, and *Trichiotinus viridans*. Precipitin tests exist for a wider range of antigens but depend on institutional availability and experience.

Pulmonary Physiology

Classically, patients with EAA have a restrictive pattern with decreased forced vital capacity (FVC), total lung capacity (TLC), and diffusion capacity (DL_{CO}). However, patients with farmer's lung more often exhibit obstructive physiology than those with EAA caused by other antigens. About 40% of patients with farmer's lung exhibited obstructive physiology in 6-year follow-up. Patients with subacute and chronic EAA may have a mixed pattern of obstruction and restriction. Methacholine challenge testing is often positive. Gas exchange abnormalities, if present, are characterized by hypoxemia that worsens with exercise. Exercise-induced hypoxemia is usually present early in disease.

In the setting of diagnostic uncertainty, an inhalational challenge using aerosolized material of the suspected causative antigen may be helpful. However, this is not recommended for most patients with suspected EAA. There are no purified, standardized, commercially available antigens to be used for this application, and most centers do not have experience with this technique. Patients may have an immediate reaction, but more frequently a delayed reaction occurs after several hours. In a study of patients with pigeon breeder's disease, which also included normal subjects and those with ILD, all patients with EAA versus approximately 18% of those with ILD and 0% of healthy controls had an increase in body temperature and significant decreases in FVC, arterial oxygen tension (PaO_2), and oxygen saturation (SaO_2) after inhalational challenge with pigeon serum.

Bronchoalveolar Lavage

A *lymphocytic alveolitis* characterizes the BAL fluid of patients with EAA. In fact, a BAL lymphocyte count of less than 30% makes the diagnosis of EAA unlikely, except in smokers and more chronic forms of EAA in which lymphocytosis is less prominent. However, a BAL lymphocytosis is not specific because it may be present in many other conditions, including sarcoidosis, chronic beryllium disease, and several autoimmune lung diseases. Analysis of lymphocyte subsets is variable depending on smoking status, disease stage, and antigen exposure. A predominance of $CD8^+$ T cells is a common feature in nonsmokers with acute or subacute EAA, whereas $CD4^+$ predominance is more common in smokers and in those with chronic or fibrotic EAA. Regardless of the subset (CD4, CD8), T lymphocytes are usually activated in patients with EAA, with a polarized type I cytokine profile, as reflected by a predominance of interferon-γ (IFN-γ)–producing T cells.

Histopathology

Findings on transbronchial biopsy are nonspecific and nondiagnostic in 50% of patients with EAA. Proceeding to surgical lung biopsy may be necessary when faced with diagnostic uncertainty, because features of EAA overlap with many other inflammatory lung diseases. The histologic findings vary depending on the stage of disease, although lung biopsies are rarely required in patients with acute EAA. Findings in acute EAA include neutrophilic and eosinophilic alveolar infiltration, small-vessel vasculitis, diffuse alveolar damage, and vascular immunoglobulin and complement deposition. A classic triad of histopathologic features is found in subacute EAA: lymphocytic alveolitis; small, loose non-necrotizing epithelioid cell granulomas; and cellular bronchiolitis (**Figures 55-4 and 55-5**). Foamy macrophages are present in air spaces, while lymphocytes are more prominent in the interstitium. Additionally, foci of obliterative bronchiolitis, intraalveolar fibrosis, and cellular NSIP may be found in subacute EAA.

In chronic EAA, variable stages of interstitial fibrosis may be found. Several patterns may be present, including NSIP,

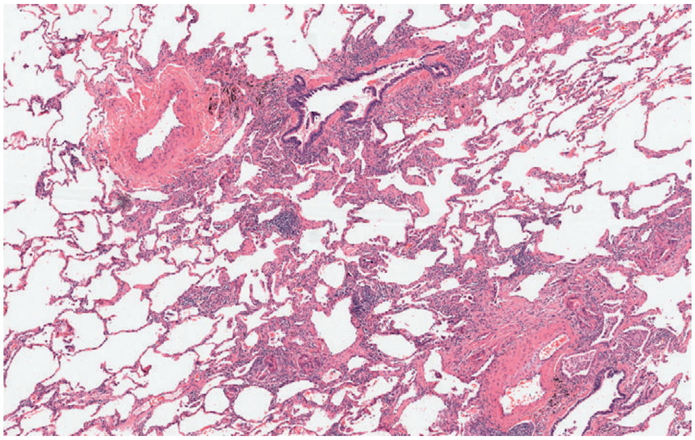

Figure 55-4 Histologic appearance of bronchiolocentric chronic lymphocytic inflammation within the interstitium, along with scattered, poorly formed non-necrotizing granulomas and multinucleated giant cells (hematoxylin-eosin stain [H&E]; magnification 4×).

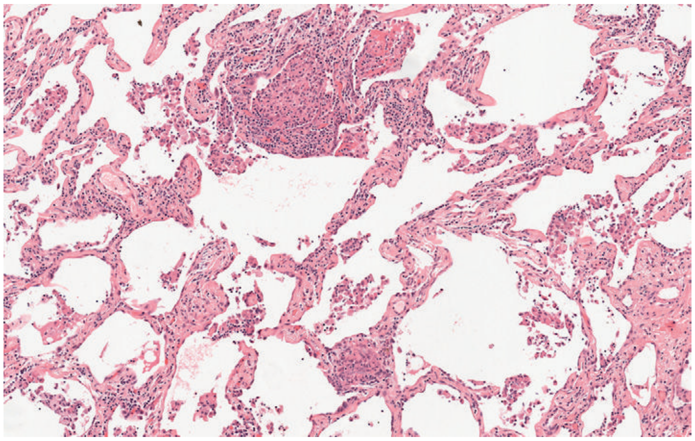

Figure 55-5 Histopathologic features of interstitial expansion by lymphocytes and histiocytes, with poorly formed non-necrotizing granulomas; air spaces contain rare fibrinous exudates and scattered macrophages (hematoxylin-eosin stain [H&E]; 10×).

centrilobular and peribronchiolar fibrosis, bridging fibrosis (between centrilobular and perilobular areas), and a UIP-like pattern. The presence of mild to moderate lymphocytic infiltration, giant cells, poorly formed granulomas, and bridging fibrosis is more specific for EAA and can help differentiate EAA from other fibrotic lung diseases.

Immunopathogenesis

Typically, EAA has been regarded as a T helper cell type 1 (Th1) polarizing inflammatory disease characterized by the production of IFN-γ, TNF-α, interleukin-12 (IL-12), and IL-18. However, there is increasing evidence that IL-17 and TLR6 are also important to the development of EAA and progression of fibrosis in murine models. Moreover, the adoptive transfer of T regulatory cells ($CD4^+$, $CD25^+$) that downregulate immune responses attenuate the development of disease in murine models of EAA. Thus, Treg cells may be a future potential therapeutic target in EAA. Further research is needed to better understand the immunopathogenesis of EAA to target the inflammatory cascade therapeutically.

TREATMENT

Early diagnosis and elimination of antigen exposure are key elements in minimizing morbidity from EAA and treating the disease. Antigen elimination is the most effective approach. For example, maple bark stripper's lung and bagassosis are now rare because of changes in handling organic substrates that minimize growth of microorganisms. Indoor sources of moisture that may lead to microbial contamination, such as humidifiers, leaking pipes, or appliances, and indoor hot tubs should be eliminated. A detailed environmental exposure history is important to identify potential causal antigens and remove the patient from exposure. However, in bird fancier's lung associated with residential exposures, removal of birds from the home may not be sufficient; high levels of bird antigens may persist in the home and require extensive environmental cleanup. Efforts to ensure exposure abatement are often costly and difficult to assess for adequacy. It is therefore important for patients with EAA to receive regular clinical follow-up, PFTs, and imaging to monitor for progression and to direct further efforts at minimizing antigen exposure.

Oral corticosteroids are the first-line pharmacologic agents used at all stages of disease. Corticosteroids can shorten the duration of illness in acute EAA but do not improve long-term prognosis. Generally, patients should be started on high doses of prednisone, followed by gradual tapering once there is clinical improvement. Initiating prednisone at 0.5 mg/kg/day for 1 month, followed by a gradual taper until reaching a maintenance dose of 10 to 15 mg/day, is the recommended empiric regimen. PFTs should be performed within 2 months of therapy initiation, along with a clinical assessment of symptoms and possible steroid side effects. Prednisone should be discontinued when symptoms have resolved or there is no clear clinical or functional response. Inhaled corticosteroids can be useful adjuncts to steroid therapy, along with inhaled β-agonists if airway hyperresponsiveness is prominent. However, no randomized controlled clinical trials (RCTs) support the use of inhaled therapies in EAA. Supplemental oxygen is recommended in patients with hypoxemia.

In EAA patients taking corticosteroids without improvement or with severe steroid side effects, steroid-sparing agents such as azathioprine should be considered because of reported anecdotal success. In patients with progressive fibrotic EAA, early referral for lung transplantation should be considered.

Debate continues as to whether *hot tub lung* represents an infectious or hypersensitivity reaction to nontuberculous mycobacterial (NTM) aerosols and whether treatment with antimycobacterial antibiotics is necessary. The literature suggests that most patients improve with removal from exposure and treatment with corticosteroids. Thus, most immunocompetent patients with hot tub lung do not require prolonged courses of antimycobacterial therapy.

PROGNOSIS

The natural history of EAA is variable and probably depends on the type and duration of antigen exposure and the host immune response. Acute EAA generally resolves within several weeks with corticosteroid therapy and removal from antigen exposure. However, continued symptoms and progressive lung impairment have been reported after recurrent acute attacks and even after a single acute attack. Additionally, persistent airway hyperresponsiveness and emphysema may impact long-term recovery.

Mortality estimates for patients with chronic EAA range from 1% to 10%. Patients with more severe lung fibrosis on biopsy specimens, honeycomb change on imaging, and digital clubbing have a worse prognosis. Moreover, patients with fibrotic EAA can present with acute exacerbations not triggered by recurrent antigen exposure. Unfortunately, they seem to have a similar poor prognosis as those with acute exacerbations of IPF. A recent study has shown that all-cause mortality in patients with EAA is three times higher than in the general population. The reason for this difference is unclear and needs further investigation.

Both prevention of disease and prevention of progression are key areas for intervention. Primary prevention is important in at-risk work environments and begins with informing workers of exposure risks and offering appropriate respiratory protection. Engineering controls and other workplace interventions are essential, such as improving ventilation systems, mechanizing feeding processes on farms, using additives to prevent the growth of mold in hay and silage, preventive maintenance on heating and cooling systems, enclosing selected metalworking fluid machining operations, and regular home cleaning to eliminate microbial colonization. Once EAA has been diagnosed, similar interventions can still be undertaken with a focus on elimination of antigen exposure to prevent disease progression.

CONTROVERSIES AND PITFALLS: A FOCUS ON TREATMENT

Minimal evidence exists to guide treatment decisions for patients with EAA. When to start therapy and choice of pharmacologic agent are often challenging decisions. If, despite antigen elimination, the patient does not improve or even worsens oral corticosteroid therapy should be initiated. The recommended starting dose is 0.5 mg/kg of prednisone (usually 40-60 mg) once daily for 1 month, followed by a gradual taper. PFTs (e.g., DLCO) along with the patient's symptoms should be assessed every 2 to 3 months to determine the clinical response to treatment. Prednisone may be tapered by 5-mg increments every 1 to 2 weeks, with close patient monitoring and adjustment as needed. Corticosteroid therapy should be tapered and discontinued if there is no clear response after 3 months.

Steroid-sparing agents (e.g., azathioprine) have been used with anecdotal success in patients who have failed prednisone or cannot tolerate steroids because of side effects. Some EAA patients require a steroid-sparing immunosuppressive agent for long-term preservation of lung function.

Again, antigen elimination, sometimes with several weeks of tapering oral corticosteroids, is effective for treatment of immunocompetent patients with hot tub lung, with no need for antibiotic therapy.

Long-acting inhaled steroids and β-agonists may be helpful in some EAA patients with airway hyperreactivity. Supplemental oxygen therapy is indicated in patients with hypoxemia. Early referral for lung transplantation should be considered in those with progressive fibrotic EAA.

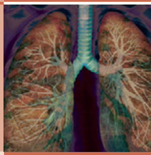
PARENCHYMAL LUNG DISEASES



Chapter 56
Toxic Inhalational Lung Injury

Lee S. Newman • Kathryn G. Bird

A variety of chemicals, when liberated into the atmosphere as gases, fumes, or mist, can cause irritant lung injury or asphyxiation. As summarized in Table 56-1, any level of the respiratory tract can be the target for toxins, which produce a wide range of disorders, from tracheitis and bronchitis to pulmonary edema.

EPIDEMIOLOGY

Smoke inhalation is common among the general population. The use of potentially toxic chemicals in industry continues to rise, and accidental spills, explosions, and fires can result in complex exposures, with little known of the health consequences. The potential health effects produced by inhaled toxins in the United States may be tremendous. More than 500,000 workers risk occupational exposure to ammonia (NH_3) and other gases such as sulfur dioxide (SO_2). More than 100,000 individuals have potential exposure to hydrogen sulfide (H_2S). Tens of thousands risk smoke inhalation from household fires. The number of people environmentally exposed to potentially hazardous levels of air pollutants such as ozone can be estimated in the tens of millions. The threat of biologic and other weaponized agents increases inhalational exposure risks. Also, the World Trade Center collapse showed that firefighters and other rescue workers who respond to emergencies form an additional class of patients at risk from exposures to complex mixtures of dust, fumes, and gas.

ETIOLOGY AND RISK FACTORS

Major risk factors for inhalational exposure and injury are related to the environment and not to the individual. Exposures occur randomly in the general environment, such as when a chemical spill occurs on a highway or railroad, carbon monoxide (CO) leaks in a home, or a person incorrectly mixes household chemicals together and releases a gas or aerosol. Smoke that comprises the pyrolysis products of synthetic materials is a common cause of injury to the respiratory tract, as well as a cause of pulmonary insufficiency and death from fires.

Occupational injuries more often occur when workers handle chemicals, work in areas that are inadequately ventilated, or enter exposed areas with improper protective equipment. Table 56-2 lists sources of occupational exposure to major chemical causes of irritant lung injury and asphyxiation.

Factors that influence the acute effects of toxic chemicals include solubility, particle size, concentration, duration of exposure, chemical properties, and individual factors such as minute ventilation. The more water-soluble compounds dissolve in the upper respiratory tract and airways, whereas the less water-soluble agents tend to bypass the upper airway and affect peripheral airways and pulmonary parenchyma (Figure 56-1).

Pathology

In general, the upper airway can be affected by most inhaled toxins, which result in edema of the nasal passage, posterior oropharynx, and larynx. In severe cases, mucous membrane ulceration and hemorrhage ensue. Toxins of low water solubility may reach the lung parenchyma without necessarily producing upper airway lesions. If breath holding, laryngospasm, and normal "scrubbing" activities of the nasopharynx fail to contain the exposure, lesions develop in the trachea and bronchi (e.g., paralysis of cilia, increased mucus production, goblet cell hyperplasia, injury to airway epithelium, epithelial denudation, exudation, submucosal hemorrhage, edema). Pseudomembranes may form along the trachea and bronchi, causing various degrees of bronchiolitis, bronchiolitis obliterans (Figure 56-2), and organizing pneumonia (Figure 56-3). Bronchiolitis has been associated with exposures to oxides of nitrogen—nitric oxide (NO), nitrogen dioxide (NO_2), and nitrogen peroxide (N_2O_4)—as well as sulfur dioxide, ammonia, chlorine (Cl_2), phosgene, fly ash that contains trichloroethylene (C_2HCl_3), ozone (O_3), hydrogen sulfide, hydrogen fluoride (HF), metal oxide fumes, dusts (e.g., asbestos, silica, talc, grain dust), freebase cocaine, tobacco smoke, and fire smoke.

Parenchymal injury is less common than airway damage. When alveolar or interstitial injury occurs, both epithelial damage and endothelial damage are observed, resulting in alveolocapillary leak and the pathologic changes of adult respiratory distress syndrome (ARDS). *Diffuse alveolar damage* (DAD) is a common histologic pattern in acute interstitial lung disease caused by inhaled toxins. It is characterized by widespread, diffuse edema, epithelial necrosis and cell sloughing (with exudates that fill the alveolar spaces), and formation of hyaline membranes (Figure 56-4). Later, DAD may organize, which leads to proliferation of type II pneumonocytes, resorption of the hyaline membranes and exudates, and fibroblast proliferation. Long-term survivors of such parenchymal injury may fully recover or may have various degrees of permanent interstitial fibrosis.

Pathogenesis

Asphyxiants, such as methane (CH_4) and carbon dioxide (CO_2), displace oxygen (O_2) from the air or, in the case of CO, interfere with normal oxidative metabolism and O_2 transport. Typically, the more soluble gases produce greater injury in the upper airway, whereas less soluble gases injure distal airways and parenchyma. Some of the irritant gases produce direct

Table 56-1 Inhalational Toxins and Range of Toxicity

Toxins	Effects
Ammonia	Mucous membrane irritation and sloughing Bronchiectasis, pulmonary interstitial fibrosis
Ammonia, phosgene, hydrogen sulfide	Laryngeal edema and obstruction
Carbon monoxide, cyanide, hydrogen sulfide	Asphyxiation
Chlorine, phosgene	Acute respiratory distress syndrome
Hydrofluoric acid	Systemic effects, hypocalcemia, hypomagnesemia
Hydrogen chloride, chlorine	Tracheobronchitis
Hydrogen fluoride, mustard gas	Chemical pneumonitis
Hydrogen sulfide	Bacterial pneumonia
Nitric oxide	Systemic effects, methemoglobinemia
Oxides of nitrogen, sulfur oxides	Obliterative bronchiolitis (bronchiolitis obliterans)
Sulfur dioxide, hydrogen chloride, oxides of nitrogen, ozone	Bronchoconstriction, airway edema, asthma

cellular injury because they are alkalis (e.g., ammonia) or acids (e.g., phosgene). Others, such as ozone and oxides of nitrogen, form oxygen free radicals that cause respiratory tract injury. These gases may also produce smooth muscle bronchoconstriction and stimulate afferent parasympathetic receptors, which explain some of their ability to induce airway hyperreactivity and bronchoconstriction.

Chronic lower-level exposures to various toxic gases (e.g., SO_2, Cl_2) can induce copious mucus secretion, cough, bronchoconstriction, and bronchitis as a physiologic response to the inhalational exposure. Chronic bronchitis is common among workers exposed to relatively low levels of irritants and may increase their risk for development of chronic airflow obstruction and accelerated longitudinal decline in forced expiratory volume in 1 second (FEV_1). In some cases, nonspecific airway hyperreactivity is induced by persistent, nonspecific irritant exposures.

CLINICAL FEATURES AND DIAGNOSIS

Diagnosis should focus on the nature of the compound inhaled, the magnitude and duration of exposure, and the water solubility of the inhaled agent. Inhalational injury is suspected in those who have facial burns or inflamed nares. Headache and dizziness, along with chest pains and emesis, suggest systemic poisons (e.g., cyanide, H_2S). Unconscious victims found in confined spaces are assumed to have received longer inhalational exposures than conscious ones because of the unprotected airways and concentrated exposures. Evidence of hoarseness, upper airway stridor, wheezing or rales, cough, and sputum production is assessed. Chest radiographs may show pulmonary edema, atelectasis, or infiltrates (Figure 56-5), although they are often negative early after exposure. Flow-volume loops are the most sensitive noninvasive indicators of upper and lower airway obstruction. Hypoxemia in the face of a normal arterial partial pressure of oxygen (PaO_2) suggests CO toxicity. Carboxyhemoglobin levels are obtained for all fire and explosion victims. Metabolic acidosis may indicate cyanide or H_2S intoxication.

In patients who have persistent symptoms months after exposure, bronchial provocation tests with methacholine may help assess whether the patient has *reactive airway dysfunction syndrome*. Computed tomography (CT) may help determine if permanent fibrotic changes have developed.

Table 56-2 Inhalational Toxins and Source of Exposure

Toxin	Sources of Exposure
Ammonia	Agriculture, explosives, plastics
Carbon monoxide	Firefighters, smoke inhalation, smelters, miners, transportation, home furnaces
Chlorine	Household cleaners, paper, textiles, sewage treatment, swimming pools
Hydrofluoric acid	Fertilizers, insecticides, glass and ceramic etching, masonry, metalworking, pharmaceuticals, chemical manufacture
Hydrogen chloride	Fertilizers, textiles, dyes, rubber manufacture
Hydrogen cyanide	Metallurgy, electroplating, plastics, polyurethane manufacture
Hydrogen sulfide	Metallurgy, chemical manufacture, wastewater treatment, natural gas and oil drilling, paper mills, coke ovens, rayon manufacture, rubber vulcanization
Mustard gas	Chemical warfare
Oxides of nitrogen	Air pollution, welding, hockey rinks, chemical and dye manufacture, agriculture
Ozone	Welding, air pollution, high altitude, chemical manufacture
Phosgene	Firefighters; paint strippers; chemical, pharmaceutical, and dye manufacturing; chemical warfare
Sulfur dioxide	Air pollution, smelting, power plants, chemical manufacture, paper manufacture, food preparation

CHEMICAL IRRITANTS

Ammonia

Ammonia is a colorless, water-soluble, alkaline gas with a pungent odor. Because it is usually transported as a liquid, many accidents occur when it is being transferred from tanks to farm equipment. When it comes in contact with the mucosa, NH_3 reacts with H_2O to form a strong alkali, *ammonium hydroxide* (NH_4OH). Within hours of acute irritation, there may be sloughing of the upper airway mucosa, edema, and obstruction. Laryngeal edema can present without other obvious clinical signs of burns, but if skin burns are present, inhalational injury is likely. Unusual complications include pneumonia and ARDS, which occur within hours to a few days of exposure. Long-term consequences include persistent bronchitis, bronchiectasis, airflow obstruction, interstitial fibrosis, and impaired gas exchange.

Treatment of NH_3 poisoning is supportive: bronchodilators, O_2 therapy, and observation for need for airway protection.

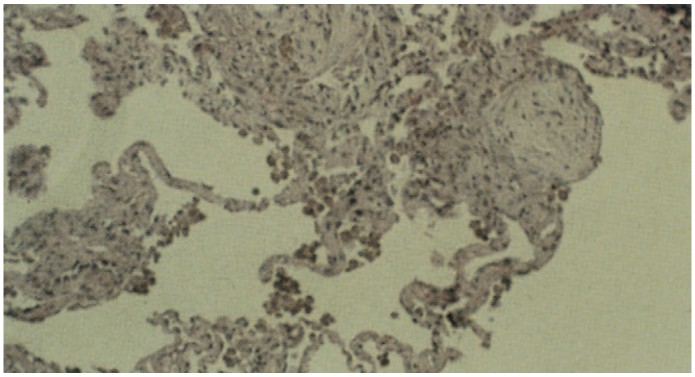

Figure 56-3 Histopathologic features of organizing pneumonia after sulfur dioxide inhalation.

Early intubation may be required to protect the airway from acute laryngeal obstruction.

Hydrogen Chloride

Hydrogen chloride (HCl) is highly water-soluble, and injures the mucosa of the upper airways because of its acidity. Typically encountered in the manufacture of fertilizers, textiles, rubber, and dyes, acute HCl exposure causes mucous membrane irritation of the eyes and airways at levels as low as 5 to 10 parts per million (ppm). Higher levels of exposure can cause acute airflow obstruction and gas exchange abnormalities. Meat wrappers become exposed to HCl when they heat polyvinyl chloride film.

Hydrofluoric Acid

Hydrofluoric acid is a highly corrosive chemical primarily causing dermal injury to the hands. Hydrofluoric acid releases

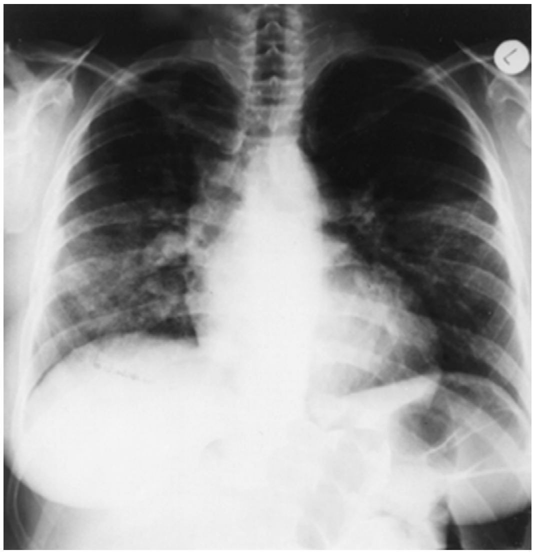

Figure 56-5 Radiographic changes produced by diffuse alveolar damage. Chest radiograph of the same patient as in Figure 56-4 shows acute, diffuse alveolar and interstitial infiltrates.

free hydrogen ions (H^+) that penetrate and corrode the skin, potentially down to bone, producing bone demineralization and necrosis. The respiratory effects parallel those of the skin, except effects in the lungs have a rapid onset and patients present with acute respiratory distress. Hydrofluoric acid is water-soluble and thus predominantly exerts its effects on the upper airways, resulting in rapid onset of tissue damage and bronchoconstriction, in some cases even leading to chemical pneumonitis, delayed-onset pulmonary edema, and death.

Sulfur Dioxide

Sulfur dioxide and sulfuric acid (H_2SO_4) aerosols are produced by fossil fuel combustion. These toxic gases are encountered in power plants and in various industrial processes, such as smelting, chemical manufacture, paper manufacture, food preservation, metal and ore refining, and refrigeration. Past SO_2 air pollution catastrophes have increased mortality rates for patients with chronic lung disease and elderly patients.

As little as 0.5 ppm of SO_2 can be detected in air from its characteristic odor. Levels of 6 to 10 ppm may immediately irritate eyes and the nasopharynx. High exposures ($\geq$50 ppm) injure the larynx, trachea, bronchi, and alveoli. A wide range of individual variability in the response to SO_2 is found, but atopic and asthmatic patients show the most susceptibility. Prior exposure to ozone may potentiate the effect of SO_2 in asthmatic subjects. Classically, patients first experience a burning of the eyes, nose, and throat, with associated cough, chest pain, chest tightness, and dyspnea, along with conjunctivitis, corneal burns, and pharyngeal edema, followed hours later by pulmonary edema. Obliterative bronchiolitis (OB; bronchiolitis obliterans) can develop 2 to 3 weeks after exposure. Persistent airflow obstruction has been observed in smelter workers up to 4 years after SO_2 overexposure, probably because of bronchiolitis obliterans.

Symptomatic treatment for acute SO_2 toxicity may include systemic corticosteroids. Bronchospasm in asthmatic patients may reverse spontaneously after removal from SO_2 exposure, or may require administration of bronchodilators and inhaled corticosteroids.

Chlorine

Chlorine is of intermediate solubility and liberates hydrogen chloride and oxygen free radicals when it contacts water. The result is dose-dependent epithelial cell injury. Low levels of Cl_2 exposure cause irritation of the upper airways and eyes. Increasing levels of exposure injure the nasopharynx and larynx. Higher exposures result in pulmonary edema within 6 to 24 hours. Pulmonary function tests typically show airflow obstruction and air trapping. Long-term consequences include persistent airflow obstruction in some survivors. Clinical management of Cl_2 toxicity is supportive. Even symptomatic patients who have negative physical examinations and laboratory tests must be observed for at least 6 hours because of the potential for a delay in the onset of significant airway toxicity. If symptoms persist, corticosteroids may improve outcome.

Oxides of Nitrogen

The oxides of nitrogen (NO, NO_2, N_2O_4) can produce fatal respiratory injury for some of the millions of workers who come into contact with these gases. Occupations at risk include coal miners after firing of explosives, welders who work with acetylene torches in confined spaces, hockey rink workers, and chemical workers exposed to by-product fumes in the manufacture of dyes, lacquers, and nitric acid (HNO_3). *Silo filler's lung* (silo filler's disease) occurs with inhalation of NO_2 formed from fermented corn or alfalfa in silos. The greatest risk occurs in the first few weeks after filling the silo. Because the oxides of nitrogen have low water solubility, the lower respiratory tract can be exposed to these potent oxidizers. NO_2 reacts with H_2O in the lung to form nitric and nitrous (HNO_2) acids. The oxides dissociate into O_2 free radicals, nitrates, and nitrites, which cause tissue inflammation, lipid peroxidation, and impairment of surfactant activity (among other cellular changes). Notably, nitric oxide has a high affinity for hemoglobin and thus causes methemoglobinemia.

With oxides of nitrogen, exposures of 15 to 25 ppm result in acute mucous membrane irritation of the eyes and throat. At exposure levels of 25 to 100 ppm, toxic pneumonitis and bronchiolitis can develop, often with a smothering sensation and dyspnea. Exposures above 150 ppm are often fatal, associated with OB, chemical pneumonitis, and pulmonary edema. Symptom onset may be delayed, and patients are cautioned that relapses can occur 3 to 6 weeks after initial exposure, with symptoms of cough, chills, fever, and shortness of breath. In some, persistent obstructive lung disease and chronic bronchitis develop. Case reports suggest improvement after corticosteroids in patients exposed to oxides of nitrogen who manifest bronchiolar inflammation.

Phosgene

Also called *carbonyl chloride,* phosgene replaced chlorine as the preferred chemical weapon of World War I and resulted in the majority of "gas attack" fatalities. Phosgene is an intermediate product in the manufacture of isocyanates, pesticides, dyes, and pharmaceuticals. It has a low odor threshold at 1 ppm and produces a characteristic smell of musty hay. As a result of its poor water solubility, phosgene causes only mild upper airway and eye irritant symptoms, and deposits distally in the lung where it hydrolyzes to form hydrochloric acid (aqueous HCl) and CO_2. At high levels of exposure, dyspnea, chest tightness, and cough occur. Acute exposure produces necrosis and sloughing of tracheal, bronchial, and bronchiolar mucosa with associated edema, hemorrhage, and atelectasis. Progressive respiratory failure and ARDS may follow.

Mustard Gas

Sulfur mustard gas (dichlorodiethyl sulfide) was first used as a chemical warfare agent in Europe in 1917. Actually, mustard agents are not gases, but liquids at environmental temperatures. These agents are volatile, enter vapor phase at ambient temperatures, and have low water solubility. Exposure to dichlorodiethyl sulfide produces eye irritation and swelling within 2 to 3 hours. With higher exposure, blurred vision, conjunctival edema, and iritis can occur, with potential for corneal ulceration. The skin becomes pruritic and erythematous, and, 4 to 16 hours later, forms blisters. Acute respiratory damage may be evident within a few hours or, more commonly, several days later. Chemical pneumonitis and pulmonary edema can also occur, with upper airway irritation, sneezing, hoarseness, epistaxis, cough, and dyspnea. Acute injury includes edema, inflammation, and destruction of the airway epithelium, with pseudomembranes developing, similar to those seen with diphtheria. Secondary complications include infection and airway stenosis. The long-term effects of mustard gas include death caused by respiratory infections, chronic bronchitis, and accelerated longitudinal decline in airflow. Additional weaponized agents are discussed later.

Ozone

Ozone is a light blue gas with an acrid "electric" odor. O_3 occurs naturally in the stratosphere, produced by the interaction between O_2 and ultraviolet (UV) light. In the troposphere, O_3 is produced from photochemical reactions between oxides of nitrogen and volatile organic compounds. As a major component of environmental air pollution, O_3 remains a serious pollutant for urban populations worldwide. Its low water solubility causes ozone to principally affect the lower respiratory tract. Healthy individuals exposed to low O_3 concentrations experience acute increases in airway resistance, and decreases in FEV_1 and forced vital capacity, probably through a neural reflex mechanism. With acute exposures to low concentrations, patients can experience chest pain, dyspnea, and cough. Exposure to concentrations as low as 0.08 ppm for 6 hours, with intermittent exercise, may cause lung function and inflammatory changes. Exposure to 0.12 ppm for 1 hour is the U.S. Environmental Protection Agency (EPA) Air Quality Standard.

CHEMICAL ASPHYXIANTS

Nitrous oxide, carbon monoxide, hydrogen cyanide (HCN), and hydrogen sulfide interfere with oxygen delivery, which results in asphyxiation. Others, such as methane, ethane (C_2H_6), argon (Ar), and helium (He_2), are more innocuous at low concentrations, but at high exposure levels can displace oxygen or block the reaction of cytochrome oxidase or hemoglobin, impairing cellular respiratory and O_2 transport. Several important asphyxiants are discussed in the following sections.

Carbon Monoxide

Carbon monoxide is colorless, tasteless, and odorless, and is the major cause of death by poisoning in the United States and most industrialized countries. Exposure results from incomplete combustion of carbon-containing materials such as gasoline, coal, and wood. Home CO exposures occur from furnace gas leaks or fire smoke inhalation. Methylene chloride (CH_2Cl_2), used in paint strippers and household solvents, metabolizes into CO and can be deadly if handled in poorly ventilated areas.

Severe forms of CO poisoning are characterized by unconsciousness, seizures, syncope, coma, neurologic deficits, pulmonary edema, myocardial ischemia, and metabolic acidosis. Lower exposures produce symptoms of headache, nausea, weakness, giddiness, and tinnitus. Confusion typically occurs at carboxyhemoglobin levels greater than 30%, with coma ensuing at 35% to 45%, and death at 50%. Affected individuals are at risk for delayed neuropsychological effects. Carboxyhemoglobin levels correlate poorly with the clinical severity of neurologic sequelae. CO half-life in individuals at rest is approximately 4 hours and can be reduced to 60 to 90 minutes by breathing 100% O_2 by face mask or to less than 60 minutes with O_2 administered by manual bag-assisted ventilation.

Nonrandomized studies show that hyperbaric oxygen reverses the acute effects of CO poisoning and is the most rapid means of reversing acute toxicity. Additional treatments may improve acute neurologic defects. Results of controlled trials are unclear as to the efficacy of hyperbaric oxygen as a treatment for the delayed neuropsychological symptoms. Cardiac monitoring is warranted for patients who have carboxyhemoglobin levels greater than 25% because of the risk of arrhythmias and myocardial infarction.

Hydrogen Cyanide

Individuals exposed to smoke generated by the combustion or pyrolysis of plastics and polyurethanes are at risk of hydrogen cyanide toxicity. The fumes are absorbed through the skin and respiratory tract. By binding to the cytochrome A–cytochrome A_3 subcomplex, hydrogen cyanide blocks oxidative phosphorylation and mitochondrial oxygen utilization, which results in lactic acidosis.

Symptoms produced by exposures to 50 ppm of cyanide gas include headache, tachycardia, tachypnea, and dizziness. Exposures greater than 100 ppm can cause confusion, apnea, and seizures. The patient may emit a bitter almond odor, but this is not a reliable or consistent marker of exposure. Diagnosis rests with the occupational and environmental history. Venous blood appears hyperoxygenated, and the patient may have a distinctive red appearance before respiratory insufficiency, although this also is not a reliable clinical sign. Carboxyhemoglobin levels are measured to differentiate cyanide intoxication from CO poisoning. Treatment focuses on life support measures and detoxification. Early mechanical ventilation, hyperoxygenation, and treatment of metabolic acidosis are critical. Both amyl nitrate and sodium nitrite are recommended.

Hydrogen Sulfide

Hydrogen sulfide is both a respiratory irritant and asphyxiant. As a colorless, naturally occurring gas, H_2S is found in marshes and sulfur springs and as a decay product of organic matter. It is known for its typical "rotten egg" odor. Occupational exposure occurs in the manufacture of chemicals and metals, in petroleum refineries, natural gas plants, coke ovens, paper mills, rubber vulcanization, rayon manufacture, and in tanneries. Heavier than air, H_2S accumulates in low-lying areas; it causes poisoning during oil drilling, wastewater treatment, and natural-gas field leaks. The H_2S reaction with metalloenzymes, such as cytochrome oxidase, accounts for much of its toxicity in humans.

The odor threshold for H_2S is low (0.13 ppm). At concentrations of 50 ppm, H_2S is a mucous membrane irritant. Above 100 ppm, the gas fatigues the sense of olfaction, which makes individuals insensitive to its continued presence. When inhaled, H_2S preferentially affects the lower respiratory tract. At concentrations of 250 ppm, pulmonary edema can occur. At

500 ppm, systemic and neurologic effects develop, with sudden loss of consciousness seen above 700 ppm. Above 1000 ppm, H_2S produces hyperpnea and apnea, which paralyze respiratory drive centers, resulting in death by asphyxia. Prolonged low-level (50 ppm) exposures can cause respiratory tract inflammation and drying; typical symptoms of cough, sore throat, hoarseness, rhinitis, and chest tightness occur between 50 and 250 ppm. At higher acute exposure levels, such symptoms may not manifest because of the rapid absorption of the gas through the lung into the bloodstream.

Management of the patient with H_2S poisoning is generally supportive, with prompt endotracheal intubation and mechanical ventilation for severe cases of intoxication. Oxygen enhances sulfide metabolism and benefits hypoxic tissue. Because the mechanism of H_2S toxicity is similar to that of cyanide, induction of methemoglobinemia with infusion of 3% sodium nitrite or inhalation of amyl nitrate is recommended. Hyperbaric oxygen therapy may be beneficial.

METALS

Arsenic

Arsenic is added to metals as a hardener and is also found in pigments, wood preservatives, herbicides, desiccants, and sheep and cattle dips. This metal has many valences, with As(III), As(V), and arsine gas being the most hazardous. Exposure primarily occurs with smelting and pesticide manufacture and application. Acute inhalational exposure causes abdominal pain, diarrhea, vomiting, peripheral neuropathy, seizures, circulatory collapse, and death. Chronic exposure can cause alopecia, paresthesias, and keratoses on the palms and soles of the feet. More serious symptoms include cardiac failure, renal disease, angiosarcoma of the liver, and lung cancer. Chelation with dimercaprol improves excretion of arsenic.

Beryllium

The light metal beryllium is used as an alloy for its high tensile strength and is found in industries involving nuclear weapons production, aerospace, ceramics, and electronics. Processes that generate beryllium dust and fumes may lead to acute pneumonitis that can largely be avoided through protective measures. *Chronic beryllium disease* (CBD) occurs after seemingly small and short-term exposure to the metal, as a result of a hypersensitivity immune response. Some individuals are genetically predisposed to CBD if exposed. Symptoms include dyspnea, dry cough, and fatigue, with rales (crackles) the most common finding on lung auscultation. The disease is diagnosed through the beryllium lymphocyte proliferation test (BeLPT), which can be performed on blood or bronchoalveolar lavage (BAL). This test distinguishes CBD from sarcoidosis and other similar diseases. Noncaseating granuloma formation and lung fibrosis are pathologic consequences. Immunosuppressant therapy (e.g., corticosteroids) is required as the CBD progresses.

Cadmium

Cadmium is used for electroplating, as a pigment in paint to prevent corrosion, and in batteries. It is also a by-product of smelting and refining. Inhaled cadmium accumulates in the liver and kidneys and can cause headache, myalgia, nausea, fever, cough, dyspnea, and chest tightness. Long-term exposure causes pulmonary fibrosis, emphysema, lung cancer, and prostate cancer. Severe poisoning can be treated with calcium disodium edetate ($CaNa_2EDTA$) to increase excretion.

Chromium

Chromium provides corrosion resistance for electroplating appliances, automotive parts, machinery, and tools. It may be encountered in mining, welding, and cement workers. Chromium (VI) is the most hazardous of the forms of chromium, known to cause eye and respiratory system irritation, ulceration and erosion of the nasal septum, and lung cancer. Acute exposure can be treated with oxygen and bronchodilators while nasal ulcerations should be treated with 10% $CaNa_2EDTA$ ointment.

Cobalt

Cobalt imparts hardness to alloys and is used as a pigment in glass, paint, and ceramics. Cobalt-related lung disease has been well described in diamond polishers and those working with tungsten carbide grinders. Occupational exposures can cause asthma and several forms of interstitial lung disease, including hard metal disease (cobalt lung, tungsten carbide disease), giant cell pneumonitis, and pulmonary fibrosis, as well as cardiomyopathy and possibly lung cancer. Removal from exposure can help in the management of asthma, hard metal disease, and giant cell pneumonitis.

Nickel

Nickel provides durability and prevents corrosion in alloys. Occupational exposure occurs through mining, milling, and refining. Insoluble nickel accumulates in the respiratory tract and can cause rhinitis, sinusitis, anosmia, asthma, interstitial pneumonitis, and lung cancer. Nonoccupational exposures through skin contact with nickel-containing jewelry are a common cause of nickel allergy and increase the risk for asthma in those occupationally exposed. Exposure can be monitored through excess urine nickel excretion.

INFLAMMATORY AND AUTOIMMUNE AGENTS

Inhalational Fume Fever

A variety of clinically similar conditions are caused by inhalation of metal fumes or dust. Metal fumes of copper, magnesium, and most often zinc are formed during activities such as welding and cause *metal fume fever.* Similarly, the combustion products of polytetrafluoroethylene (PTFE, Teflon) resins may be inhaled and cause *polymer fume fever. Organic dust toxic syndrome* occurs through the inhalation of *bioaerosols* (e.g., moldy silage, wood chips, sewage sludge, cotton, grain dust) that are contaminated with bacteria, endotoxins, or fungi.

These inflammatory conditions are characterized by flulike symptoms, including chills, myalgia, headache, fever, malaise, cough, and chest discomfort. On physical examination, crackles may be heard. Diagnosis is made by history and clinical evaluation. Laboratory values may show a leukocytosis with a left shift and elevated serum lactate dehydrogenase. The pathophysiology is not completely understood, but stimulation of the immune system may lead to symptoms, based on studies of cytokine production in BAL fluid and blood of affected individuals.

Treatment is symptomatic, and inhalational fume fever is self-limited, generally peaking at 18 hours and lasting 24 hours. Removal from further exposure is necessary. These conditions share some clinical overlap with *hypersensitivity pneumonitis*, a lung condition caused by bioaerosols and certain chemicals that induce specific cellular and humoral immune responses.

Table 56-3 Categories of Biochemical Poisons and Weapons: Specific Agents, Pulmonary Effects, and Treatment

Toxin	Pulmonary Effect	Treatment
Biotoxins/Poisoning Agents		
Ricin (phytotoxin)	Cough, pulmonary edema	Pulmonary toilet, oxygen, mechanical ventilation, cardiopulmonary resuscitation
Blister Agents/Vesicants		
Lewisite	Respiratory tract irritation, coryza sneezing, hoarseness, epistaxis, dyspnea and cough, pneumonitis, pulmonary edema, respiratory failure	Dimercaprol (antilewisite, British antilewisite [BAL])
Lung-Damaging Agents		
Chloropicrin	Coughing, dyspnea, chest tightness, pulmonary edema	β_2-Adrenergic agonists and corticosteroids for bronchospasm
Nerve Agents		
Sarin, Soman, Tabun, VX	Respiratory failure	Atropine, 2-PAM (pralidoxime); benzodiazepines for convulsions
Riot Control/Tearing Agents		
Chloroacetophenone	Rhinorrhea, cough, sneezing, chest tightness, dyspnea, pulmonary edema, bronchospasm	
Vomiting Agents		
Adamsite (diphenylamine chlorarsine)	Rhinorrhea, cough, sneezing	Oxygen; bronchodilators for bronchospasm

Biochemical Toxins and Weaponized Agents

A variety of agents have been developed and used to cause mass injury or disruption. Table 56-3 provides an overview of pulmonary effects and treatment of these toxicities. With all chemical exposures, individuals should be removed from exposure and given supportive care.

COMPLEX EXPOSURES

In practice, patients with inhalational injuries are frequently exposed to complex mixtures of toxic compounds rather than a single agent. Such admixtures may be poorly characterized, and may contain combustion products, pyrolysis products, metals, particulates, and gas. Recent studies illustrate the ability of such mixtures to produce a range of airway and diffuse interstitial lung lesions.

As a consequence of exposures immediately after the World Trade Center collapse in 2001, pulmonary function decline, reactive airways dysfunction syndrome (RADS), asthma, reactive upper airways dysfunction syndrome (RUDS), sinus complaints, gastroesophageal reflux disease (GERD), and cases of inflammatory pulmonary parenchymal diseases (e.g., sarcoidosis) have been documented among rescue and recovery workers and volunteers. Specifically, in rescue workers with a high level of exposure, 8% experienced new onset of cough, 95% had symptoms of dyspnea, 87% had GERD, 54% had nasal congestion, and 23% of workers were identified as having bronchial hyperreactivity 6 months later. About 16% of rescue workers met the diagnosis criteria for RADS 1 year after the collapse. In a longitudinal study of pulmonary function in rescue workers before and after exposure, the average adjusted FEV_1 decreased 372 mL during the year after September 2001, which translates to an estimated 12 years of aging-related FEV_1 decline.

Factors such as dust alkalinity may have contributed to some of these conditions, although as often the case in acute situations, detailed information about the inhalational exposures in those workers is limited. Detailed qualitative and quantitative analyses of airborne pollutants with their changing composition during initial rescue/recovery and subsequent cleanup have been published, but incomplete air quality monitoring during and early after the structural collapse make full individual assessment of this exposure problematic.

CONTROVERSIES AND PITFALLS

Many of the uncertainties in this arena of pulmonary medicine pertain to the management and treatment of inhalational injury, for which a few general comments apply. In patients with severe inhalational injury, intubation may be required for airway protection. Careful observation, preferably in an intensive care setting, is recommended for suspected cases of significant inhalational injury. Some advocate direct laryngoscopy or fiberoptic bronchoscopy to assess for laryngeal edema. However, no clear guidelines are available to direct clinicians as to when intubation, laryngoscopy, or bronchoscopy is warranted. Although many clinicians may empirically prescribe corticosteroids, such medications have not been proved efficacious for many of the conditions described. Designing randomized controlled trials to treat sporadic acute inhalational injuries is difficult.

A common clinical pitfall is to dismiss prematurely patients who may be at risk for delayed-onset respiratory disorders such as asthma, OB (bronchiolitis obliterans), chemical pneumonitis, or pulmonary edema. Given sufficient dose and solubility, most acutely inhaled substances pose a risk for immediate or delayed-onset pulmonary edema, which warrants careful observation. Even those toxin victims who are thought to be stable and ready for discharge from the emergency department must be given detailed instructions about the warning signs of delayed-onset respiratory tract injury.

Routine spirometry in groups considered at high risk for acute inhalational exposures may be warranted, based on the exposures of New York City firefighter and rescue worker clinics.

PULMONARY VASCULAR DISORDERS, VASCULITIDES, AND HEMORRHAGE

Chapter 57

Pulmonary Embolism

Michael P. Gruber • Todd M. Bull

> *The philosophies of one age have become the absurdities of the next, and the foolishness of yesterday has become the wisdom of tomorrow.*
>
> William Osler

Pulmonary embolism (PE) and *deep vein thrombosis* (DVT) are different manifestations of the same pathologic process best grouped under the designation *venous thromboembolism* (VTE). As a disease entity, VTE is responsible for significant morbidity and mortality while imparting great socioeconomic impact. Appropriately, much attention has been devoted to its diagnosis and treatment. Although the medical literature has at times presented conflicting opinions, increased numbers of better-designed trials are helping to build consensus toward the optimal approach for the management of PE. This is not to say that significant controversies do not still exist. As in all areas of medicine, as one question is answered, others arise. This chapter presents an overview of the most important literature regarding the clinical approach to PE.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

EPIDEMIOLOGY

PE is a common clinical problem. In the United States, hospital-based studies estimate the incidence of PE at 1 case per 1000 persons per year, equating to 200,000 to 300,000 hospital admissions per year. Estimates suggest that as many as 30,000 to 50,000 people die from PE annually in the United States, with an estimated 3-month disease-specific mortality rate of 10%. In nearly 20% of cases, the presenting clinical manifestation is sudden death. Data reported from Europe and other parts of the world are broadly similar.

Significant differences in mortality associated with PE for age, gender, and race have been observed. Age-adjusted PE mortality rates are as much as 50% higher among African Americans than whites. Within and between racial strata, PE mortality rates are 20% to 30% higher in men than in women. African American men have the highest reported mortality from PE, at 6.0 deaths per 100,000 persons, followed by African American women at 4.8 deaths per 100,000 persons. The mortality for PE in white males is 2.4 deaths per 100,000 persons and is the lowest in white females at 2.3 deaths per 100,000 persons. The incidence of PE also is age-dependent, with increasing incidence of death with advancing age. From 1979 to 1998, accounting for both gender and race, age-specific mortality rates doubled for each 10-year age group after 15 to 24 years.

In recent decades, the overall mortality rate from PE has decreased dramatically. From 1998 to 2009, the annual in-hospital mortality decreased by approximately 30%. The decline has been observed across gender and ethnic groups and has been attributed to improved risk factor modification, including improved prophylaxis of DVT, better detection and treatment of DVT, and/or enhanced PE diagnostic techniques, which has led to a decrease in disease misclassification.

RISK FACTORS

The etiopathogenesis of VTE, which includes PE and DVT, is a dynamic process resulting from synergistic interaction between acquired and genetic risk factors. Historically, Rudolph Virchow is credited with describing the classic triad of vascular endothelial injury, hypercoagulability, and venous stasis as the combination of host factors that predispose to VTE. VTE risk factors traditionally are categorized as either genetic (inherited thrombophilia) or acquired.

Inherited Thrombophilia

Inherited thrombophilias may result from qualitative or quantitative defects in coagulation factor inhibitors (antithrombin, protein C, protein S), increased levels or function of coagulation factors (activated protein C resistance, factor V Leiden mutation, prothrombin gene mutation, elevated factor VIII levels), hyperhomocysteinemia, defects in fibrolysis, or altered platelet function. Epidemiologic features of the common inherited thrombophilias are shown in Table 57-1.

Antithrombin Deficiency

Formerly termed *antithrombin III*, antithrombin (AT) is a single-chain vitamin K–independent glycoprotein belonging to the serine protease inhibitor superfamily. AT functions as a natural anticoagulant by binding and inactivating thrombin and the activated coagulation factors IXa, Xa, XIa, and XIIa. The AT molecule also has an active heparin-binding site, which, when heparin-bound, has marked affinity and function for binding and inactivating coagulation factors such as thrombin. The augmentation of the inhibitory activity of AT by heparin is the basis for the clinical use of heparin therapy. Mutations in AT lead to decreased ability of the molecule to inhibit the coagulation cascade, thereby leading to increased risk for thrombosis. AT deficiency is inherited as an autosomal dominant trait affecting males and females equally. Most affected persons are heterozygotic for AT deficiency, because homozygotic inheritance typically is fetal-lethal. Heterozygote AT-deficient people have AT levels that are 40% to 70% of normal. Two different types of AT deficiency caused by more

Table 57-1 **Inherited Thrombophilias**

Disorder/Defect/ Mutation	Prevalence (%)		Inheritance Pattern	Relative Risk	Clinical Feature(s)
	General Population	Patients with VTE			
AT deficiency	0.2	1-3	AD	20	VTE, heparin resistance
Protein C deficiency	0.2-0.4	3-5	AD	10	VTE
Protein S deficiency	0.03-0.1	1-5	AD	10	VTE and ATE
Factor V Leiden	5	10-50	AD	5	VTE and ATE
Prothrombin G20210A	2-5	6-18	AD	3	VTE
Hyperhomocysteinemia	5	10	Not known	3	VTE and premature ASCVD
Elevated factor VIII	11	25	Not known	5	VTE

AD, autosomal dominant; *ASCVD*, atherosclerotic cardiovascular disease; *AT*, antithrombin; *ATE*, arterial thromboembolism; *VTE*, venous thromboembolism.
Data from Franchini M, Veneri D, Salvagno GL, et al: Inherited thrombophilia, *Crit Rev Clin Lab Sci* 43:249–290, 2006.

than 250 mutations have been described: Type I AT deficiency is characterized by a quantitative reduction in normally functioning AT. Type II AT deficiency is characterized by both quantitative and qualitative defects, with three different subtypes classified on the basis of the type of receptor defect: (1) abnormality of active thrombin binding site, (2) abnormality of heparin-binding site, and (3) abnormalities of both thrombin- and heparin-binding sites. These classification categories are clinically relevant in that defects in the active thrombin-binding site confer a higher risk for VTE than defects that involve only the heparin-binding site or that are strictly quantitative.

Despite a low prevalence, AT deficiency is considered the most severe inherited thrombophilia, with increased risk of thrombosis as much as 20-fold over that in the absence of such deficiency. In patients with AT deficiency, VTE typically develops during the latter part of the second or third decade of life. The most common sites of thrombosis include the lower extremity and iliofemoral veins. However, other sites including the upper extremities, mesenteric veins, vena cava, renal veins, and retinal veins have been reported. Thrombotic events in AT-deficient persons often are precipitated by acquired thrombophilic risk factors such as surgery, trauma, pregnancy, drugs, or infection. Approximately 60% of affected persons experience recurrent thrombotic events, and clinical signs of PE are evident in up to 40% of these patients.

The diagnosis of AT deficiency should be determined by a functional assay of heparin cofactor activity, which is able to detect all cases of AT deficiency of clinical relevance. AT levels usually are not influenced by warfarin therapy but can be decreased during the acute phase of a thrombotic event, in disseminated intravascular coagulation, or with the concomitant use of heparin. Heparin therapy can lower AT levels by as much as 30%. Screening for AT deficiency is recommended within at least 2 weeks of an acute thrombotic event or at least 5 days after discontinuation of heparin therapy.

Protein C Deficiency

Protein C is a vitamin K–dependent glycoprotein synthesized in the liver. Protein C is activated by the thrombin-thrombomodulin complex. Protein C circulates as an inactive precursor and exerts its anticoagulant function after activation to the serine protease, activated protein C. Once activated, protein C proteolytically degrades activated coagulation factors Va and VIIIa. More than 160 qualitative or quantitative mutations in protein C have been described. Protein C is inherited as an autosomal dominant trait affecting both males and females equally. Homozygous persons typically have more severe and earlier-onset thrombophilia.

Two different subtypes of inherited protein C deficiency have been identified. Type I deficiency is a quantitative disorder characterized by parallel reductions in functional and antigenic levels of protein C to 50% of normal levels. Type II deficiency is a qualitative defect with reductions in functional levels of protein C but preserved antigenic function.

The prevalence of protein C deficiency is estimated at 0.2% to 0.4% in the general population and 3% to 5% in people with VTE. Three clinical syndromes are associated with protein C deficiency: (1) VTE in teenagers and adults, (2) neonatal purpura fulminans in homozygous or doubly heterozygous newborns, or (3) warfarin-induced skin necrosis. Acquired protein C deficiency occurs in a variety of clinical settings, including liver disease, infection, septic shock, disseminated intravascular coagulation, acute respiratory distress syndrome, and postoperative states, and in association with chemotherapeutic drugs.

The diagnosis of protein C deficiency should be made by means of functional testing based on activation with thrombin-thrombomodulin or snake venom. Pregnancy and oral contraceptive use can increase plasma protein C levels. Protein C levels are decreased in acute thrombotic events and during therapy with warfarin. In the absence of warfarin therapy and known medical conditions that result in acquired protein C deficiency, patients with a protein C level less than 55% of normal are very likely to have a genetic abnormality, whereas levels from 55% to 65% normal are consistent with either a deficient state or low normal values. Thus, repeat testing and/or genetic testing is recommended in most populations.

Protein S Deficiency

Protein S is a vitamin K–dependent glycoprotein synthesized by hepatocytes, megakaryocytes, and endothelial cells. Protein S functions as a cofactor of activated protein C for the degradation of activated factors Va and VIIIa. Protein S circulates in plasma in equilibrium as a free functionally active form and an inactive form bound to a carrier protein (C4BP). The bioavailability of protein S is closely linked to the concentration of C4BP. C4BP functions as an important regulator in the protein C–protein S inhibitor pathway.

Three subtypes of protein S deficiency have been defined on the basis of total protein S concentrations, free protein S concentrations, and activated protein C cofactor activity. Type I protein S deficiency is associated with approximately 50% of normal protein S levels, more marked decrease in free protein S concentrations, and decreased functional activity. Type II deficiency is characterized by normal total and free protein S levels but decreased functional activity. Type III deficiency, also known as type IIa, is characterized by normal total protein levels but decreased free protein concentrations and decreased functional activity. Conditions that result in reductions in protein C levels, as mentioned in the preceding section, can similarly influence protein S levels. The prevalence of protein S deficiency is estimated to be 0.03% to 0.1% in the general population and 1% to 5% in patients with VTE. The clinical presentation of VTE in patients with protein S deficiency is similar to that in those with protein C deficiency. Warfarin-induced skin necrosis has been reported with protein S deficiency.

Measurement of the free protein S concentration is the preferred screening test for protein S deficiency. As with protein C, acute thrombosis, pregnancy, oral contraceptive use, comorbid disease, or use of warfarin can alter assay results. Heparin does not alter plasma protein S or protein C concentrations and thus is an acceptable antithrombotic agent for use during diagnostic workup. In patients on warfarin therapy, recommendations support waiting at least 2 weeks after discontinuation to investigate for suspected protein S deficiency.

Factor V Leiden and Activated Protein C Resistance

Factor V Leiden is the most common recognized cause of inherited thrombophilia, accounting for 20% to 50% of new VTE cases. Factor V circulates in the plasma as an inactive cofactor. After activation by thrombin, factor Va serves as a cofactor in the conversion of prothrombin to thrombin. In 1993, investigators in Leiden, The Netherlands, identified a single point mutation in the factor V gene in a cohort of patients with unexplained VTE. The molecular defect is a single amino acid change (arginine^{506} to glutamine) at one of the activated protein C (APC) cleavage sites, making the factor V molecule resistant to activated protein C at this site. The result of this genetic defect, termed *factor V Leiden,* is the most common cause of inherited APC resistance, although other mutations have been identified. Factor V Leiden is a common mutation. The prevalence of factor V Leiden in the general population is estimated at 5%. People who are heterozygous for the factor C Leiden mutation have approximately a five-fold increase in VTE risk over that in the general population. People who are homozygous for the mutation are estimated to have an 80-fold increase in VTE risk over that in the general population.

The major clinical manifestation of thrombosis in people with factor V Leiden is venous. Thrombosis in the deep veins of the lower extremities is common, whereas involvement of superficial, portal, and cerebral veins is less common. As might be expected with the high frequency of this mutation in the general population, a synergistic effect with other inherited or acquired VTE risk factors has been observed. In addition to inherited APC resistance, acquired APC resistance has been reported. Users of third-generation oral contraceptives, patients with malignancy, and persons with connective tissue disease—in particular, systemic lupus erythematosus and the antiphospholipid antibody syndrome—have APC resistance.

Activated partial thromboplastin time (aPTT)–based assays serve as the screening test for APC resistance. The aPTT is performed in the presence and then absence of a standardized amount of APC, and the two clotting times are expressed as an APC ratio (aPTT in the presence to aPTT in the absence of APC). APC resistance is associated with a reduced APC ratio. Results of the standard aPTT screening test may be influenced by a variety of factors, including inflammatory states, pregnancy, oral contraceptives, antiphospholipid antibodies, and anticoagulation. Genetic testing for the factor V Leiden mutation also is available.

Prothrombin Gene Mutation

Prothrombin (factor II), the precursor of thrombin, is a vitamin K–dependent protein synthesized in the liver. In 1996, researchers identified a single nucleotide change (guanine to adenine) at nucleotide position 20210 in the prothrombin gene as a risk factor for thrombosis. The prevalence of this mutation is 6% to 18% in people with VTE and 2% to 5% in the general population. Heterozygote carriers of this mutation have 30% higher plasma prothrombin levels than normal, which corresponds to a three-fold higher risk of thrombosis over that in the general population. In view of the relatively low thrombotic risk, controversy remains as to whether this mutation confers an increased risk for recurrent VTE. Studies have shown that the estimated risk of thrombosis associated with the prothrombin G20210A mutation is significantly increased only in those persons with additional thrombotic risk factors. Moreover, studies have demonstrated that the prothrombin G20210A mutation often is co-inherited with factor V Leiden mutation. Approximately 1% to 10% of symptomatic factor V Leiden carriers also have the prothrombin G20210A gene mutation. Diagnostic evaluation for the prothrombin G20210A gene mutation is best completed by direct genomic DNA analysis.

Elevated Factor VIII Levels

High levels of factor VIII are a strong independent risk factor for VTE. The prevalence of increased factor VIII levels in the general population is approximately 11%. In up to 25% of people presenting with VTE, factor VIII levels are higher than normal. Research has demonstrated that for each 10% increase in factor VIII levels, the risk of single-episode and recurrent VTE increases by 10% and 24%, respectively. Elevation in factor VIII level has been shown to remain an independent risk factor for VTE with institution of appropriate controls for inflammation, blood group antigens, and von Willebrand factor levels.

Hyperhomocysteinemia

Homocysteine is an intermediary amino acid formed by the conversion of methionine to cysteine. Hyperhomocysteinemia may result from either acquired or heritable factors. Homocysteine is metabolized by means of two pathways. The first involves the cystathionine B-synthase (CBS) enzyme and requires vitamin B_6 as a cofactor. The second involves the enzyme methionine synthase and requires both vitamin B_{12} and methyltetrahydrofolate reductase (MTHFR). Acquired forms of hyperhomocysteinemia may result from dietary deficiencies in vitamin B_{12} or B_6 or folate. Inherited forms may result from genetic defects in the CBS or MTHFR enzymes.

Evidence suggests that hyperhomocysteinemia is a risk factor for VTE. In people with homocysteine levels higher than two standard deviations above normal, the odds ratio for VTE is two to three times greater than in the control groups. Elevated homocysteine levels also have been associated with premature coronary artery disease and cerebrovascular disease, although debate regarding the strength of these associations continues.

Screening for hyperhomocysteinemia is suggested in patients with unexplained VTE. Sensitive laboratory assays are available for the quantification of total plasma homocysteine concentrations. If elevated plasma homocysteine levels are identified, additional laboratory evaluation may be warranted. Treatment varies with the underlying cause but typically involves supplementation with folate and vitamins B_{12} and B_6.

Hypercoagulability Testing

Ongoing research continues to identify new and increasingly prevalent inherited thrombophilic defects in patients with VTE. Thus, which patients to screen, which tests to perform, and when to initiate hypercoagulability testing constitute important questions. Despite the high prevalence of inherited defects, only limited evidence or expert opinion indicates that the identification of an inherited thrombophilia influences either the duration of therapy or risk of recurrence. Arguments for screening acknowledge the increasing prevalence of identified inherited thrombophilias and, with the increase in the discovery of new mutations, the identification of persons with multiple prothrombotic defects. Multiple defects are now found in 1% to 2% of patients with initial-episode idiopathic VTE. Thus, the identification of patients with multiple defects may affect the risk of VTE recurrence, duration of anticoagulation therapy, and/or alteration of management when additional risk factors for the acquired form of VTE are present, such as surgery, pregnancy, or hormonal therapy. Arguments against screening cite the lack of available evidence supporting alteration in anticoagulation management in the presence of hereditary thrombophilia. The 2008 American College of Chest Physicians (ACCP) Antithrombotic and Thrombolytic Therapy Evidence-Based Clinical Practice Guidelines state that “the presence of hereditary thrombophilia has not been used as a major factor to guide duration of anticoagulation in VTE in these guidelines because evidence from prospective studies suggests that these factors are not major determinates of risk of recurrence.” A 2009 Cochrane database study failed to identify a single randomized controlled trial evaluating the benefit of testing for inherited thrombophilia after VTE in relation to risk of recurrent VTE.

Given the lack of available evidence that testing and identifying inherited thrombophilia influences the duration of therapy, VTE outcomes from screening of asymptomatic relatives, or risk of recurrent VTE, current recommendations for screening are based primarily on clinical judgment and expert opinion. Key points to recognize regarding first-episode VTE are that (1) the strongest risk factor for recurrent VTE is a history of VTE—of particular importance if the first VTE event was idiopathic—and (2) all patients with VTE are at increased risk for recurrence for several years after the initial event. In view of current limitations in medical evidence regarding the impact of inherited thrombophilia with respect to duration of therapy and risk of recurrence, consultation with a hematologic expert is recommended regarding individual patient management decisions.

Screening for Inherited Thrombophilia

In general, the following patient groups may be considered for screening: (1) those with a first VTE before the age of 50 years without an identifiable risk factor such as recent surgery, (2) those with a history of recurrent VTE, and (3) those with a first-degree relative with recurrent VTE. All such patients should be considered “strongly thrombophilic” on the basis of thrombotic history and are appropriate candidates for hereditary thrombophilia testing. The standard testing approach to screening for inherited thrombophilias includes appropriate studies to detect activated protein C resistance/factor V Leiden mutation, prothrombin gene mutation, antiphospholipid antibodies, antithrombin deficiency, protein C deficiency, and protein S deficiency.

Several factors must be considered in decisions regarding screening for inherited thrombophilia in patients presenting with VTE. First, acute VTE can transiently reduce plasma levels of antithrombin, protein C, and protein S, resulting in erroneously low levels. Second, treatment with heparin can result in up to a 30% decrease in antithrombin levels over the first several days of therapy. Third, warfarin reduces the functional activity of protein C and protein S and can rarely elevate levels of antithrombin, potentially resulting in falsely normal levels of antithrombin in deficient patients. To sidestep the effects of therapy on measured levels, it is recommended to test for these defects at least 2 weeks after cessation of anticoagulation therapy. If levels are obtained at time of presentation and are within normal limits, then a deficiency generally is excluded. If levels are low at time of presentation, then repeat testing is recommended on cessation of initial therapy. Screening tests for factor V Leiden mutation, prothrombin gene mutation, anticardiolipin antibodies, or antiphospholipid antibodies are not affected by concurrent use of heparin or warfarin therapy. If an inherited thrombophilia is identified, it is recommended to screen all first-degree relatives of the patient.

Management of Inherited Thrombophilia

The initial management of VTE in patients with inherited thrombophilia does not differ from that in other patients. The long-term management of patients with VTE and inherited thrombophilia remains an area of question. Because no randomized controlled trials have evaluated the optimal duration of anticoagulation therapy in inherited thrombophilia, therapy must be tailored to the individual patient. General guidelines suggest indefinite anticoagulation in patients with a history of (1) a single episode of idiopathic VTE in the presence of more than one allelic abnormality (e.g., homozygosity for factor V Leiden, heterozygosity for factor V Leiden and prothrombin mutation), (2) one spontaneous life-threatening thrombosis such as near-fatal PE or cerebral, mesenteric, or portal vein thrombosis associated with a heritable risk factor, or (3) one episode of spontaneous thrombosis in association with antiphospholipid antibody syndrome or antithrombin deficiency. In patients with heterozygosity for inherited thrombophilia and a single episode of idiopathic VTE, the recommended duration of anticoagulation therapy remains in question. Expert consultation is advised to determine the optimum duration of anticoagulation.

Acquired Risk Factors

Acquired risk factors for VTE are far more prevalent than inherited thrombophilias. Box 57-1 lists common risk factors for acquired VTE.

Surgery and Trauma

The risk of VTE among surgical patients can be stratified by patient age, type of surgery, and comorbid conditions. The incidence of VTE in surgical patients is highest for those aged 65 years or older. High-risk procedures include orthopedic surgery; neurosurgery; thoracic, abdominal, or pelvic surgery for malignancy; renal transplantation; and cardiovascular surgery. The risks from surgery may be less with neuraxial anesthesia than with general anesthesia.

Box 57-1 Acquired Risk Factors for Venous Thromboembolism

- Age >40 years
- Smoking
- Obesity (body weight >120 kg)
- Malignancy
  - Chemotherapy
- Oral contraceptive use or hormone replacement therapy
- Prolonged immobilization
  - Hospitalization
  - Prolonged air travel
- Surgery/trauma
- Acute inflammatory states
  - Acute infection
  - Inflammatory bowel disease
  - Connective tissuedisease
- Intravascular devices
  - Pacemaker or implantable cardioverter-defibrillator leads
  - Indwelling venous catheters
- Pregnancy/postpartum period
- Atherosclerotic cardiovascular disease
- Congestive heart failure
- Cerebrovascular accident
- Previous venous thromboembolism
- Varicose veins/venous stasis
- Acquired hypercoagulability
  - Nephrotic syndrome
  - Lupus anticoagulant
  - Antiphospholipid antibody syndrome
  - Hyperhomocysteinemia
  - Heparin-induced thrombocytopenia

The association between trauma and VTE has long been recognized. As with surgical risks, the risk of VTE after trauma is related to predisposing host factors; the location, nature, and extent of injuries; and the use of prophylaxis. The risk of VTE in trauma victims is highest with advancing age. Injuries involving the lower extremities or pelvis confer the highest VTE risk. Other VTE risk factors associated with trauma include spinal cord injuries with paralysis, head injuries, vascular injuries, circulatory shock on hospital admission, requirement for mechanical ventilation for longer than 3 days, and the need for a major surgical procedure.

Age

The incidence of VTE increases significantly with advancing age for both idiopathic and secondary forms of the condition, suggesting that the biology of aging and not simply an increased accumulation of VTE risk factors may be involved. In one study, the annual incidence rates for VTE increased from 17 per 100,000 persons for patients 40 to 49 years of age to 232 per 100,000 persons for patients 70 to 79 years of age.

Pregnancy

Pregnancy is associated with increased risk for VTE as a consequence of the hypercoagulability associated with this condition, as well as the increased resistance to venous return by compression from the gravid uterus. VTE will develop in approximately 1 in 2000 women during pregnancy. Age-adjusted estimates of the risk of VTE range from 5 to 50 times higher in pregnant than in nonpregnant women. The risk in the postpartum period is approximately five times higher than during pregnancy. Previous superficial vein thrombosis is an independent risk factor for the occurrence of venous thrombosis during pregnancy and in the postpartum period.

Hormone Replacement Therapy

Hormone therapy is associated with a two- to four-fold increased risk of VTE. The risk of thrombosis increases within 4 months of the initiation of therapy and is unaffected by the duration of use. The VTE risk decreases to baseline levels within 3 months of discontinuation of hormone therapy. First- and third-generation oral contraceptives carry a higher risk for VTE than that reported with second-generation agents. Therapy with selective estrogen receptor modulators, including tamoxifen and raloxifene, has been associated with increased rates of VTE.

Cancer

Malignancy accounts for approximately 20% of cases of incident VTE in the community. Many primary malignancies are associated with VTE. Risk for VTE in patients with cancer seems highest among those with pancreatic cancer, lymphoma, malignant brain tumors, hepatocellular carcinoma, leukemia, colorectalcarcinoma, and other digestive cancers. Furthermore, the use of certain chemotherapy regimens in patients with cancer, including thalidomide, tamoxifen, and L-asparaginase, is associated with higher VTE risk.

Obesity

Emerging evidence supports obesity as an independent risk factor for VTE. The relative risk of VTE for obese people is greater in women than in men, with the greatest effect being noted before the age of 40 years. In addition to its role as an independent risk factor in the context of VTE, obesity is a common contributing factor for VTE occurring in people undergoing long-duration air travel and in women concomitantly taking oral contraceptives or hormone replacement agents.

Previous Venous Thromboembolism

Previous VTE is a major risk factor for recurrence. The magnitude of the risk depends on host factors. Persons with reversible risk factors such as immobility or surgery exhibit a lower rate of recurrence than that noted for those with nonmodifiable risk factors, such as malignancy or inherited thrombophilia.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a life-threatening disorder that follows exposure to unfractionated (UF) or, less commonly, low-molecular-weight heparin (LMWH). HIT classically manifests with a low platelet count (less than 150,000/μL) or a relative decrease in platelet count by 50% from baseline typically within 5 to 10 days of the initiation of heparin or LMWH therapy. The incidence of HIT among patients treated with UF heparin is 10 times higher than among those receiving LMWH. In patients with HIT, the risk of thrombosis is more than 30 times that in the control population. The risk of thrombosis remains high for days to weeks after discontinuation of heparin, even after the platelet counts return to normal.

HIT is caused by antibodies against complexes of platelet factor 4 (PF4) and heparin. The heparin-PF4–antibody complex binds to the platelet surface, where it is recognized by circulating IgA, IgG, and IgM antibodies. Immunoglobulin recognition leads to further platelet activation and release of PF4, thus creating a positive feedback loop. The activated platelets aggregate, resulting in thrombocytopenia and thrombosis. Early-onset HIT, defined as that with onset within hours after initiation of heparin therapy, may be seen in approximately 30% of patients with persistent antibodies to heparin if such therapy is given within the previous 3 months. Diagnosis of HIT is based on recognition of the clinical syndrome and specific serologic testing. Serologic assays can detect circulating IgG, IgA, and IgM heparin-dependent antibodies with high sensitivity (97%) but modest specificity (74% to 86%). Therefore, positive results on serologic assays must be confirmed by more specific tests, including serotonin release assays, heparin-induced platelet aggregation assays, or solid phase immunoassays.

The first intervention in a patient with suspected HIT is immediate cessation of all exposure to heparin, including heparin-bonded catheters and heparin flushes. LMWH should be avoided, because it may cross-react with heparin-induced antibodies. In addition to heparin cessation, patients with suspected HIT should be started on alternative anticoagulation because of high risk of thrombosis. In patients with suspected HIT and/or the need for alternative anticoagulation, direct thrombin inhibitors such as lepirudin or argatroban may be used. The duration of alternative anticoagulant therapy and the subsequent use of oral anticoagulants will depend on whether the patient has had a thrombotic event or requires continued anticoagulation. For patients with HIT without evidence of thrombus, therapeutic doses of alternative anticoagulation should be continued until the platelet counts return to normal. Consideration should be given to continuing anticoagulation therapy with alternative anticoagulation or warfarin for 2 to 4 weeks after the diagnosis of HIT, because of persistent high risks of thrombosis over this period. For a patient with HIT and thrombosis, therapeutic doses of alternative anticoagulation should be continued until the platelet count has normalized; then the patient should be transferred to warfarin therapy with at least a 5-day overlap until the international normalized ratio (INR) is in the therapeutic range for at least 48 hours. Skin necrosis and warfarin-induced venous gangrene of the limbs have been reported during shorter periods of overlap or shorter duration of therapeutic INR.

PATHOGENESIS

Between 60% and 90% of pulmonary emboli arise from the deep veins of the lower extremity and pelvis. Other sources of thrombi include the renal veins, upper extremities, or right side of the heart. Iliofemoral thrombi are the most frequently clinically recognized causes of PE. Thrombi dislodge and embolize to the pulmonary arteries, where they cause hemodynamic abnormalities and impair gas exchange. The hemodynamic response to PE is determined by the embolic burden in association with the host's hemodynamic reserve and compensatory adaptive response. After traveling through the right heart, large thrombi may lodge and obstruct the main pulmonary arteries or travel distally within the pulmonary vascular tree, leading to hemodynamic alterations. In addition to the physical obstruction to flow, acute PE triggers the release of vasoactive substances, resulting in further increase in pulmonary vascular resistance and right ventricular afterload. Because right ventricular afterload increases, increased right ventricular wall tension may lead to right ventricular dilatation and hypokinesis with further right ventricular dysfunction, tricuspid regurgitation, and right ventricular failure. Right ventricular pressure overload can lead to flattening or bowing of the interventricular septum toward the left ventricle with resulting impairment of left ventricular filling, systemic arterial hypotension, and cardiac arrest. Increased right ventricular wall stress caused by right ventricular pressure overload may also lead to right-sided stress-induced ischemia.

Impaired gas exchange may result from impaired ventilation-perfusion matching, increased alveolar dead space, or right-to-left shunting through a patent foramen ovale. Stimulation of pulmonary irritant receptors results in hyperventilation, contributing to the observed hypocapnia and respiratory alkalosis. The presence of hypercapnia in acute PE suggests a large amount of physiologic dead space and impaired minute ventilation, which can result from massive PE.

CLINICAL FEATURES

The clinical consequences of PE range from incidental and clinically unimportant to circulatory collapse and sudden death. Equally challenging, the clinical signs and symptoms related to PE are diverse and nonspecific. Therefore, clinicians use a combination of history and examination findings in association with clinical prediction tools to determine appropriate diagnostic tests and the need for therapeutic interventions. Considerations in the differential diagnosis for acute PE are listed in Box 57-2.

MEDICAL HISTORY

Patients with PE often have one or more identifiable risk factors for the development of VTE at the time of clinical presentation (see earlier, under "Risk Factors"). Details should be sought regarding the patient's personal and family history of prior VTE, coexisting medical conditions, functional status, travel history, and current medications. Major risk factors for VTE include surgery or trauma within the preceding 30 days, prolonged immobility, advanced age, malignancy, previous VTE, known thrombophilia, recent myocardial infarction or stroke (cerebrovascular accident), or indwelling venous catheter. Moderate risk factors include obesity, use of estrogen or hormone replacement therapy, and family history of VTE. Scoring systems such as the Wells score and the Geneva score have been devised to help assess the patient's probability of being diagnosed with a PE (see under "Diagnosis" later in the chapter).

SYMPTOMS AND SIGNS

Acute PE embolism may manifest with a wide spectrum of signs and symptoms. The most common symptom in angiographically confirmed acute PE is dyspnea (Table 57-2). Less frequently, patients with acute PE present with hemoptysis, wheezing, or chest pain. Frequent findings on physical examination include tachypnea (respiratory rate greater than 20 breaths/minute), tachycardia (heart rate greater than 100

Data from Stein PD, Terrin ML, Hales CA, et al: Clinical, laboratory, roentgenographic, and electrocardiographic findings in patients with acute pulmonary embolism and no pre-existing cardiac or pulmonary disease, *Chest* 100:598–603, 1991.

beats/minute), and crackles on lung auscultation (see Table 57-2). The presence of syncope, cyanosis, jugular venous distention, pulsatile liver, or parasternal heave or auscultation of an accentuated pulmonic component of the second heart sound, right-sided third heart sound, and/or an audible systolic murmur at the left sternal border may reflect significant right ventricular dysfunction.

LABORATORY TESTS

Standard laboratory tests do not significantly contribute to the evaluation of patients with suspected PE. Routine laboratory findings such as increased erythrocyte sedimentation rate and/or leukocytosis are nonspecific. Common laboratory tests performed as part of the evaluation for PE include arterial blood gas analysis and D-dimer, B-type natriuretic peptide (BNP), and troponin assays. Both troponin and BNP measurements have been suggested as prognostic indicators, differentiating between low risk and intermediate risk for PE-related complications, including hemodynamic collapse and death. Elevated levels of BNP and troponin have yet to become incorporated into formal PE guidelines for risk stratification and treatment, although this change is likely in the future. Normal levels of BNP and troponin have high negative predictive values that identify patients at low risk for adverse outcome related to PE. Alternatively, in hemodynamically stable patients with acute PE and elevated BNP and/or troponin levels, echocardiography is indicated to assess for right ventricular dysfunction, which is likely under these circumstances. Because of the short half-life of these markers and the characteristic delay between the acute event and their release into the circulation, if the duration of symptoms is less than 6 hours, a second laboratory measurement of both BNP and troponin levels is clinically warranted.

Arterial Blood Gas Analysis

Arterial blood gas analysis cannot accurately be used as a diagnostic tool to discriminate between patients with and without PE. Typically, patients with acute PE present with hypocapnia and respiratory alkalosis. The partial pressure of oxygen (PO_2) may be increased, decreased, or normal in patients with PE. The alveolar-arterial oxygen gradient, PO_2(A–a), typically is increased; however, this finding also lacks sufficient discriminatory characteristics to be useful as a screening test. Thus, a normal PO_2 and PO_2(A–a) do not obviate the need for further diagnostic investigation in patients with clinical findings suggestive of disease.

D-Dimer Assay

D-dimer is a plasmin-derived fibrin degradation product most commonly measured by a quantitative enzyme-linked immunosorbent assay (ELISA). D-dimer testing is characterized as highly sensitive with a high negative predictive value useful in the exclusion of VTE, particularly in the outpatient or emergency department setting. With most assays, a level higher than 500 ng/mL is considered abnormal. Used in combination with a low clinical probability of disease, a negative result on D-dimer assay (value lower than 500 ng/mL) has a 99% negative predictive value for PE. D-dimer assays lack specificity (30% to 75%). Elevated D-dimer levels are observed in persons with inflammatory states, infection, acute coronary syndromes, or malignancy or patients who have undergone recent surgery. Current evidence supports that a quantitative D-dimer level lower than 500 ng/mL measured by ELISA can exclude the diagnosis of VTE in patient with low/intermediate pretest probability of disease. At present, D-dimer testing should not be used as the sole modality to rule out VTE in patients with high pretest probability for disease. Clinicians should note that D-dimer assays vary in their sensitivities and specificities. Thus, it is important to be aware of the assay used for appropriate interpretation of results.

B-Type Natriuretic Peptide Assay

BNP is a hormone released by ventricular myocardial cells in response to volume overload and wall stretch. Because of its lack of sensitivity and specificity, BNP is not a useful diagnostic test for PE. In the absence of right ventricular dysfunction, BNP levels are typically normal in the setting of acute PE. However, increased levels of BNP seem to have prognostic significance in people with PE.

Elevation of BNP levels (to greater than 90 pg/mL) obtained within 4 hours of admission have a sensitivity of 85% and specificity of 75% for predicting PE-related clinical outcomes such as death, need for emergent thrombolysis, cardiopulmonary resuscitation, mechanical ventilation, vasopressor therapy, or emergency surgical embolectomy. Normal BNP values in the setting of acute PE have a 97% to 100% negative predictive value for in-hospital death.

Troponin Assay

Cardiac troponins are sensitive and specific markers of myocardial cell damage. Troponin elevation in acute PE is presumed to be related to acute right-sided heart strain with resulting myocyte ischemia and microinfarction. Troponin I and troponin T levels are elevated in 30% to 50% of people with large PE.

However, these elevations are mild and short-lived compared with those observed in acute coronary syndromes. Like BNP, troponin levels correlate with right-sided heart dysfunction in acute PE. Normal troponin T values in the setting of acute PE have a 97% to 100% negative predictive value for in-hospital death.

DIAGNOSIS

The diagnosis of pulmonary embolic disease can present a significant challenge. Typical presenting clinical signs of dyspnea and chest pain are nonspecific and can be confused as manifestations of other serious disease states such as acute myocardial infarction or pneumonia. Many patients with thromboembolic disease present with atypical symptoms, and the diagnosis of PE becomes even more difficult when comorbid conditions such as congestive heart failure (CHF) or chronic obstructive pulmonary disease (COPD) could otherwise explain their presenting complaints. Because of the high prevalence of VTE and the potentially serious consequences of misdiagnosis, it is essential to maintain a high degree of clinical suspicion for the possibility of PE.

CLINICAL ASSESSMENT

Typical clinical features of PE have already been described; here, it is important to stress that clinical judgment is an essential initial step in the evaluation of thromboembolic disease and figures prominently in diagnostic algorithms. The importance of the clinician's assessment of the probability of PE initially was highlighted in the 1990 landmark Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study. Physicians in this study were asked to record their clinical impression (high, intermediate, or low probability) as to the likelihood of PE in patients they were treating before learning the results of the radiographic study (ventilation-perfusion scan or pulmonary arteriogram). The clinical impression was based on an agreed-on set of data but without standardized diagnostic algorithms. One very important finding of the PIOPED study was that diagnosis or exclusion of PE was possible only with clear and concordant clinical and radiographic findings. If the clinical impression did not match the findings on imaging (ventilation-perfusion scan in this study), pulmonary thromboembolic disease could not be confirmed or ruled out by that imaging study, and further investigation was necessary. Since the publication of PIOPED, numerous attempts have been made to standardize the definition of "clinical impression." This has resulted in a variety of scoring systems, assigning points to historical, physical, and laboratory features of an individual patient. Patients receive scores on the basis of inherent risk factors and presenting signs that are then used to predict likelihood of disease. Currently, the two most commonly used scoring systems are the *Wells criteria* and the *Geneva score* (Table 57-3). These two scoring systems and subsequent modifications have been validated in a number of studies. By themselves, scoring systems lack adequate sensitivity or specificity to diagnose or exclude disease. Their true usefulness comes in conjunction with other laboratory or imaging studies, allowing the assessment of disease risk.

Table 57-3 Wells and Geneva Scoring Systems Used in Risk Assessment for the Diagnosis of Pulmonary Embolism (PE)*

Wells Score	Points	Geneva Score	Points
Previous VTE	1.5	Previous VTE	2
Heart rate >100 beats/min	1.5	Heart rate >100 beats/min	1
Recent surgery or immobilization	1.5	Recent surgery	3
Clinical signs of DVT	3	Age (years)	
		60-79	1
		≥80	2
Alternative diagnosis less likely	3	Pa_{CO_2}	
		<36 mm Hg	2
		36-38.9 mm Hg	1
Hemoptysis	1	Pa_{O_2}	
		<48.7 mm Hg	4
		48.7-59.9 mm Hg	3
		60-71.2 mm Hg	2
		71.3-82.4 mm Hg	1
Cancer	1	Atelectasis	1
		Elevated hemidiaphragm	1
Clinical Probability		***Clinical Probability***	
Low	0-1	Low	0-4
Intermediate	2-6	Intermediate	5-8
High	>6	High	≥9

*Both scoring systems divide patients into groups with low, intermediate, and high clinical probability for the diagnosis of PE. For the Wells score: total points of <2 indicates a low clinical probability for PE, a score of 2-5 is intermediate, and a score of >6 indicates high probability of PE. For the Geneva score: total score of <0-4 indicates low probability for PE, 5-8 points indicates intermediate probability, and a score of 9 points or more indicates high probability for PE. These scoring systems and their variations have been validated in prospective cohorts of patients. In aggregate, a low clinical probability score indicates a subgroup with a 10% prevalence of PE. Intermediate clinical probability indicates prevalence of approximately 30% and high clinical probability indicates >70% prevalence of PE approximately.
DVT, deep vein thrombosis; *PE*, pulmonary embolism; *VTE*, venous thromboembolism.

Electrocardiograms and Chest Radiographs

Electrocardiograms (ECG) and chest radiographs frequently are used in the evaluation of patients initially seen with dyspnea or chest pain. Although these studies are neither adequately sensitive nor specific to diagnose or exclude PE, they can suggest the diagnosis. ECG findings such as T wave inversions in the anterior leads, in particular V1 to V4, are typical of right ventricular strain and should raise suspicion for pulmonary thromboembolic disease (Figure 57-1). Other typical ECG changes include a deep S wave in lead I, a Q wave in lead III, and T wave inversions in lead III. Rhythm and conduction abnormalities such as new-onset atrial fibrillation or right bundle branch block occasionally are noted in association with acute PE.

In the evaluation for PE, chest radiographs predominantly serve to exclude other potential explanations for the patient's symptoms (e.g., a lobar infiltrate consistent with pneumonia). Occasionally, the chest radiograph will demonstrate changes suggestive of PE, such as focal oligemia (Westermark sign), a peripheral wedge-shaped density that indicates infarct

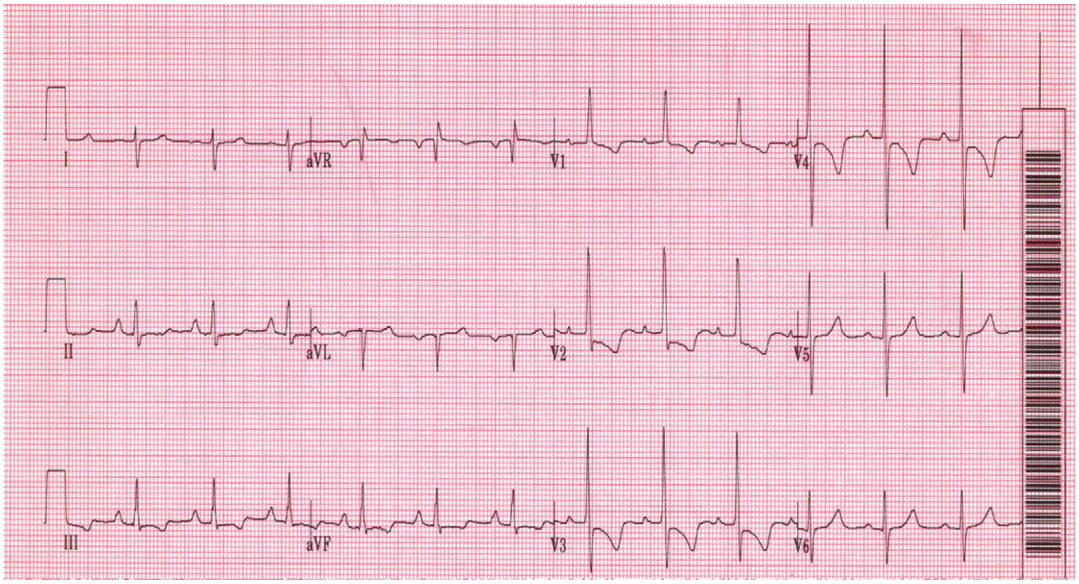

Figure 57-1 Electrocardiogram (ECG) in a patient with right ventricular (RV) strain secondary to thromboembolic disease. Note the right axis deviation, deep S wave in lead I, inverted T wave in lead III, and RV strain pattern in leads V1 to V4. The patient was diagnosed with chronic thromboembolic pulmonary hypertension secondary to multiple pulmonary emboli (PEs).

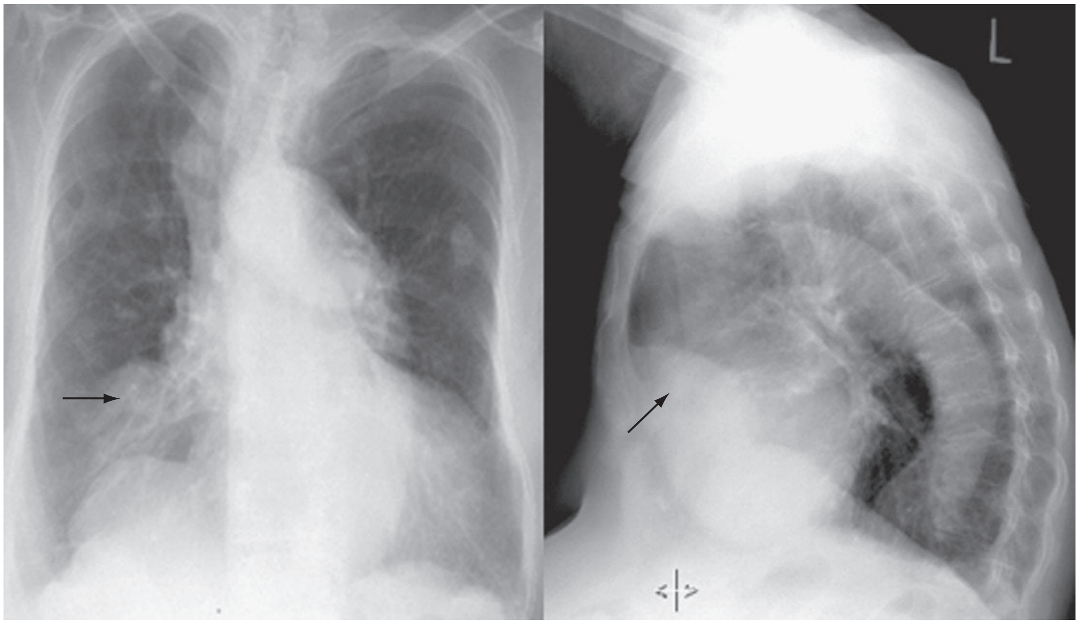

Figure 57-2 Chest radiographs showing a wedge-shaped pulmonary infarct (Hampton hump) secondary to a pulmonary embolism. The infarct is located in the anterior segment of the right middle lobe (*arrows* on both left and right images).

(Hampton hump) (Figure 57-2), or an enlarged right descending pulmonary artery (Palla sign).

D-Dimer Assay

Measurement of plasma D-dimer levels in peripheral blood has become an important screening tool to help exclude the presence of VTE. Plasma D-dimer is a degradation product of cross-linked fibrin. After a thrombotic event, endogenous fibrinolysis results in clot dissolution and a measurable increase in plasma D-dimer levels. An elevated D-dimer, however, is not specific for the presence of VTE. Numerous other conditions (e.g., trauma, inflammation, surgery) can raise plasma D-dimer levels; therefore, an abnormal laboratory result has a low positive predictive value for VTE.

Laboratory tests to measure D-dimer levels in peripheral blood have been available since the mid-1980s, but their acceptance as an early screening tool in the evaluation of VTE is relatively recent. Contributing to the initial confusion regarding the usefulness of D-dimer in the assessment of VTE was the presence of significant variability among the various D-dimer assays (ELISA, quantitative latex agglutination, semiquantitative agglutination latex, and whole blood agglutination assays) in both sensitivity and specificity. ELISAs have the highest sensitivity and are therefore superior in their ability to exclude the diagnosis of VTE. Numerous studies have validated the usefulness of D-dimer assays in the evaluation for this entity. A D-dimer ELISA level of less than 500 ng/mL is strong evidence against PE in patients with a low or intermediate clinical probability score. Van Belle and colleagues, reporting for the Christopher Study investigators, demonstrated that the incidence of PE was only 0.5% at 3 months in patients with a low clinical probability score (determined using a modified version of the Wells criteria) and a D-dimer plasma level of 500 ng/mL or less. Other VTE outcome studies have demonstrated similar results, showing the D-dimer assay to have a sensitivity of between 92% and 99% for the diagnosis of VTE. As previously noted, however, the specificity for this study has been reported to be as low as 25%.

Venous Compression Ultrasonography

Ultrasound evaluation of the deep venous system to search for thrombosis frequently is used to assist with the diagnosis of PE. This approach is pragmatic, because the treatments for both DVT and PE are similar, and the first disease process begets the second. Ultrasound imaging frequently is used when the initial tests for PE are nondiagnostic. A positive ultrasound test result confirms the need for anticoagulation and obviates the need for further diagnostic studies. A negative result, however, is more difficult to interpret and requires consideration of certain caveats in considering a treatment plan. In the presence of acute PE, DVT is detectable by compression ultrasound studies in only approximately 50% of cases (50% sensitivity). In patients with nondiagnostic chest imaging studies, compression ultrasound imaging of the proximal vein detects DVT in approximately 5% of cases. Normal findings on bilateral proximal venous ultrasound studies, therefore, do not rule out PE in patients with nondiagnostic lung scans. However, they do imply a reduced probability of this event (negative likelihood ratio of approximately 0.7). Negative results on ultrasound imaging therefore imply a lower short-term risk for development of thromboembolic disease or for a fatal thromboembolic event if anticoagulant therapy is withheld. Some studies have recommended a follow-up serial ultrasound study when anticoagulation therapy is withheld on the basis of initially negative ultrasound findings. These studies, examining a variety of time frames (2 days to 2 weeks), have reported that approximately 2% of patients with an initially negative venous ultrasound will be diagnosed with a DVT by serial testing. If ultrasound imaging continues to yield negative findings during serial examinations, the risk of subsequent symptomatic VTE is low, similar to that observed after a normal-appearing pulmonary angiogram (1% incidence at 6 months).

Contrast Venography

Venography was for many years the only reliable technique to confirm or exclude the possibility of a DVT but is now only of historical interest. Compression ultrasonography has all but replaced this more invasive approach for assessment of suspected DVT. Venography has a reported sensitivity ranging from 70% to 100% and specificity of 60% to 88% for the diagnosis of DVT. Potential complications of contrast venography include nephrotoxicity (secondary to contrast dye), bleeding complications from the venous puncture, and postprocedure phlebitis.

Ventilation-Perfusion Lung Scan

For many years, the ventilation-perfusion lung scan was considered the imaging study of choice to evaluate for PE (Figure 57-3). Recently, computed tomography angiography (CTA) has replaced the ventilation-perfusion lung scan as the predominant diagnostic test. However, the ventilation-perfusion scan maintains an important place in the evaluation of patients for thromboembolic disease who have contraindications to CTA such as renal insufficiency or contrast allergy. As mentioned previously, the PIOPED study correlated the clinical probability of a PE (high, intermediate, or low probability as assessed by history and clinical findings) with the interpretation of the ventilation-perfusion scan (high, intermediate, or low probability or normal perfusion). With concordance of the clinical assessment and the interpretation of the V/Q scan in the high or low probability range, PE can be diagnosed or excluded with reasonable certainty. When the clinical assessment and the interpretation of the ventilation-perfusion scan are discordant (i.e., high clinical probability but low-probability ventilation-perfusion scan, or vice versa), the possibility of PE cannot be adequately assessed, and other studies are required. A normal-appearing ventilation-perfusion scan (with a normal perfusion component) essentially excludes the diagnosis of PE.

Echocardiogram

Transthoracic and transesophageal echocardiography have limited use in the diagnosis of PE. The sensitivity and specificity of these tests are inadequate for diagnosis, because the offending emboli are rarely proximal enough to be visualized. Echocardiography can assist in acute care management decisions for those patients too unstable to be moved from a critical care setting for more definitive imaging studies. Although it is rare to visualize a thrombus within the pulmonary arteries by echocardiogram, changes in right ventricular size and function and increases in tricuspid regurgitation imply acute right heart strain. In the appropriate clinical scenario, these changes in the right ventricle can suggest the diagnosis of acute PE (Figure 57-4).

A more important role of echocardiography in the evaluation of patients with PE is that of risk stratification. Multiple studies have demonstrated that patients in whom right ventricular dysfunction develops in association with an acute PE have increased mortality compared with those with preserved right ventricular function. This observation is not surprising, because worsening right ventricular function relates directly to the degree the pulmonary vascular bed is affected by the thrombus and, therefore, the size of the embolic event. Some investigators have suggested that more aggressive therapy, such as thrombolysis, is indicated in patients with right ventricular dysfunction. This issue is discussed further in the section on treatment of PE.

Computed Tomography Angiography

CT pulmonary angiography (i.e., CTA) has become a favored study for the evaluation of PE over the past decade (Figure 57-5, *B*). CTA provides a number of potential advantages over other imaging modalities in the diagnosis of PE, including (1) direct visualization of the embolus, (2) the ability to assess for other potential causes for the patient's complaints such as pneumonia, and (3) imaging algorithms that scan through the pelvis and lower extremities, as well as the chest, allowing simultaneous evaluation for PE and for DVT. The ability to evaluate for other thoracic disease is of no small consequence, because up to two thirds of patients initially suspected to have PE eventually receive another diagnosis for their symptoms. Many of these subsequently diagnosed disorders (i.e., pneumonia, thoracic aorta dissection, pneumothorax) are associated with lung changes that can be visualized on CT scan. The interobserver agreement for CT is better than that for ventilation-perfusion scan. The initial hardware used for assessment of PE was

single-detector scanners that provided high specificity for the diagnosis of PE (greater than 90%), but their sensitivity was unacceptable (approximately 72%) for the exclusion of this potentially life-threatening diagnosis. Multidetector (40-, 64-, and 96-slice) scanners in current use, however, have significantly improved the sensitivity and specificity of CTA for the diagnosis of PE. The very high spatial resolution of these studies allows rapid evaluation of pulmonary vessels down to the sixth-order branches during a single breath hold, with consequent increased detection rate for segmental and subsegmental PEs.

A number of outcome studies have demonstrated that a technically adequate negative multidetector CTA study is sufficient to exclude PE (sensitivity and specificity greater than 95%). The Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II) study initially raised some questions regarding the positive and negative predictive power of these studies. The investigators of PIOPED II sought to establish the sensitivity and specificity of multidetector CT scanners in the diagnosis of PE in the same fashion as that used by the original PIOPED for evaluation of ventilation-perfusion scans. These workers undertook a multicenter, prospective study assessing the accuracy of multidetector CTA alone and also of CTA combined with computed tomography venography (CTV) to include venous phase imaging (i.e., CTA-CTV) for the diagnosis of acute PE. However, in contrast with the original PIOPED study, which used pulmonary angiography as the reference test to which ventilation-perfusion lung scan was compared,

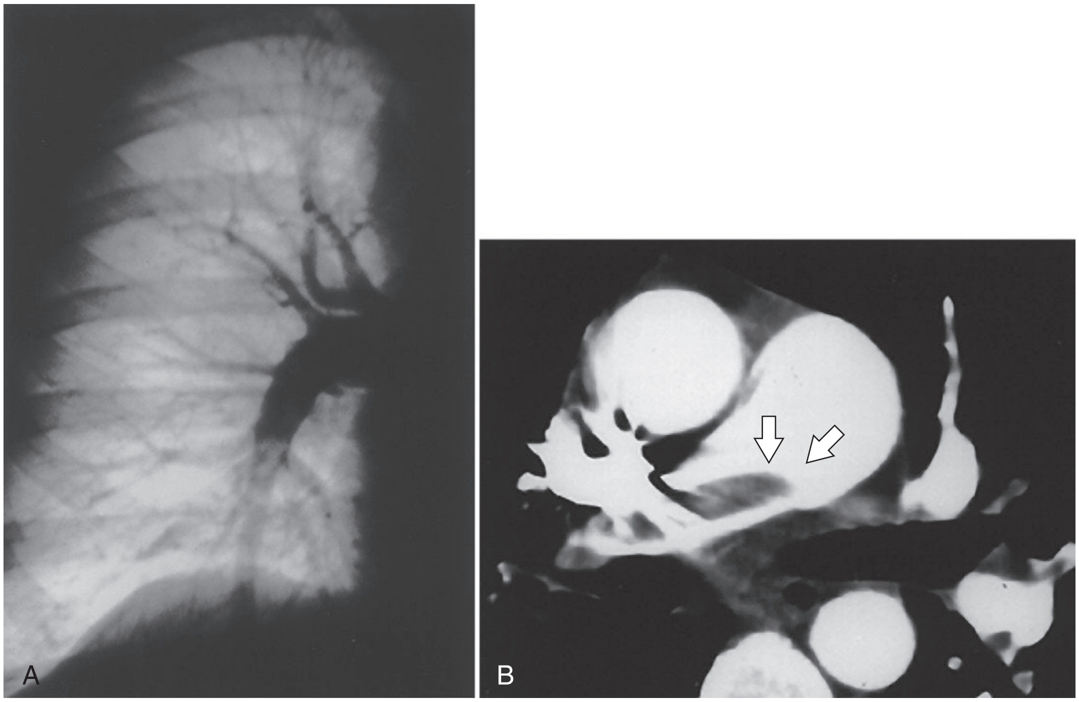

Figure 57-5 Pulmonary imaging for embolism. **A,** Pulmonary angiogram showing a filling defect in the right lower lobe pulmonary artery. **B,** A spiral (helical) computed tomography angiogram, obtained in another case, showing multiple filling defects (*arrows*).

PIOPED II used a composite reference test for VTE that was based on the ventilation-perfusion lung scan, venous compression ultrasound imaging of the lower extremities, and digital subtraction pulmonary angiography (performed in only a minority of cases). They reported the specificity of CTA for the diagnosis of PE to be 96%, but with a sensitivity of only 83%. Venous scanning of the pelvis and lower extremities improved the sensitivity of the study. The sensitivity of CTA-CTV for the diagnosis of PE was 90%, with a specificity of 95%.

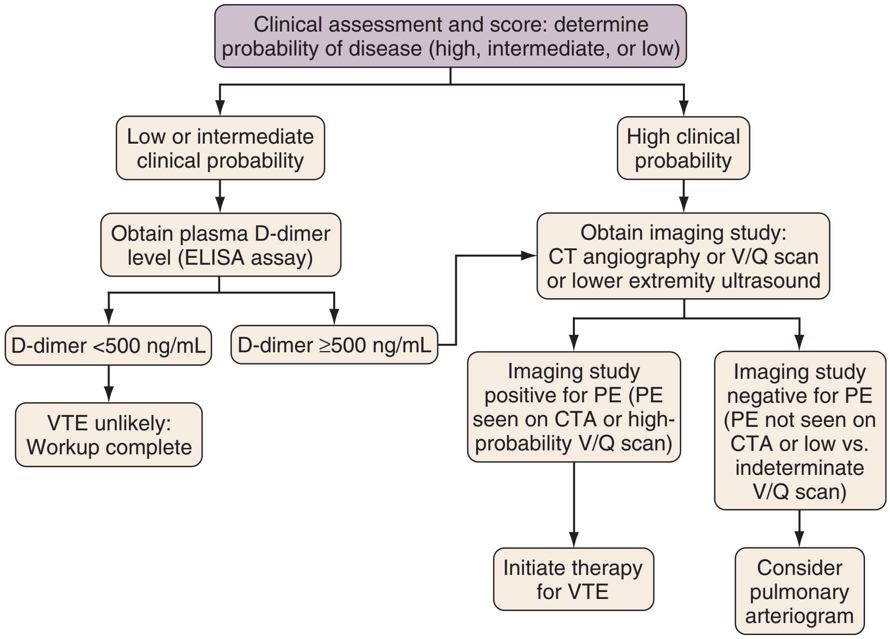
PIOPED II also attempted to associate clinical probability with imaging studies to assess positive and negative predictive values. The results were reminiscent of the original PIOPED study in that the positive predictive value of the CT studies was 96% with a concordantly high or low clinical probability, 92% with an intermediate clinical probability, and nondiagnostic with a discordant clinical probability. As discussed earlier, however, a number of large outcome studies demonstrated the efficacy of CTA in the evaluation of PE and the safety of withholding anticoagulation in patients with negative CTA findings. CTA now plays the predominant role in diagnostic algorithms for the evaluation of PE (Figure 57-6).

Pulmonary Arteriography

Pulmonary angiography or digital subtraction angiography (DSA) previously had been the "gold standard" modality for the diagnosis of PE (see Figure 57-5, *A*). Because of its invasive nature, it also is associated with the most inherent risk. Arrhythmias, hypotension, bleeding, and nephrotoxicity from contrast dye are potential complications. The mortality rate associated with pulmonary angiography has been estimated at 0.5%, with major nonfatal adverse events occurring with a frequency of 1%. Angiography also is more expensive than the noninvasive means of evaluating for PE and not always immediately available. As other imaging modalities, such as CTA, have gained popularity in the assessment of PE, angiography has become less used, so less experience with its application has been accrued. Approximately 1% of patients with a normal-appearing pulmonary angiogram will be diagnosed with a VTE at 6 months, implying that the result on angiography was falsely negative. Although large, segmental embolic events are readily appreciated, interobserver variability can be significant in evaluating smaller subsegmental emboli. The main role for DSA at present is for the evaluation of patients with chronic thromboembolic disease being considered for pulmonary endarterectomy (PEA) to assess surgical resectability.

Magnetic Resonance Imaging

Magnetic resonance angiography (MRA) and venography (MRV) were recently evaluated as diagnostic tests for VTE. The multicenter Prospective Investigation of Pulmonary Embolic Disease III (PIOPED III) study evaluated the sensitivity and specificity of MRA and then MRA in combination with MRV (i.e., MRA-MRV) in the assessment of PE. As in PIOPED II, the results were compared with a composite reference standard that included CTA and CTV, ventilation-perfusion scan, venous ultrasonography, D-dimer assay, and clinical assessment. MRA and MRA-MRV fared poorly in the diagnosis of PE. Of interest, the MRA study was technically inadequate in 25% of the 371 patients enrolled. When all enrolled patients were considered, MRA identified only 57% of patients with PE. If only patients with technically adequate studies were considered, the sensitivity of MRA for the diagnosis of PE was 78% and the specificity was 99%. In patients with a technically adequate MRA-MRV study, the sensitivity was 92% and the specificity was 96%; however, in only 52% of patients were both studies technically adequate. These poor results stem from the difficulty of capturing adequate images of the chest vasculature due to motion artifact as well as the difficulty of identifying abrupt termination of contrast in a vessel by MRA. With current MRA technology, the pulmonary vessel without contrast is lost in the background of the lung. In CTA, the same vessel remains visible making a cutoff from PE easier to visualize. The investigators



Clinical assessment and score: determine probability of disease (high, intermediate, or low)
Low or intermediate clinical probability
High clinical probability
Obtain plasma D-dimer level (ELISA assay)
Obtain imaging study: CT angiography or V/Q scan or lower extremity ultrasound
D-dimer <500 ng/mL
D-dimer ≥500 ng/mL
VTE unlikely: Workup complete
Imaging study positive for PE (PE seen on CTA or high-probability V/Q scan)
Imaging study negative for PE (PE not seen on CTA or low vs. indeterminate V/Q scan)
Initiate therapy for VTE
Consider pulmonary arteriogram

Figure 57-6 Diagnostic algorithm for evaluation of pulmonary embolism (PE). CTA (or CTA-CTV) is becoming the initial imaging study of choice. Ultrasound imaging and ventilation-perfusion (V/Q) scan can be used in patients in whom CTA is contraindicated (e.g., renal insufficiency) or when additional studies are needed to assist with the diagnosis. *CTA*, computed tomography angiography; *CTV*, computed tomography venography; *ELISA*, enzyme-linked immunosorbent assay; *VTE*, venous thromboembolism.

recommended that MRA for evaluation of PE be done only in centers with significant experience in the performance of this study, and only when other tests for the evaluation of PE are contraindicated. Even in with these caveats, however, it is difficult to conceive of many clinical scenarios in which MRA-MRV would be used in the evaluation of PE.

TREATMENT

The basic approach to treatment of PE has not changed appreciably over the past half-century. More recently, however, refinements in recommendations regarding duration of therapy have evolved. In addition, some exciting recent additions of medications for anticoagulation are likely to alter selection and duration of therapy in the near future. The possibility of placement of mechanical barriers to prevent further embolization to the pulmonary vasculature also is now readily available, although data on the appropriate use of these devices are lacking. Thrombolysis remains an option for rapidly dissolving the offending thrombus but is associated with a higher incidence of bleeding complications. The discussion regarding treatment of PE can be divided into two distinct entities: (1) treatment for the acute event and (2) secondary prophylaxis against recurrent VTE.

TREATMENT OF ACUTE PULMONARY EMBOLISM

Anticoagulation

Heparin and Vitamin K Antagonists

The goal of the initial treatment of PE is to obtain adequate, rapid anticoagulation while minimizing bleeding complications. For many years the consensus has been that the initial treatment of acute nonmassive PE should include heparin for a period of at least 5 days overlapping with the initiation of a vitamin K antagonist (VKA). The VKA should be started on the first day of treatment if possible, but recommendations for 5 days of heparin therapy hold even if the desired level of VKA anticoagulation is achieved earlier. This recommendation stems from studies in patients with DVT that demonstrated a higher incidence of recurrence if heparin therapy was truncated.

The goal of therapy with use of UF heparin is an aPTT between 1.5 and 2.0 times the control level. An important development in the use of UF heparin in the treatment of VTE was the implementation of weight-based dosing to rapidly obtain appropriate levels of anticoagulation. This recommendation stemmed from the frequent observation of recurrent thromboembolism in subtherapeutic heparin dosing. UF heparin was the treatment of choice for initial therapy of VTE for decades. More recently, however, LMWH has replaced UF heparin for first-line therapy in most cases. LMWH has better bioavailability and a longer half-life than UF heparin. These features permit once- or twice-daily subcutaneous dosing without the need for coagulation monitoring in appropriate clinical populations (i.e., normal renal function). The ability to obtain a predictable and reliable level of anticoagulation through a subcutaneous route then allows for the possibility of outpatient therapy, significantly decreasing health care costs and increasing patient satisfaction. LMWH was first demonstrated efficacious in the treatment of DVT. In addition, the use of LMWH for at-home therapy of DVT was quickly shown to be both safe and effective. Its use has more recently been studied for initial treatment of acute submassive PE, for which it also was found to be efficacious and safe. These trials showed no difference in morbidity or mortality in patients treated with LMWH versus those treated with UF heparin. A small number of patients in these studies were treated at home or were allowed to go home early receiving subcutaneous LMWH. No difference in outcome was observed in the at-home population. Treatment with LMWH is less commonly associated with HIT than is UF heparin. Although heparin and VKA have played a central role in the treatment of VTE for years, innovations in other medications altering the coagulation cascade are advancing rapidly. Perhaps the most exciting therapeutic advances in the treatment of VTE involve the orally available direct factor Xa inhibitors.

Factor Xa inhibitors

Factor Xa is strategically positioned at the juncture of the intrinsic and extrinsic coagulation pathways proximal to thrombin. The new oral factor Xa inhibitors have excellent bioavailability and induce rapid, predictable systemic anticoagulation.

A recent study comparing 3, 6, or 12 months of the oral Xa inhibitor rivaroxaban against 5 days of subcutaneous enoxaparin followed by 3, 6, or 12 months of an oral vitamin K antagonist demonstrated no significant differences in the primary end point of recurrent VTE (noninferiority). No differences were observed in the incidence of significant bleeding between groups. The investigators simultaneously reported the outcomes of a long-term continuation study in which patients with VTE (DVT or PE) who had already been treated with 6 to 12 months of oral vitamin K antagonists were then randomized to either an additional 6 to 12 months of oral rivaroxaban versus placebo. A significant decrease in the primary end point of recurrent VTE was noted in the patients treated with the oral Xa inhibitor. No statistically significant difference in bleeding events between groups was observed.

These medications have the potential to significantly alter the management of VTE. Their excellent bioavailability, rapid onset, predictable effect, and ease of use will greatly facilitate outpatient therapy. Close monitoring of coagulation levels, as is required with the vitamin K antagonists, is unnecessary, and the risk of over- or underanticoagulation is negligible. In the absence of unforeseen complications, use of these medications may be expected to rapidly become the standard of care in the management of VTE. One potential complicating factor regarding the use of the Xa inhibitors is the lack of a specific antidote for rapid reversal of anticoagulation. Rivaroxaban is cleared both hepatically and through the kidney, and unlike VKAs, it does not interact with food and has few drug-drug interactions. A third study by the same investigators comparing oral rivaroxaban to 5 days of subcutaneous enoxaparin and then 6 to 12 months of an oral vitamin K antagonist in patients with acute PE also demonstrated non-inferiority.

The subcutaneously administered Xa inhibitor fondaparinux also has been demonstrated to be efficacious in the treatment of VTE. Fondaparinux has a relatively long half-life (17 hours) and can be administered once daily. Another factor Xa inhibitor, idraparinux, also is being evaluated in the treatment of VTE. This agent has an even longer half-life (80 hours) than fondaparinux and could thus be administered on a weekly basis. Both fondaparinux and idraparinux are cleared by the kidney and must therefore be used with caution in patients with renal insufficiency.

Direct Thrombin Inhibitors

The direct thrombin inhibitors include hirudin, argatroban, and bivalirudin. Their potential advantage over heparin includes their ability to inactivate clot-bound thrombin and their resistance to circulating inhibitors released by activated platelets including PF4 and heparinase. Of importance, these agents do not cause HIT and are approved for the treatment of this dangerous condition, which is currently their primary role in the treatment of VTE.

Thrombolytics

For many years, significant interest has focused on the use of thrombolytic agents to rapidly dissolve pulmonary emboli in hopes of improving clinical outcomes. These agents have been successfully applied in acute coronary syndromes to help dissolve intracoronary thrombus, so their application to pulmonary vascular thrombus would seem reasonable. Although the use of these agents in the treatment of acute PE has been associated with earlier dissolution of clot, improved physiologic parameters, and resolution of imaging changes, most relevant studies did not show decreased patient mortality. As would be expected, however, an increase in significant bleeding complications was noted in patients receiving thrombolysis compared with those on anticoagulation alone. Attention has since been turned toward identifying subsets of patients with PE who might benefit from this therapy. Jerjes-Sanchez and associates evaluated the efficacy of thrombolytic therapy in patients with massive PE who presented in cardiogenic shock. The study was a small prospective, randomized controlled trial, enrolling a total of only 8 patients before it was terminated early (a total of 40 patients had been planned for enrollment). The 4 patients who received thrombolytics (streptokinase in this study) followed by heparin survived and at 2 years of follow-up demonstrated no evidence of pulmonary hypertension. The 4 who received heparin alone died within 1 to 3 hours of arrival in the emergency department. It is highly unlikely this study will be repeated, and by essentially uniform expert agreement, patients who develop cardiogenic shock related to PE should receive thrombolytics in the absence of major contraindications. A more controversial use of these medications is in patients with PE without hemodynamic compromise but with right ventricular dysfunction. A number of studies have demonstrated that patients with right ventricular dysfunction associated with PE have a significantly increased mortality. It would therefore seem reasonable to treat this group of patients more aggressively.

Two large studies have suggested a potential benefit of thrombolytics in patients with PE and right ventricular dysfunction or pulmonary hypertension, although both of these studies have received criticism regarding their design. The first study, the Management Strategies and Prognosis of Pulmonary Embolism Trial (MAPPET), demonstrated a survival benefit in patients with right ventricular dysfunction who received heparin and a thrombolytic (alteplase, streptokinase, and urokinase were the medications used) compared with heparin alone. The 30-day mortality rate for those who received thrombolysis was 4.7%, versus 11.1% for those receiving heparin alone. In addition, recurrent PE was significantly less frequent in those receiving thrombolytic therapy (7.7% versus 18.7%). This study was not randomized, however, and further inspection of the results reveals that the patients who received heparin alone were significantly older than those who received thrombolysis. This finding is relevant in that older age is a recognized risk factor for mortality in PE. The patients who received thrombolytics plus heparin also had less severe underlying cardiac and pulmonary disease than those receiving heparin alone, which also may have influenced the mortality outcomes.

The second study demonstrating an improvement in outcome for patients receiving thrombolytics was the Management Strategies and Prognosis of Pulmonary Embolism Trial-3 (MAPPET-3). This was a randomized prospective study examining the use of medical thrombolysis in PE associated with right ventricular dysfunction. The primary end point of this study was a combined end point of survival and escalation of therapy. A significant benefit in terms of this combined primary end point was reported in patients who received thrombolytics (alteplase) and heparin versus those who received heparin alone. Close review of this study, however, demonstrates no survival benefit between the two groups. Rather, the difference in the primary end point between groups was due to a difference in escalation of therapy, and in most patients this escalation of therapy related to later thrombolysis for PE. A number of experts have cited this article as evidence of benefit of thrombolytics in patients with PE and right ventricular dysfunction, although other workers are more skeptical of its use in this patient population. An interesting area of current exploration is the potential benefit of thrombolysis for submassive PE with right ventricular dysfunction in terms of long-term exercise tolerance and New York Heart Association (NYHA) functional class.

PROPHYLAXIS AGAINST RECURRENT VENOUS THROMBOEMBOLISM (SECONDARY PREVENTION)

Clear evidence has shown that "early" discontinuation of anticoagulation after an acute VTE results in a substantially increased risk for symptomatic extension of the thrombus, embolization, or recurrence of clot. The difficulty, however, is defining *early*. Most studies examining optimal duration of anticoagulation have found that the longer a person receives anticoagulation after a DVT or PE, the less likely they are to have a repeat VTE. Furthermore, when anticoagulation is discontinued, the risk of VTE increases substantially and is significantly above that in persons without a history of VTE. This elevation in risk is reflected in the clinical scoring systems (Wells score, Geneva score) discussed earlier. Of note, however, chronic anticoagulation presents its own inherent risks, cost, and requirements for lifestyle modification. The challenge then becomes balancing the inherent risk of anticoagulation with the individual patient's risk of recurrent disease. The ACCP has published consensus statement recommendations regarding the duration of chronic anticoagulation to prevent recurrent VTE by considering patient risk factors and presentation (Table 57-4). These recommendations by necessity are directed at broad categories of patients. When applying these standards, therefore, clinicians must consider the individual patient's risk of adverse outcomes with anticoagulation. As discussed earlier, however, the recent availability of the oral Xa inhibitors may change the risk-benefit ratio, resulting in longer periods of anticoagulation after VTE. The EINSTEIN investigators demonstrated that continuation of the oral Xa inhibitor rivaroxaban for an additional 6 to 12 months after completion of 6 to 12 months of anticoagulation resulted in significantly fewer episodes of recurrent VTE (1.3% versus 7.1%). Only a slight increase in nonfatal major bleeding (0.7%) was observed in the treatment cohort compared with the placebo cohort (0%).

Table 57-4 Recommendations for Duration of Anticoagulation in Patients Diagnosed With Venous Thromboembolism (VTE)

Indication for Anticoagulation	Duration of Therapy
First VTE with reversible or transient risk factor	Minimum of 3 months
First episode of idiopathic VTE	Minimum of 6-12 months; consider use for indefinite period
VTE associated with malignancy	LMWH for the first 3-6 months; then indefinitely or until the malignancy resolves
First episode of VTE associated with hypercoagulable state	12 months; suggest indefinitely
Two or more documented episodes of VTE	Indefinite

LMWH, low-molecular-weight heparin.

TREATING PULMONARY EMBOLISM ASSOCIATED WITH MALIGNANCY

The pathophysiology of venous thrombosis in patients with cancer is complex and is influenced by a number of variables, including tumor type, stage, and overall tumor burden. Malignancies such as renal cell carcinoma are associated with a 43% incidence of VTE. Patients with DVT or PE related to cancer have increased 6-month mortality over patients with cancer not complicated by VTE. The CLOT (Randomized Comparison of *L*ow-Molecular-Weight Heparin versus Oral Anticoagulant *T*herapy for the Prevention of VTE in Patients with Cancer) study demonstrated that LMWH (dalteparin) was more efficacious in the prevention of recurrent VTE in patients with malignancy than warfarin. Patients with cancer complicated by acute DVT, PE, or both were randomly assigned to receive 6 months of either warfarin or the LMWH dalteparin. Patients receiving dalteparin had less recurrent VTE than those receiving warfarin (9% versus 17%).

TREATMENT OF PULMONARY EMBOLISM IN PREGNANCY

Treatment of PE in pregnancy is complicated by risk to both the mother and the fetus. Warfarin is contraindicated in pregnancy because of its ability to cross the placenta and its association with both fetal hemorrhage and teratogenic effects such as central nervous system and neural developmental defects and nasal hypoplasia. Both UF heparin and LMWH can be used in the treatment of VTE in pregnancy, because neither crosses the placenta. Long-term use of UF heparin is associated with an increased risk for osteoporosis, but the risk is lower in patients treated with LMWH. Current recommendations for the treatment of VTE in pregnancy advocate the use of LMWH because of its favorable dosing and monitoring characteristics and its lower toxicity compared with other agents. An important consideration in this context, however, is that the maternal volume of distribution increases significantly during pregnancy, so the LMWH dose must be adjusted accordingly. Full-dose anticoagulation significantly increases the risk of hemorrhage at the time of delivery; therefore, LMWH and UF heparin should be discontinued 24 hours before planned induction of labor.

If spontaneous labor occurs, consideration should be given to reversal of anticoagulation with protamine. Anticoagulation can be restarted within 12 to 24 hours of delivery in the absence of ongoing bleeding. Warfarin, UF heparin, and LWMH are not excreted in breast milk, so these medications can be administered to breast-feeding women.

Pulmonary Embolectomy

Surgical resection of acute PE is a consideration in some patients. The operation is plagued by a high reported mortality (with rates as high as 30% in some series), in part because it typically is undertaken in already critically ill, hemodynamically unstable patients. Patients selected to undergo emergency embolectomy for this indication frequently have been found to have a large PE with resulting right ventricular dysfunction (a marker of increased mortality in itself). In such patients, anticoagulation or therapeutic thrombolysis often has failed to effect improvement or is contraindicated.

TREATMENT OF CHRONIC THROMBOEMBOLIC DISEASE

In most patients, the usual histopathologic and clinical course of PE eventuates in complete resolution of the thrombus and restoration of normal pulmonary artery pressures, usually within 30 days of the event. On the basis of a prospective incidence study, however, Pengo and colleagues reported that up to 4% of patients who survive a symptomatic PE may develop a condition termed *chronic thromboembolic pulmonary hypertension* (CTEPH). Most of these patients are seen late in the clinical course after significant pulmonary artery hypertension (PAH) develops; therefore, little is known about the natural history of this disease. In the currently accepted model for the pathogenesis of CTEPH, acute PE, either symptomatic or asymptomatic, serves as the initiating event, followed by disease progression. For reasons that are unknown, these emboli do not resolve but rather become coated by endothelial cells, a process referred to as *endothelialization*, making them inaccessible to endogenous or exogenous thrombolysis. This process eventually results in remodeling and obstruction of the pulmonary vascular bed and PAH.

What predisposes patients to CTEPH is unclear. Increased factor VIII levels have been detected in the peripheral blood of some of these patients, and an increased incidence of anticardiolipin antibodies also has been reported. The predicted 5-year survival rate for untreated severe CTEPH (i.e., mean pulmonary artery pressure greater than 50 mm Hg) is poor, with some estimates as low as 10%.

The treatment for CTEPH differs significantly from that for acute PE. Although these patients require anticoagulation to prevent further embolic events, the endothelialized clot is not accessible to these medications. Therapy, therefore, revolves around either removing the thrombus surgically or treating the elevation in pulmonary artery pressures medically. Surgical resection, termed *pulmonary endarterectomy* (PEA), is the treatment of choice in eligible patients (**Figure 57-7**). It is performed by dissecting away the endothelialized thrombus through careful separation of the thrombus from the pulmonary artery wall. This procedure is associated with significant operative and postoperative risk (as reflected by reported 5% to 10% mortality rates) and should be performed only in experienced centers. When PEA is successful, outcomes include significant improvement in pulmonary artery pressure, right-sided heart function, cardiac output, and functional class. A substantial number of patients (10% to 50%) with CTEPH referred for PEA, however, are deemed to be ineligible because of inaccessible distal thrombus or other serious comorbid conditions. Furthermore, persistent PH after successful PEA is frequent, with substantial small-vessel occlusion or arteriopathy. For these reasons, medical therapy for CTEPH has been applied. These treatments include nonspecific therapies such as administration of diuretics to improve fluid status, long-term oxygen therapy for hypoxemia, and digoxin to improve right ventricular contractility. More recently, however, novel therapies more specific for the treatment of PAH and approved for the treatment of idiopathic pulmonary artery hypertension (IPAH) have garnered attention as potentially useful in the medical management of CTEPH. Such therapies include use of the prostacyclin analogues (epoprostenol, treprostinil, and iloprost), endothelin receptor antagonists (bosentan), and the phosphodiesterase-5 (PDE-5) inhibitors (sildenafil). Evidence for the success of these medications, however, is limited to case series, retrospective studies, and prospective cohort studies. The only randomized controlled clinical trial to date that has included patients with CTEPH, as well as patients with other causes of PAH, is the Aerosolized Iloprost Randomized (AIR) study. Iloprost is an inhaled prostacyclin analogue approved for the treatment of PAH. This study did not demonstrate significant beneficial effects of inhaled iloprost in the CTEPH population, however.

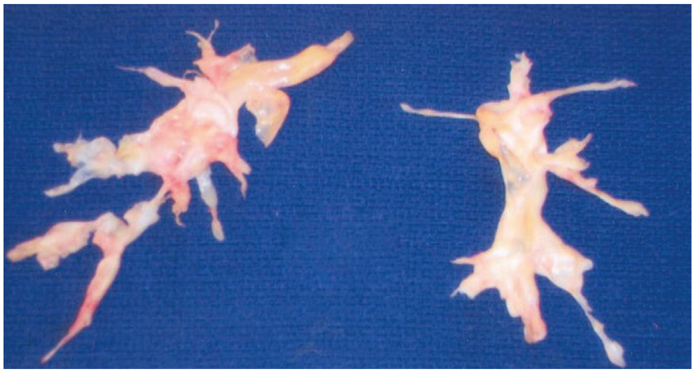


Figure 57-7 Thrombus removed from right and left pulmonary arteries in a patient with chronic thromboembolic pulmonary artery hypertension.

PREVENTION OF PULMONARY EMBOLISM

General Approach to Prophylaxis

VTE is a major cause of morbidity and mortality. Approximately 10% of in-hospital deaths are attributed to PE. Recognition of the prevalence and consequences associated with VTE has led to recommendations regarding primary prevention or thromboprophylaxis. Thromboprophylaxis has been demonstrated to be highly efficacious in a variety of patient populations and is associated with minimal risk. Recommendations for VTE prophylaxis advocate assessing the individual patient's risk for thrombosis and adjusting the aggressiveness of the approach on the basis of that risk. Although means of assessing patient-specific risk have been described, these systems are cumbersome, have not been adequately validated, and are unlikely to be used routinely in clinical practice. An easier, more applicable method involves a "group-specific" approach applied routinely to all patients falling within a specific target group. A full discussion of these recommendations is reviewed in detail in the Seventh ACCP Conference consensus statement on the prevention of VTE. The statement divides patients into medical and surgical groups. The surgical patients are classified on the basis of individual risk factors, such as age, preexisting conditions, and the type of surgery planned. Recommendations are then made regarding the most appropriate type of thromboprophylaxis. A similar approach is used for medical patients. Of note, most medically managed patients admitted to the hospital in the current era will have at least one and probably multiple risk factors for VTE. Therefore, thromboprophylaxis is indicated in most hospitalized patients and is considered to be an essential component of optimal clinical care.

In most cases, the agents recommended for prophylaxis are anticoagulants. These anticoagulants include subcutaneous UF heparin or LMWH, with occasional recommendations for agents such as Xa inhibitors (fondaparinux) or oral vitamin K antagonists in high-risk groups such as postoperative patients recovering from hip or knee surgery. In a developing consensus, the use of mechanical compressive devices as the sole means of thromboprophylaxis against VTE is discouraged. The ACCP currently recommends that mechanical methods of thromboprophylaxis be used primarily in patients at high risk for bleeding or as an adjunct to anticoagulant-based prophylaxis.

Currently, however, data supporting a role for such methods as adjunctive therapy are limited.

Inferior Vena Cava Filters

The concept of mechanically obstructing the vena cava to prevent embolization to the pulmonary vasculature is not new, being originally conceived by Trousseau in 1868. Techniques to insert this protective barrier have been refined substantially over the years, however, and now the placement of inferior vena cava (IVC) filters can be achieved safely and reliably. More recently, the development of retrievable IVC filters has expanded the number of patients considered for this procedure. The two most common scenarios in which IVC filters are used are (1) inability to anticoagulate and (2) failure of adequate anticoagulation in patients with known VTE. Other scenarios meriting consideration of IVC filter placement include high risk for PE despite use of recommended thromboprophylaxis, such as in trauma victims with lower extremity or pelvic fractures, high risk of death from pulmonary embolic disease in some patients, and/or those with severe pulmonary hypertension and a known DVT.

Only one randomized trial of IVC filters for the treatment of VTE has been published. This study demonstrated a decrease in the incidence of PE in the first 12 days after placement of the device (1.1% versus 4.8%) but an increase in the incidence of DVT at 2 years after placement (11.6% versus 20%). The incidence of PE at 2 years after filter placement was only slightly decreased (3.4% versus 6.2%). An 8-year follow-up study in the same cohort demonstrated a decrease in the recurrence of PE in the patients with IVC filters (6.2% versus 15.1%), but a significantly increased occurrence of DVTs was noted in the patients who received filters (35.7% versus 27.5%). No difference was found in the incidence of the postthrombotic syndrome or mortality between the cohorts. All patients in this study received anticoagulation for a minimum of 3 months, and many remained on anticoagulation indefinitely.

No randomized trials have been conducted to examine the incidence of PE in patients who received an IVC filter but did not receive anticoagulation. Retrievable filters are a potential option in patients who have only a transiently increased risk for VTE (**Figure 57-8**). The filters should be removed before endothelization of the struts occurs, which usually is within 7 to 21 days of placement. An increasing number of case reports and case series, however, have demonstrated the ability to remove retrievable filters months after their placement. The risk of complications rises with delayed removal. Randomized controlled trials demonstrating the efficacy of retrievable filters in terms of outcomes have yet to be performed.

NONTHROMBOTIC PULMONARY EMBOLI

Although most pulmonary emboli arise from DVT, other clinically significant forms of emboli may have an impact on the lung vasculature, as summarized in **Box 57-3**.

Box 57-3 Causes of Nonthrombotic Pulmonary Emboli

  - Arterial
- Amniotic fluid embolism
- Tumor embolism
- Septic pulmonary embolism

Fat Embolism Syndrome

Fat embolism syndrome (FES) is a poorly understood complication of skeletal trauma. Although rare, FES most often occurs after fractures of long bones or other conditions resulting in bone marrow disruption. FES is characterized by the appearance of free fat and fatty acids in the blood, lungs, brain, kidneys, and other organs. The classic triad of respiratory insufficiency, neurologic abnormalities, and petechial rash occurs in 0.5% to 2.0% of solitary long bone fractures. The incidence increases to 5% to 10% in multiple fractures with pelvic involvement.

FES is a clinical diagnosis that typically manifests within 12 to 72 hours of initial injury. Respiratory impairment leads to hypoxemia in up to 30% of patients and, on occasion, to respiratory failure and the need for mechanical ventilation. The chest radiograph often shows diffuse infiltrates but can appear normal. Cerebral symptoms may occur in 60% of patients and tend to follow the pulmonary symptoms. Neurologic findings may range from restlessness, confusion, and altered sensorium to focal deficits, seizures, and coma. The characteristic petechial rash is observed in 50% of patients and usually is found on the neck, in the axillary region, or on the trunk, or petechiae may appear on the conjunctiva. The rash often is the last of the triad to develop and resolves within a range of hours to days.

Treatment of FES includes aggressive supportive care and early ventilatory support. Steroids have been demonstrated to be efficacious as prophylaxis for FES, although experience with steroids as specific treatment remains anecdotal.

Air Embolism

Air embolism is a consequence of entry of air into the vascular system, resulting in mechanical obstruction, end-organ ischemia, and/or hemodynamic compromise. Air can enter the venous system under two simultaneous conditions: (1) presence of a direct communication between the source of air and the venous system and (2) development of a pressure gradient favoring the passage of air into the venous system. Under high pressure, gas may be forced into the venous system such as with laparoscopic procedures, pressurized infusion sets, or mechanical ventilation. Conversely, generating high negative intrathoracic pressures (as in hyperventilation, exacerbation of underlying lung disease, hypovolemia, or upright positioning) may predispose patients to *venous air embolism* by increasing the pressure gradient between the atmosphere and the thorax.

In most instances, venous air embolism occurs in relation to placement of central venous catheters (zero to 2% incidence). The mortality rate for this entity associated with central venous catheters has been reported to be as high as 32%. In humans, the lethal volume of air is estimated to be 300 to 500 mL. With a pressure gradient of only 5 cm H_2O (as with normal tidal breathing), air can pass through a 14 gauge catheter at a rate of 100 mL/second. The clinical symptoms of venous air embolism are nonspecific. Care providers must maintain a high index of suspicion to consider this diagnosis in patients who exhibit sudden cardiopulmonary and/or neurologic decompensation in the appropriate clinical setting. Patients may experience a gasping reflex, light-headedness, dizziness, chest pain, or sudden-onset dyspnea. If venous gas reaches the arterial circulation, myocardial or central nervous system injury may occur. Physical examination may reveal tachycardia, tachypnea, and elevated jugular venous pressure. A mill-wheel murmur, produced by movement of air bubbles in the right ventricle, is considered the only specific sign, but it is a rare, transient, and

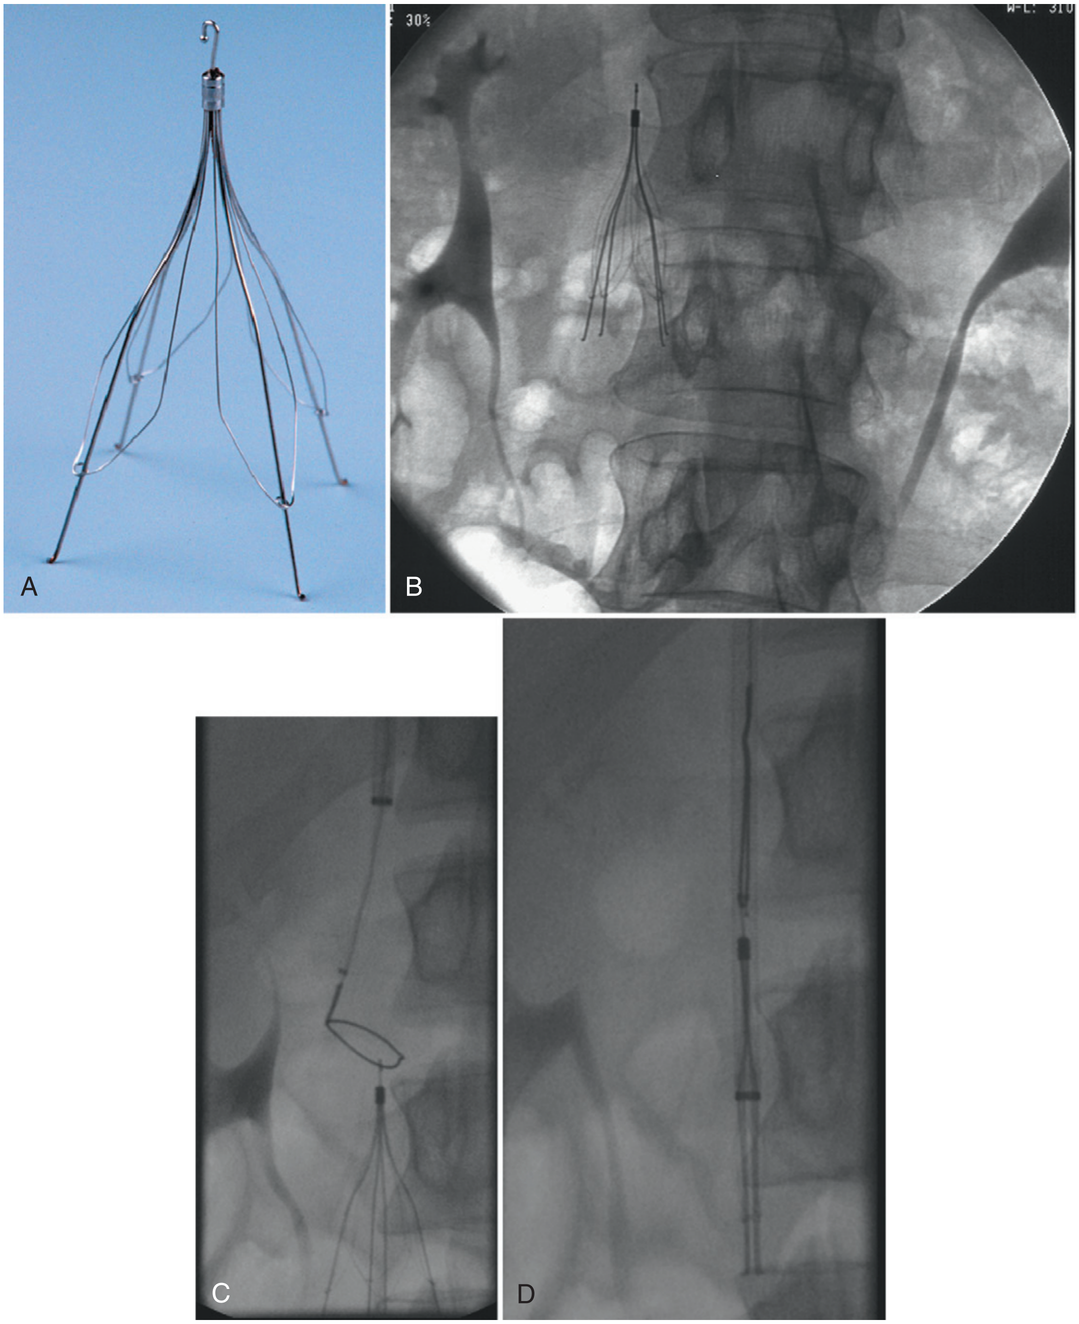

Figure 57-8 Inferior vena cava (IVC) retrievable filter. **A,** Gunter Tulip IVC filter. **B,** Filter is seen after deployment in the IVC. **C,** Preparation for retrieval of the filter. A snare is inserted percutaneously, which is used to engage the end of the filter. **D,** The filter is retracted and drawn into a sheath for percutaneous extraction.

late finding. Wheezing or rales may occur secondary to induced bronchospasm.

Transthoracic or transesophageal echocardiography is the most sensitive method for detection of venous air and may show evidence of both acute right ventricular dilatation and pulmonary hypertension. Indwelling pulmonary artery catheters will show an acute increase in pulmonary artery pressure. Although this finding has a sensitivity of only 45%, the presence of a pulmonary artery catheter at the time of onset of venous air embolism can result in early therapeutic intervention. If venous air embolism is suspected, the patient should be placed left side down in Trendelenburg position, allowing air to migrate toward the right apex of the heart, thereby diminishing pulmonary outflow obstruction. Manual removal of air from an indwelling central line or pulmonary artery catheter may be attempted and is most effective at or above the right atrial junction, not in the right ventricular or pulmonary artery outflow tract. Closed-chest cardiac massage improves survival to the same extent as that achieved by proper positioning, presumably by mechanically forcing air out of the right ventricle and pulmonary outflow tract. Patients should be administered 100% inspired oxygen (F_{IO_2}) to increase the rate of bubble absorption. For patients with persistence of cardiopulmonary or cerebrovascular deficits despite application of these modalities, hyperbaric oxygen therapy should be initiated.

Amniotic Fluid Embolism Syndrome

Amniotic fluid embolism syndrome (AFES) is a rare complication of pregnancy with variable manifestations and high morbidity and mortality. The reported incidence of this catastrophic syndrome ranges from 1 in 8000 to 1 in 80,000 pregnancies. Amniotic fluid is a complex mixture of both maternal and fetal components, including particulate matter such as fetal squamous cells, lanugo hairs, and variably meconium. Amniotic fluid is postulated to enter the maternal circulation through endocervical veins, through the site of placental insertion, or through uterine trauma. Once in the circulation, amniotic fluid triggers an immunologically mediated systemic inflammatory response leading to cardiovascular compromise, respiratory failure, coagulopathy, and disseminated intravascular coagulation. AFES occurs during labor but before delivery in 70% of cases, after vaginal delivery in 11%, and during cesarean section in 19%. Of the patients in whom AFES developed after delivery, 69% experienced clinical onset within the first 5 minutes post partum. AFES also has been reported to occur as early as the second trimester and as late as 36 hours post partum. AFES may occur during therapeutic abortion, amniocentesis, and labor and delivery and in the setting of abdominal trauma. Factors historically associated with increased risk for AFES include advanced maternal age, multiparity, large fetal size, premature placental separation, fetal death, fetal male sex, meconium staining, and a history of allergy or atopy in the mother.

The clinical presentation of AFES often is dramatic, with sudden-onset respiratory distress, cyanosis, convulsions, and cardiovascular collapse classically occurring during labor and delivery. Rapid progression to asystole or pulseless electrical activity has been described. Among patients who survive the initial event, a major coagulopathy develops later on in 40% of the cases.

The diagnosis of AFES is clinical. Early aggressive support is imperative, because most maternal deaths occur within 1 hour of symptom onset. AFES is a life-threatening condition that necessitates prompt resuscitation, including airway and hemodynamic support in an intensive care setting. The maternal mortality rate for AFES ranges from 30% to 90%. The fetal survival rate is 40% when the fetus is in utero at the time of AFES onset. Furthermore, AFES is associated with significant morbidity, with neurologically intact survival observed in only 15% of maternal survivors in some reports.

Tumor Embolism

Pulmonary tumor embolism occurs when solid tumors seed the systemic circulation with individual cells, clusters of cells, or large tumor fragments. Emboli travel to the pulmonary vasculature, causing microvasculature obstruction. Furthermore, tumor emboli may activate the coagulation system, resulting in concomitant thrombotic obstruction. The pathologic spectrum of tumor embolism ranges from large tumor masses that may mimic PE, on one end, to the more common microvessel embolism in small arterioles and capillaries that cause a subacute clinical syndrome, on the other. The incidence of tumor embolism is estimated by autopsy series to be 3% to 26% in patients with solid tumors. Tumor embolism seems to be more common in patients with mucin-producing adenocarcinomas such as breast, gastric, and lung carcinoma; however, this observation may be explained by the higher prevalence of these tumors within the general population.

CONTROVERSIES AND PITFALLS

Although great progress has been made in expansion of the current understanding and approach to the clinical entity of PE, new developments frequently bring with them new questions and controversies. Some of these dilemmas are discussed next.

ISOLATED SUBSEGMENTAL PULMONARY EMBOLI

The development of faster, multidetector scanners has improved the clinician’s ability to see the subsegments of the pulmonary vasculature on CTA. This ability, however, has raised an interesting conundrum: Are isolated small, subsegmental pulmonary emboli clinically meaningful? On one side of this argument are researchers who believe that any thrombus in the pulmonary vasculature is pathologic, and that even if a subsegmental thrombus does not have immediate clinical effects, it implies a risk for subsequent PE that therefore merits anticoagulation. The converse argument is that very small thrombi may intermittently occur in normal people, and that perhaps it is the lungs’ role to serve as a filter for these “microclots,” thereby preventing them from migrating into the arterial circulation. This possibility, although interesting to consider, has never been substantiated. At present, no consensus has been reached on the appropriate clinical approach toward an isolated subsegmental PE detected by multidetector CTA, and very little expert opinion on this topic has been published.

OUTPATIENT TREATMENT OF PULMONARY EMBOLISM

As discussed earlier in this chapter, LMWH has been demonstrated to be safe and effective in the treatment of submassive PE. The oral Xa inhibitor rivaroxaban currently is being studied in the management of PE and was found to be effective for the treatment of DVT. Initial reports of success with these agents raise the possibility of treating patients with PE at home, thereby avoiding a hospital stay. This paradigm is well accepted in the treatment of DVT, for which it has been demonstrated to be safe and cost-effective, as well as popular from a patient perspective. Some of the studies examining the use of LMWH for the treatment of PE have permitted small percentages of the patients enrolled either to be treated entirely on an outpatient basis or to be discharged early from the hospital to complete home therapy. No increases in adverse events were found in patients managed as outpatients. This possibility of home therapy raises concern, however, because patients with PE have an increased mortality compared with patients with DVT. It is possible that treating them in a less monitored environment will carry an increased risk of death. Also, studies examining the use of LMWH in the treatment of PE have excluded patients with hemodynamically significant thromboembolic disease, a subgroup recognized to have even higher mortality. Realistically, however, more and more patients with PE are being treated as outpatients. This approach merits caution in patients known to have adverse hemodynamic changes or right ventricular dilatation or strain related to the thromboembolic event. This group of patients probably should be observed in an inpatient setting, at least initially in their treatment course.

THROMBOLYTIC THERAPY IN PATIENTS WITH PULMONARY EMBOLISM WITHOUT HEMODYNAMIC INSTABILITY

Convincing evidence is lacking for a survival advantage in hemodynamically stable patients with pulmonary emboli who are treated with thrombolytics plus anticoagulation over that in those treated with anticoagulation alone. Two studies have suggested that thrombolytics improve outcomes in patients with pulmonary emboli and right ventricular dysfunction; however, both have been criticized for suboptimal design. Although it is currently agreed that patients with hemodynamic collapse secondary to PE should receive thrombolysis if possible, controversy exists regarding the use of this therapy in less severely affected patients. However, the use of thrombolytics in hemodynamically stable patients with evidence of right ventricular dysfunction is gaining support in a number of expert societies.

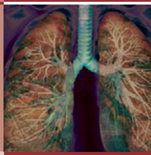
Section 9
PULMONARY VASCULAR DISORDERS, VASCULITIDES, AND HEMORRHAGE



Chapter 58
Pulmonary Hypertension

Kristin B. Highland • Andre Holmes

Pulmonary arterial hypertension (PAH) is a rare, pathologically complex disease characterized by a progressive increase in pulmonary arterial pressure associated with variable degrees of pulmonary vascular remodeling, vasoconstriction, and in situ thrombosis. These changes lead in turn to increased pulmonary vascular resistance (PVR) and eventual right-sided heart failure and death. PAH has a nonspecific clinical expression; therefore, the diagnosis often is established late in the disease course, making treatment problematic. Without treatment, the median survival after diagnosis of idiopathic pulmonary arterial hypertension (IPAH) is only 2.8 years.

DEFINITION

The current definition of *pulmonary hypertension* (PH) is a mean pulmonary artery pressure (mPAP) greater than 25 mm Hg measured with the patient at rest. A systolic pulmonary artery pressure (sPAP) greater than 35 to 40 mm Hg on echocardiogram should prompt further workup for PH, but determination of sPAP is not adequate as a stand-alone test.

In an exhaustive systematic review of the literature that included data from 1887 healthy people enrolled in 47 studies from 13 countries, mPAP measured with the subject at rest was 14.0 ± 3.3 mm Hg; this finding was independent of sex and ethnicity and only slightly influenced by age (in subjects younger than 30 years, 12 ± 3.1 mm Hg; in those older than 50 years, 14.7 ± 4.0 mm Hg). Therefore, if the upper limit of normal is defined by the mean plus two times the standard deviation, the upper limit for mPAP determined at rest in a healthy person is 20.6 mm Hg; this value is considerably lower than the established definition for PH of greater than 25 mm Hg. This same systematic review showed that mPAP measured during exercise was dependent on age, exercise type, and exercise intensity, making it difficult to establish a threshold value that would accurately define exercise-induced PH. As a result, the former exercise criterion of greater than 30 mm Hg was abandoned during the Fourth World Symposium on Pulmonary Hypertension held in 2008 in Dana Point, California.

Although modestly elevated mPAP in the setting of chronic lung disease often is associated with a poor prognosis, the significance of a "borderline" mPAP (20 to 25 mm Hg) in subjects who are otherwise healthy remains unclear. This uncertainty highlights the importance of the clinical assessment and the need for early biomarkers, rather than a focus on hemodynamics alone, especially because these data suggest that the prevalence of mPAP values greater than 25 mm Hg will be substantially higher than that indicated by the known prevalence of PAH.

CLASSIFICATION

Pulmonary hypertension was previously classified as either primary or secondary, depending on the absence or the presence, respectively, of identifiable causes or risk factors. The diagnosis of *primary pulmonary hypertension* was one of exclusion after ruling out all other causes for PH. Subsequent classification schemes have attempted to create categories of PH that share pathologic and clinical features, as well as similar therapeutic options. These classification schemes have allowed investigators to conduct clinical trials in well-defined patient groups with a shared underlying pathogenesis for their PH, resulting in the development of new targeted drug therapies; consequently, improvements in both quality of life and survival can now be expected in this otherwise deadly disease. This more inclusive category of PAH also has afforded increased opportunities for treatment of some less common forms of the disorder that were previously too rare for individual treatment studies. The most recent classification scheme was the product of the aforementioned Fourth World Symposium on Pulmonary Hypertension (**Box 58-1**).

GROUP 1: PULMONARY ARTERIAL HYPERTENSION

PAH is a subset of PH defined as a mPAP greater than 25 mm Hg determined with the patient at rest and a normal pulmonary capillary wedge pressure (PCWP) and/or left ventricular end-diastolic pressure (LVEDP) and a lesion localized to the pulmonary arteriole (**Figure 58-1,** *A* to C). Unfortunately, a limitation of these classification schemes is the fact that many of these patients have "multifactorial pulmonary hypertension." The clinician is thus faced with treating PH in a variety of clinical scenarios that often include features from more than one of the World Health Organization (WHO) classification categories (i.e., groups 1 to 5, with an additional 1′ grouping as described later on). For example, the clinical presentation may include somewhat elevated pulmonary venous pressures, mild to moderate obstructive or restrictive lung disease, or a form of valvular heart disease that typically would not account for pulmonary hypertension severity. Patients with such "out of proportion" PH are not included in clinical trials; therefore, data pertaining to the safety and efficacy of conventional PAH therapies in this population are extremely limited.

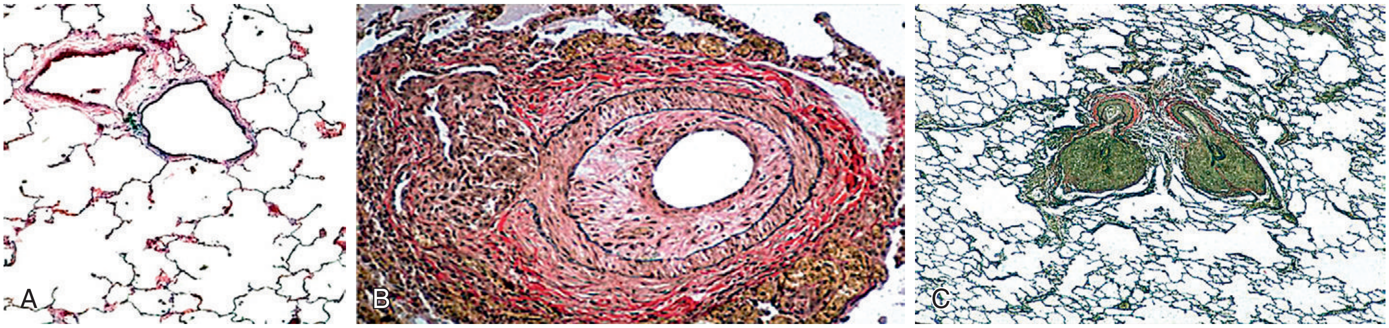


Figure 58-1 Histologic preparations (Von Giesen elastic stain) of normal lung and of specimens from patients with pulmonary arterial hypertension (PAH). **A,** Normal pulmonary arteriole flanked by a normal bronchiole (the latter at the 11 o'clock position). **B,** Concentric obliterative lesion characteristic of PAH. Intimal proliferation with encroachment on the lumen can be seen. A plexiform lesion is present to the left of the artery (at the 9 o'clock position). 40× objective. **C,** Plexiform lesions characteristic of PAH. 10× objective.

- **5** Pulmonary hypertension with multifactorial mechanisms

Idiopathic Pulmonary Arterial Hypertension

IPAH is a rare disease and remains a diagnosis of exclusion. Patients with this sporadic form of PAH do not have a family history of PAH or any identifiable risk factors. A female preponderance, with a gender ratio of 1.7 : 1, has been recognized, and the mean age at diagnosis is 37 years. The incidence of IPAH is approximately 1 to 2 cases per 1 million population, with a prevalence of approximately 6 per 1 million. Although IPAH originally was believed to be a disease of child-bearing women, cases of IPAH recently have been reported in a number of patients older than 70 years of age.

Heritable Pulmonary Arterial Hypertension

Several germline mutations have been associated with heritable PAH. These include mutations in the genes encoding bone morphogenetic protein receptor type II (i.e., *BMPR2*), active-like kinase type 1 (ALK-1), and endoglin.

Sporadic mutations in *BMPR2* have been identified in approximately 11% to 40% of patients with presumably the idiopathic form of PAH and are seen in 70% to 80% of patients with familial PAH but are relatively uncommon in patients with so-called associated PAH (i.e., category 1.4 in Box 58-1). Although penetrance is low and only approximately 25% of carriers will go on to develop PAH, genetic anticipation also has been demonstrated (i.e., in affected families, each successive generation has more severe PAH developing at an earlier age). *BMPR2* has been localized to chromosomal region 2q31-32, and inheritance occurs in an autosomal dominant fashion. Recently, it has been suggested that patients with PAH associated with *BMPR2* mutations may represent a subgroup with more severe disease who are less likely to demonstrate vasoreactivity than those with IPAH. Because this mutation can occur sporadically in as many as 25% of patients with PAH and does not occur in all patients with so-called familial PAH, the term *heritable* is now favored over the designation *familial*.

Like BMPR-II, ALK-1 and endoglin also are members of the transforming growth factor-β (TGF-β) superfamily and are located on endothelial cells, and mutations can result in heritable PAH. Mutations in the ALK-1 gene and/or the endoglin gene also are associated with the autosomal dominant disorder hereditary hemorrhagic telangiectasia.

Drug- and Toxin-Induced Pulmonary Arterial Hypertension

A number of risk factors for the development of PAH have been identified (Box 58-2). Risk factors for PAH include "any factor or condition that is suspected to play a predisposing or facilitating role in the development of the disease." Such risk factors have been categorized as "definite, very likely, possible, or unlikely, based on the strength of their association with [pulmonary hypertension] and their probable causal role." As a result of the Dana Point symposium, methamphetamine use was reclassified as a very likely risk factor for the development of PAH.

Pulmonary Arterial Hypertension Associated with Connective Tissue Diseases

PAH can occur in any of the connective tissue diseases but most commonly is seen in systemic sclerosis (scleroderma), mixed connective tissue disease, and systemic lupus erythematosus (SLE). The prevalence of PAH among patients with scleroderma is estimated to be between 7% and 12%. Although less well characterized, the prevalence among persons with SLE is thought to be between 1% and 4%. Of note, PAH is not the only cause of pulmonary hypertension in patients with connective tissue disease; these patients frequently have lung fibrosis and cardiac involvement. Experts recommend that all patients with systemic scleroderma have a yearly screening

Box 58-2 Risk Factors for Pulmonary Arterial Hypertension

Definite
Aminorex
Fenfluramine
Dexfenfluramine
Toxic rapeseed oil

Likely
Amphetamines
L-Tryptophan
Methamphetamines

Possible
Cocaine
Phenylpropanolamine
St. John's wort
Chemotherapeutic agents
Selective serotonin reuptake inhibitors

Unlikely
Oral contraceptives
Estrogen
Cigarette smoking

echocardiogram, because untreated PAH in patients with connective tissue disease is associated with a particularly poor prognosis.

Human Immunodeficiency Virus Infection

The prevalence of PAH in the human immunodeficiency virus (HIV)-infected population is approximately 1 per 200 persons. The mechanism for the development of PH remains unclear; it is thought to be a result of the indirect action of the virus through secondary messengers such as cytokines, growth factors, endothelin, or viral proteins. The occurrence of PAH is independent of the $CD4^+$ count, but it seems to be related to the duration of HIV infection. PAH also is more common in those patients infected through intravenous drug abuse. PAH is an independent predictor of mortality in these patients; in a substantial number of cases, however, normalization of pulmonary vascular hemodynamics can be obtained with specific therapy for PAH.

Portal Hypertension

The development of PAH in association with elevated pressure in the portal circulation is known as *portopulmonary hypertension* (POPH). Portal hypertension, rather than the presence of underlying liver disease, is the main determining risk factor for the development of POPH. Approximately 2% to 6% of patients with portal hypertension will also have PH. The diagnosis of POPH usually is made within 4 to 7 years after the diagnosis of portal hypertension. Female sex and autoimmune hepatitis are risk factors for the development of POPH; as a point of interest, hepatitis C infection is associated with a decreased risk. The presence of PAH is a contraindication to liver transplantation, so all patients being referred for transplantation require a screening echocardiogram. Right-sided heart catheterization is absolutely mandatory for the definitive diagnosis of POPH, because several factors may increase PAP in the setting of advanced liver disease. For example, high flow and an elevated cardiac output are associated with the hyperdynamic circulatory state seen in advanced liver disease, and an increased PCWP secondary to fluid overload and/or diastolic dysfunction also will increase PAP. These conditions generally are associated with a normal PVR.

Congenital Heart Disease

Persistent exposure of the pulmonary vasculature to increased blood flow and pressure results in vascular remodeling, leading to an increased PVR and eventual shunt reversal. Eisenmenger syndrome is defined as congenital heart disease with an initial large and nonrestrictive systemic-to-pulmonary shunt that induces progressive pulmonary vascular disease and PAH, with resultant reversal of flow and cyanosis. This clinical entity represents the most advanced form of PAH associated with congenital heart disease. Although Eisenmenger syndrome occurs more frequently when blood flow is extremely high and the shunt exposes the pulmonary vasculature to systemic-level pressures, such as occurs with a ventricular septal defect, patent ductus arteriosus, or truncus arteriosis, PAH also may occur with low-pressure–high-flow abnormalities such as those seen with atrial septal defects.

Schistosomiasis

Previously, schistosomiasis was categorized in group 4 as PH due to chronic thrombotic and/or embolic disease secondary to embolic obstruction of pulmonary arteries by *Schistosoma* eggs. More recent publications, however, indicate that PH can be similar in presentation to IPAH, with similar histopathologic changes. The mechanism probably is multifactorial and related to POPH, a frequent complication of this disease, and to local vascular inflammation occurring as a result of impacted *Schistosoma* eggs. This is a common cause of PH worldwide: It is estimated that more than 200 million people are infected with schistosomiasis, and anywhere from 4% to 8% of these patients will develop hepatosplenic disease; 4.6% of these will then go on to develop PAH. Schistosomiasis also may cause postcapillary hypertension, reinforcing the need for diagnosis with right-sided heart catheterization.

Chronic Hemolytic Anemia

Increasing evidence suggests that PAH is a complication of chronic hereditary and acquired hemolytic anemias, including sickle cell disease, thalassemia, hereditary spherocytosis, stomatocytosis, and microangiopathic hemolytic anemia. The mechanism of PAH in hemolysis is uncertain but may involve high rates of nitric oxide consumption by free hemoglobin, resulting in a state of resistance to nitric oxide bioactivity.

GROUP 1′: PULMONARY ARTERIAL HYPERTENSION ASSOCIATED WITH PULMONARY VENOUS OR CAPILLARY ABNORMALITIES

Rarely, the typical findings in PAH also are associated with an occlusive venopathy—*pulmonary venoocclusive disease* (PVOD)—or a microvasculopathy—*pulmonary capillary hemangiomatosis* (PCH). Patients with these diseases exhibit features of both PAH and pulmonary venous hypertension, including pulmonary hemosiderosis, interstitial edema, and lymphatic dilatation. PVOD and PCH share similar risk factors including the scleroderma spectrum of disease, HIV infection, and the use of anorexigens. These entities should be suspected in the clinical setting of PAH associated with crackles on auscultation, digital clubbing, and pulmonary edema. Ground glass opacities, septal thickening, and mediastinal adenopathy may be seen on chest computed tomography scans. PVOD and PCH are set aside from the other members of group 1 because the management, response to medical therapy (patients with PVOD and PCH tend to develop pulmonary edema after the administration of PAH-specific therapies), and prognosis are quite different from that of PAH.

GROUP 2: PULMONARY HYPERTENSION DUE TO LEFT-SIDED HEART DISEASE

Pulmonary hypertension due to left-sided heart disease is defined as a mPAP greater than 25 mm Hg measured with the subject at rest with an elevated PCWP and/or LVEDP. It represents the most frequent cause of PH (accounting for more than 90% of the cases). Causes include systolic and diastolic heart failure as well as left-sided valvular disease. Guidelines have defined a PCWP and/or LVEDP less than 15 mm Hg as abnormal. In these patients, the PVR is normal or near normal (less than 3.0 Wood units), and no gradient significant is present between mPAP and pulmonary wedge pressure (i.e., the transpulmonary gradient is less than 12 mm Hg). In some patients with left-sided heart disease, the elevation of PAP is out of proportion to that expected from the elevation of the left atrial pressure, resulting in an increased PVR. This is due to either the increase in pulmonary artery vasomotor tone or pulmonary vascular remodeling, or both. No studies using medications approved for PAH have been performed in this patient population, and the efficacy and safety of PAH treatment medications remain unknown.

GROUP 3: PULMONARY HYPERTENSION DUE TO LUNG DISEASE AND/OR HYPOXIA

Pulmonary hypertension associated with disorders of the respiratory system or hypoxemia is a category of PH that is caused mainly by inadequate oxygenation of pulmonary arterial blood as a result of either parenchymal lung disease (e.g., emphysema, interstitial lung disease), impaired control of breathing (e.g., obesity hypoventilation, obstructive sleep apnea), or residence at high altitude. As a rule, mPAP generally is modest (less than 35 mm Hg), and survival depends on the severity of the pulmonary disease, rather than on the severity of the associated hypertension. As with the category of PH out of proportion to left-sided heart disease, large randomized, controlled studies of medications approved for PAH are not available for PH out of proportion to parenchymal lung disease.

GROUP 4: CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Chronic thromboembolic pulmonary hypertension (CTEPH) is an important category of PH to exclude, because a proximal organized clot in the major pulmonary arteries may be surgically correctable by pulmonary endarterectomy. In all cases, life-long anticoagulation is indicated. The cumulative incidence of CTEPH after a first episode of pulmonary embolism approaches 4% at the 2-year follow-up examination.

GROUP 5: PULMONARY HYPERTENSION OF UNCLEAR OR MULTIFACTORIAL ETIOLOGY

Group 5 consists of several forms of PH for which the etiology is unclear or multifactorial. Potential etiopathogenic disorders include chronic myeloproliferative disorders (polycythemia vera, essential thrombocythemia, chronic myeloid leukemia), systemic disorders (sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis type 1, antineutrophil cytoplasmic antibody [ANCA]-associated vasculitis), metabolic disorders (type Ia glycogen storage disease, Gaucher disease, thyroid disease), and miscellaneous conditions (tumor obstruction, mediastinal fibrosis, end-stage renal disease).

PATHOBIOLOGY

Normal pulmonary arteries have a thin medial layer of circular muscle whose thickness is less than 5% of the diameter of the vessel (see Figure 58-1, *A*). Consequently, under physiologic conditions, the pulmonary circulation is characterized by high flow, low pressure, and low vascular resistance. The histopathologic findings in PAH are characterized by variable intimal hyperplasia, medial hypertrophy, adventitial proliferation, and fibrosis culminating in concentric obliterative lesions (see Figure 58-1, *B*) that occur in close proximity to plexiform lesions (see Figure 58-1, C). The plexiform lesion results from neointimal proliferation and progresses from a cellular to a fibrotic lesion with advancing disease. It is made up of a predominance of endothelial cells in different stages of vascular organization, suggesting an abnormal form of angiogenesis. Pulmonary vascular remodeling also has been associated with in situ thrombosis and infiltration by inflammatory and progenitor cells.

As the vascular pathology progresses, the PVR increases and PAP rises in concert, in order to maintain cardiac output. So long as the right ventricle is able to compensate for the resistance, the pressure continues to increase as the PVR increases. When the contractile reserve of the right ventricle is exhausted, right ventricular systolic failure ensues. A varying degree of right ventricular diastolic dysfunction also is present in PH and is related to right ventricular muscle mass and afterload and correlates with parameters of disease severity. The combination of reduced right ventricular output and diastolic dysfunction enhances diastolic interdependence, severely impairing left ventricular filling and ultimately resulting in hemodynamic deterioration.

Unfortunately, what is known about the pathobiology of PAH largely stems from research in patients with IPAH or from animal models that are meant to represent IPAH. Nevertheless, the pathobiologic features of PAH are thought to result from a multiple-hit hypothesis involving the interaction of a predisposing state with an inciting stimulus (**Figure 58-2**). Consequently, the resulting imbalance favors vasoconstriction, thrombosis, and mitogenesis. Restoration of this balance by inhibition of endothelin and thromboxane or augmentation of nitric oxide and prostacyclin forms the basis of today's current therapies.

Prostacyclin (i.e., prostaglandin I_2 [PGI_2]) is a product of endothelial cells generated by the action of prostacyclin synthase on arachidonic acid. Prostacyclin relaxes smooth muscle by increasing intracellular cyclic adenosine monophosphate (cAMP). It also is an inhibitor of platelet aggregation and smooth muscle cell proliferation. Patients with PAH exhibit increased excretion of urinary metabolites of thromboxane and decreased excretion of urinary metabolites of prostacyclin in comparison with normal control subjects. Likewise, prostacyclin synthase activity is reduced in patients with PAH.

Endothelin-1 is synthesized and secreted by endothelial cells and is metabolized in the normal lung. It is a potent acute

vasodilator and chronically stimulates cellular proliferation and fibrosis. Patients with PAH exhibit increased plasma levels of endothelin-1 and decreased clearance in comparison with normal control subjects.

Nitric oxide is a potent vasodilator that is produced by endothelial cells from arginine by nitric oxide synthase and acts on the vascular smooth muscle cells via cyclic guanosine monophosphate (cGMP). Phosphodiesterase-5 degrades cGMP, thus counteracting this vasodilatory pathway. Patients with PAH have decreased plasma levels of nitric oxide metabolites; likewise, endothelial nitric oxide synthase (eNOS) expression is reduced in the pulmonary arteries.

Ongoing research on other mediators and pathways (Table 58-1) promises new targets for novel therapies.

DIAGNOSTIC APPROACH

The diagnosis of PH is complex and should involve early referral to a provider with expertise in the diagnosis and treatment of the condition. Patients may present because they are concerned about symptoms, because they require further investigation of an incidental finding during previous testing, or because they belong to a high-risk population (e.g., systemic sclerosis, congenital heart disease, liver transplantation evaluation).

SIGNS AND SYMPTOMS

There are no early signs or symptoms of PH. Therefore, annual screening should be performed in high-risk populations (Table 58-2). A diagnosis of PH should be considered in any patient who presents with breathlessness in the absence of specific cardiac or pulmonary disease, or in patients who have underlying cardiac or pulmonary disease and present with increasing breathlessness that is not explained by the underlying disease itself. The initial symptoms and signs are nonspecific and may

Table 58-1 Mediators and Pathways in Pulmonary Arterial Hypertension

Increased Activity	Decreased Activity
Endothelin-1	Prostacyclin synthase
Serotonin	Nitric oxide
Thromboxane A_2	Nitric oxide synthase
Angiopoietin-1	Vasoactive intestinal peptide
Plasminogen activator inhibitor-1	Voltage-gated potassium channels
Growth factors	Fibrinolysis
Oxidant stress	
Inflammation	

Table 58-2 Recommendation for Screening for Pulmonary Arterial Hypertension

Risk Factor	Recommendation
Family history of PAH	Yes
Connective tissue disease	
Scleroderma	Yes
Other	No
Congenital heart disease	
Large ASD, nonoperated	Yes
Large VSD, nonoperated	Yes
HIV infection	No

include fatigue, progressive dyspnea on exertion, palpitations, chest pain, dizziness, and cough. Unfortunately, the mean duration of symptoms before diagnosis reported in most registries approaches 2 years. Exertional dizziness and syncope are suggestive of an inadequate cardiac output and should raise clinical suspicion for PH. As PH progresses, patients go on to develop symptoms and signs of right-sided heart failure including jugular venous distention, right ventricular heave, tricuspid regurgitation, right ventricular gallops, ascites, and edema. Establishing an accurate diagnosis has important implications for therapy.

ELECTROCARDIOGRAM

The electrocardiogram shows abnormalities in 85% of patients with established PH but is not adequately sensitive as a screen for PH. Typical changes include right axis deviation with evidence of right ventricular or right atrial hypertrophy and right ventricular strain (Figure 58-3). The degree of these changes does not always reflect the severity of disease, and a normal ECG appearance does not eliminate the diagnosis of PH. Nevertheless, the following ECG findings have negative prognostic implications: (1) right axis deviation, (2) a tall R wave and small S wave with R/S ratio greater than 1 in lead V_1, (3) qR complex in lead V_1, (4) rSR′ pattern in lead V_1, (5) a large S wave and small R wave with R/S ratio less than 1 in lead V_5 or V_6, or (6) S_1-S_2-S_3 pattern (see Figure 58-3).

CHEST RADIOGRAPH

The chest radiograph also is not particularly sensitive for detecting PH. However, incidental findings of enlarged main and hilar pulmonary arterial shadows (right descending greater than 1.6 cm, left greater than 1.8 cm), with concomitant attenuation of peripheral pulmonary vascular markings ("pruning"), and right ventricular hypertrophy as evidenced by a reduced retrosternal clear space on the lateral projection should prompt a workup for PH. Chest radiographic findings also may lead to the diagnosis of an underlying pulmonary process (Figure 58-4).

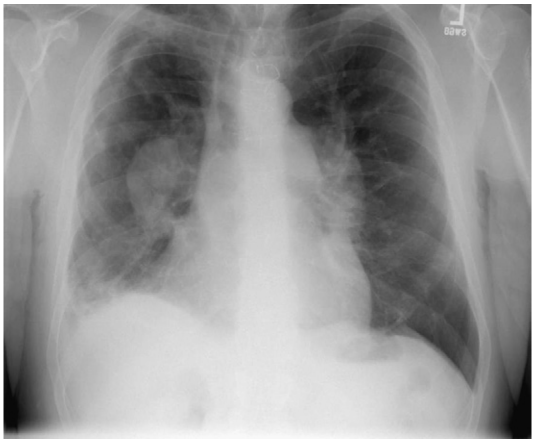

Figure 58-4 Chest radiograph obtained in a patient with pulmonary arterial hypertension (PAH). Note the massively enlarged pulmonary arteries and peripheral "pruning."

PULMONARY FUNCTION TESTING

Pulmonary function testing is a necessary part of the initial evaluation of all patients with PH, to exclude or characterize the contribution of underlying airway or parenchymal lung disease. On such testing, patients with IPAH and CTEPH typically exhibit a mild to moderate restrictive ventilatory defect and evidence of small airways dysfunction with a reduction in diffusion capacity. No correlation has been observed between the severity of PH and the reduction in diffusion; however, an isolated reduction in diffusion should alert the physician to the possibility of underlying PH. Arterial blood gas analysis typically shows hypoxemia, hypocapnia secondary to alveolar hyperventilation, and an increased alveolar-arterial oxygen gradient. Severe hypoxemia usually is the result of intracardiac shunting.

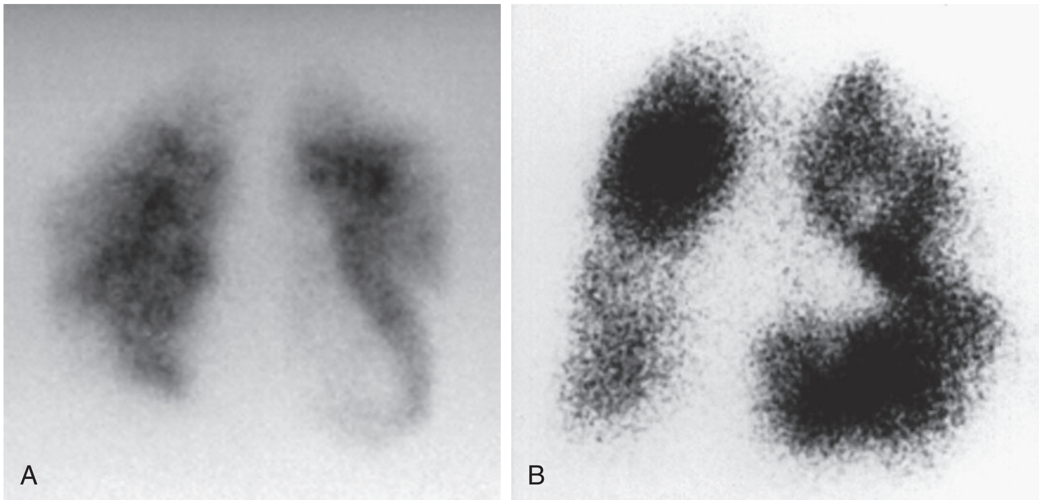

Figure 58-5 **A,** Patchy subsegmental defects on perfusion scan obtained in a patient with pulmonary arterial hypertension (PAH). **B,** Multiple segmental (or larger) defects on perfusion scan obtained in a patient with chronic thromboembolic pulmonary hypertension (CTEPH). *(From Reed AK, Evans TW, Wort SJ: Pulmonary hypertension. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, Mosby, 2008.)*

OVERNIGHT OXIMETRY/POLYSOMNOGRAPHY

Nocturnal desaturation in PH is related primarily to gas exchange abnormalities. Although the clinical consequence of nocturnal desaturation is not well understood, it is likely that hypoxia-induced pulmonary vasoconstriction exacerbates the preexistent pulmonary hypertensive state. Nocturnal desaturation cannot be predicted by exercise desaturation; therefore, overnight oximetry is recommended in all patients with PH. Use of standard oxygen-prescribing guidelines, such as those derived from the Nocturnal Oxygen Treatment Trial, are recommended for hypoxemic patients with PH to maintain an oxygen saturation greater than 90% in adults.

The literature examining the relationship between obstructive sleep apnea and PH is difficult to interpret. In general, pulmonary hypertension associated with obstructive sleep apnea is mild with an average mPAP less than 30 mm Hg. It is recommended that all patients with PH be assessed for sleep-disordered breathing, and polysomnography should be performed if the clinical presentation is highly suggestive of obstructive sleep apnea. Although these patients are at higher risk for other cardiovascular morbidity, routine screening for PH with echocardiography is not recommended in patients with obstructive sleep apnea. In patients with concomitant obstructive sleep apnea and PH, treatment of the sleep apnea with positive-pressure therapy should be provided, with the expectation that pulmonary pressures will decrease, although they may not normalize, particularly when PH is more severe.

VENTILATION-PERFUSION SCAN

PH caused by chronic thromboembolic disease is a potentially surgically curable condition that should be considered in all patients with unexplained PH. A ventilation-perfusion scan is essential to rule out chronic thromboembolic disease in all patients with unexplained pulmonary hypertension; a normal scan effectively excludes a diagnosis of chronic thromboembolic disease. In patients with PAH, the ventilation-perfusion scan typically is normal or displays only minor, patchy perfusion defects, whereas in patients with CTEPH, at least one but often several major segmental or subsegmental mismatches in ventilation and perfusion will be evident (Figure 58-5, *A* and *B*). Unmatched perfusion defects also may be seen in PVOD. The "gold standard" diagnostic modality remains contrast angiography performed at the time of catheterization, which is able to characterize the nature and extent of any thromboembolic disease.

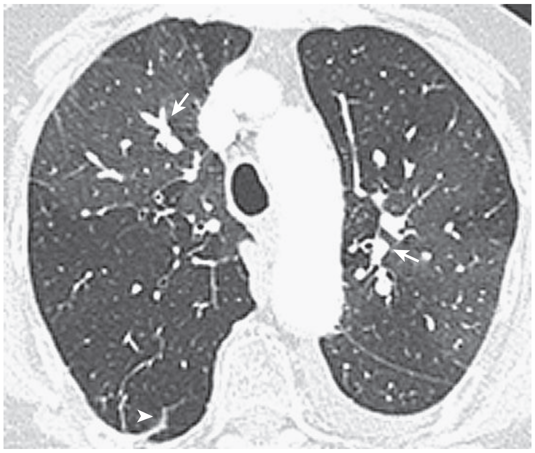

Figure 58-6 Computed tomography angiogram obtained in a patient with chronic thromboembolic pulmonary hypertension (CTEPH). Note the mosaic pattern of perfusion.

CHEST COMPUTED TOMOGRAPHY

A wide spectrum of abnormalities on computed tomography (CT) scanning has been described in patients with chronic thromboembolic disease. Such abnormalities may include right ventricular enlargement, dilated central pulmonary arteries, presence of persistent thromboembolic material within central pulmonary arteries, increased bronchial artery collateral flow, variability in the size and distribution of pulmonary arteries, parenchymal abnormalities consistent with previous infarcts, or mosaic attenuation of the pulmonary parenchyma (Figure 58-6). These are nonspecific findings, however, and their absence does not exclude the presence of surgically accessible disease, because only sixth- or seventh-generation pulmonary arteries

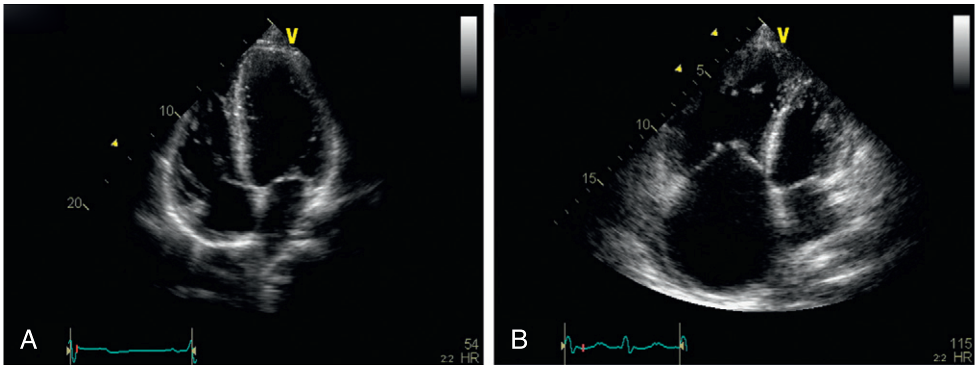

Figure 58-7 **A,** Echocardiogram, four-chamber view, obtained in a normal subject. **B,** Echocardiogram, four-chamber view, obtained in a patient with pulmonary arterial hypertension (PAH). Note the enlarged right atrium, right ventricle with intraventricular septal flattening, and small dimension of the left ventricle.

can be visualized with confidence. Therefore, contrast-enhanced CT should not be used to exclude the diagnosis of chronic thromboembolic disease.

High-resolution CT (HRCT) scanning, however, is required to exclude parenchymal lung disease as the cause of PH and may be particularly useful in helping to make the diagnosis of PVOD.

ECHOCARDIOGRAM

In patients in whom the clinical picture is suggestive of PH or in asymptomatic patients at high risk for the condition, Doppler echocardiography should be performed as a noninvasive screening test to detect elevated sPAP. It provides a noninvasive estimation of right ventricular function and sPAP and can reveal other underlying cardiac abnormalities.

Signs indicative of PH on echocardiogram include increased sPAP or tricuspid regurgitant jet, right atrial and ventricular hypertrophy, flattening of the intraventricular septum, small left ventricular dimension, and a dilated pulmonary artery (Figure 58-7, *A* and *B*). A pericardial effusion in the setting of PH carries a poor prognosis. Although echocardiography has been found to correlate with right-sided heart catheterization, Doppler echocardiography generally underestimates systolic PAP in patients with severe PH and overestimates systolic PAP in populations consisting mostly of subjects with normal pressures. Furthermore, the systolic PAP may fall in decompensated right ventricular heart failure (Figure 58-8). Echocardiography also is particularly inaccurate in persons with advanced lung disease and both underestimates and overestimates the degree of PH in these patients. With echocardiographic evidence of significant PH, a right-sided heart catheterization should always be undertaken at least once to provide an accurate baseline assessment of the pulmonary hemodynamics and to permit reversibility studies. Echocardiography is, however, useful in following disease progression, removing the need for repeated pulmonary artery catheterizations.

Contrast echocardiography can be useful to assess for intracardiac shunting suggesting the possibility of a congenital heart defect or patent foramen ovale. Agitated saline contrast or commercially available encapsulated microbubble contrast agents also can be used to enhance the spectral tricuspid regurgitant signal. As a general rule, a right ventricular systolic pressure greater than 40 mm Hg generally warrants further evaluation in the patient with unexplained dyspnea. An abnormal right-sided morphology or function also should trigger further evaluation.

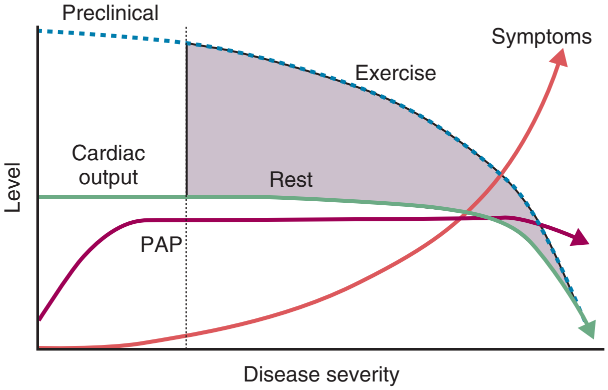

Figure 58-8 Pathophysiology of pulmonary arterial hypertension. In the early stages, cardiac output remains normal at rest but fails to increase appropriately with exercise. With disease progression, cardiac output falls and is subnormal even when the patient is at rest. *PAP*, pulmonary artery pressure. *(From Reed AK, Evans TW, Wort SJ: Pulmonary hypertension. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, Mosby, 2008.)*

Exercise echocardiography is challenging both to perform and to interpret and may not be able to discern the extent to which elevated left-sided heart filling pressure may contribute to “exercise-induced pulmonary hypertension.” Therefore, no treatment decisions can be made on the basis of exercise-induced pulmonary hypertension alone.

RIGHT-SIDED HEART CATHETERIZATION

In patients with suspected PH, right-sided heart catheterization is required to confirm the presence of PH, to establish the specific diagnosis, and to determine the severity and prognosis of PH. In particular, an elevated right atrial pressure and a depressed cardiac output are associated with worse prognosis and decreased survival. The PCWP is, by definition, normal in PAH. An elevated PCWP in the absence of left-sided heart disease should raise clinical suspicion for PVOD, although the PCWP also is commonly normal, in keeping with the patchy nature of this disease. The transpulmonary gradient (i.e., mPAP – PCWP) is significantly elevated in patients with PAH, but not in patients whose PH is due to increased cardiac output or left-sided heart myocardial or valvular disease. In other words, by definition, both PAP *and* PVR are elevated in patients with PAH.

Right-sided heart catheterization also can be used to evaluate for vasoreactivity and to guide therapy; a favorable acute response to a vasodilator (intravenous epoprostenol, adenosine, or inhaled nitric oxide) is defined as a fall in mPAP of at least 10 mm Hg to 40 mm Hg or less, with an increased or unchanged cardiac output. These "responders" have an improved survival when treated with calcium channel blockers (a 95% 5-year survival rate has been reported). Of note, patients with suspected PVOD should not be subjected to vasoreactivity studies, because such testing may precipitate life-threatening pulmonary edema.

FUNCTIONAL ASSESSMENT

In patients with PAH, serial determinations of functional class and exercise capacity assessed by the 6-minute walk test provide benchmarks for disease severity, response to therapy, progression, and survival. WHO functional classification of patients with PAH is based on a modification of the New York Heart Association (NYHA) system for heart failure and takes syncope into account as a marker of functional status.

The 6-minute walk test is simple and reproducible and has been used as the primary end point in a number of clinical trials for PAH. The 6-minute walk distance correlates inversely with functional class and PVR and directly with baseline cardiac output, peak exercise oxygen consumption, and survival. This test, however, gives no indication of the source of exercise impairment and is less discriminatory for walk distances greater than 450 m ("plateau effect"). Consequently, it is less useful for patients with systemic disease and those assigned to functional class I or II.

Although CPET is used less frequently in PAH clinical trials, owing to a lack of methodologic consistency among different centers, maximal oxygen consumption (peak V_{O_2}) determined by progressive exercise testing with cycle ergometry was found to be an independent predictor of survival in a study in patients with IPAH. In this study, a peak V_{O_2} greater than 10.4 mL/kg/minute was associated with significantly better 1-year survival than lower peak V_{O_2} values. Patients with a peak systemic blood pressure higher than 120 mm Hg also enjoyed a better 1-year survival than those patients who did not achieve this systemic blood pressure.

BIOMARKERS

Brain natriuretic peptide (BNP) is released from cardiac myocytes in response to increased ventricular wall tension. ProBNP (the prohormone) is cleaved into active BNP and the more stable amino-terminal (N-terminal) fragment (NT) proBNP. Studies in patients with PAH have demonstrated that plasma BNP and/or proBNP levels are raised in proportion to the extent of right ventricular dysfunction. Growing evidence suggests that BNP may be a potential biomarker for PAH in screening for occult disease, diagnostic evaluation, gauging prognosis, and predicting response to therapy. Baseline and serial changes in BNP correlate well with mortality and other markers such as pulmonary hemodynamics, WHO functional class, and 6-minute walk test. Of note, however, because plasma BNP levels rise in a variety of cardiopulmonary conditions and are affected by several physiologic factors, interpretation of BNP assay results requires experience and good clinical judgment; NT proBNP may have an advantage over BNP, because it is less affected by renal function and age.

Other biomarkers of interest include uric acid and troponin levels. In IPAH, uric acid levels may reflect impaired oxidative metabolism and have been shown to be increased with worsening severity of functional class and hemodynamics and correlated with mortality. Detectable cardiac troponin T also confers a poor prognosis, potentially as a consequence of the effect of right ventricular ischemia.

CARDIAC MAGNETIC RESONANCE IMAGING

Cardiac magnetic resonance imaging (MRI) is now the most accurate means for examination of the structure and function of the right ventricle and is able to accurately assess the size and function of the right ventricle with a high degree of reproducibility. Right ventricular function is an important prognostic indicator in PAH and cardiac MRI of poor right ventricular function, including stroke volume of 25 mL/m^2 or less, right ventricular end-diastolic volume of 84 mL/m^2 or greater, and left ventricular end-diastolic volume of 40 mL/m^2 or less, were found to be independent predictors of mortality and treatment failure, and pulmonary artery stiffness, as measured by relative cross-sectional area change, was predictive of survival in a cohort of 86 patients with PAH studied with MRI. Those with a relative cross-sectional area change of less than 16% had a greater mortality than those with values greater than 16%. The use of noninvasive imaging, such as cardiac MRI, to monitor disease-targeted therapy currently is being evaluated.

OTHER BLOOD TESTS

All patients should have routine hematology, biochemistry, and thyroid function tests. Antinuclear antibody testing frequently gives a positive result in patients with PAH despite absence of connective tissue disease (29% in the National Institutes of Health [NIH] registry) despite the absence of connective tissue disease. These usually are of a nonspecific pattern and are present in low titers. Strongly positive results on serologic testing should lead to further, more specific investigations to exclude PAH related to connective tissue disease. HIV testing should be considered in all patients presenting with apparent PAH.

APPROACH TO THERAPY

Treatment goals for patients with PAH include reduction in clinical signs and symptoms and improvement in exercise tolerance, functional class, hemodynamics, and quality of life, along with decreased need for hospitalization or lung transplantation (or both) and longer survival. The recommended approach to treatment can be divided into two categories: general care and PAH-specific therapy.

GENERAL THERAPY

It is expert opinion that all patients with PAH and documented hypoxemia should be on supplemental oxygen to maintain oxygen saturation above 90%. A sodium-restricted diet also is indicated in patients with PH to help maintain volume status and is particularly important in patients with right ventricular failure. Careful diuresis is indicated in patients with evidence of right ventricular failure. Caution must be exercised to avoid overdiuresis, however, because right ventricular performance is highly dependent on preload for maintenance of adequate cardiac output and systemic blood pressure.

Digoxin may produce a modest increase in cardiac output in patients with PH and right ventricular failure, along with a significant reduction in circulating norepinephrine, although the use of cardiac glycosides in treating right-sided heart dysfunction is controversial owing to the lack of prospective randomized, double-blind, placebo-controlled trials.

Improved survival has been reported with oral anticoagulation in patients with idiopathic PAH, and anticoagulation is recommended for all patients with PAH after analysis of the risk-benefit ratio for bleeding complications.

Arrhythmias, particularly atrial flutter and other tachyarrhythmias, are very poorly tolerated and often result in worsening right ventricular function. Prognosis is improved if sinus rhythm is restored. Cardioversion may be performed electrically or chemically with amiodarone, but ablation therapy may be a better option. Right ventricular failure may worsen with the addition of therapeutic agents that are strong negative inotropes.

Pregnancy and the postpartum period are associated with greater than 50% mortality in patients with PH. Therefore, the WHO recommends adequate birth control and advises discussion of termination of any pregnancy.

Patients should be immunized annually against influenza and pneumococcal pneumonia. They also should be instructed to seek the advice of their PAH treatment center for appropriate management before undergoing any form of elective surgery.

Exposure to high altitudes may contribute to hypoxic pulmonary vasoconstriction. Therefore, patients with an oxygen saturation of less than 92% should receive supplemental oxygen during air travel and when participating in sports and other activities at higher altitudes.

Calcium Channel Blockers

Calcium channel blockers may precipitate right-sided heart failure because of the negative inotropic properties of these agents and should be used only in the rare patient who has a documented vasoreactive response during right-sided heart catheterization. If the functional status of a patient who meets the definition of an acute responder does not improve to class I or II, an alternative or additional PAH therapy should be instituted. Owing to its potential negative inotropic effects, verapamil should be avoided. The main limitations to therapy in responders are systemic hypotension, peripheral edema, and hypoxia caused by increased ventilation-perfusion mismatch. More severe adverse reactions, including arrhythmias, cardiogenic shock, and death, have been reported.

DISEASE-TARGETED THERAPIES

In general, oral therapies are considered first-line treatment for PAH in patients of functional classes II and III, whereas parenteral therapy should be considered in patients of functional class IV. Clinical trials using combination therapy currently are under way. Although currently no consensus has been reached on how to monitor patients for PAH, a clear survival benefit has been recognized for goal-directed therapy. Most experts reevaluate patients every 3 to 4 months by functional class, 6-minute walk testing, and BNP assay. Follow-up echocardiography and right-sided heart catheterization also are done on a routine basis.

Phosphodiesterase Type-5 Inhibitors

The pulmonary vasodilating effects of nitric oxide are mediated through cGMP. Nitric oxide activates guanylate cyclase, which increases cGMP production. Cyclic GMP causes vasorelaxation, but its effects are attenuated by the rapid degradation of cGMP by phosphodiesterase. Sildenafil and tadalafil inhibit phosphodiesterase type 5, thus enhancing relaxation and growth inhibition of vascular smooth muscle cells. Both have demonstrated improvement in exercise capacity and functional class. In its pivotal trial, sildenafil also effected improvement in hemodynamics but did not meet the end point "time to clinical worsening," which was met in the pivotal trail for tadalafil. Side effects include headache, flushing, dyspepsia, and epistaxis. These drugs are contraindicated in patients on nitrates because of the potential for an unsafe drop in blood pressure.

Endothelin Receptor Antagonists

Endothelin-1 is a potent vasoconstrictor and smooth muscle mitogen that is overexpressed in the plasma and lung tissue of patients with PAH. Bosentan is an oral nonselective endothelin receptor antagonist, whereas ambrisentan is an oral selective endothelin type A receptor antagonist. Both of these agents have been shown to improve exercise capacity, functional class, and time to clinical worsening. In one of its pivotal trials, bosentan also was shown to improve hemodynamics. Abnormal hepatic function, defined as elevation of hepatic transaminases to three times the upper limit of normal or higher, is seen in approximately 10% of patients on bosentan and approximately 2% of patients on ambrisentan. Consequently, the U.S. Food and Drug Administration (FDA) mandates monthly liver function testing in those patients on bosentan.

In addition to potential hepatotoxicity, other side effects include anemia and the development of edema. The endothelin receptor antagonists (ERAs) are classified as pregnancy category X, so monthly pregnancy tests are required in women of child-bearing potential.

Prostanoids

Prostacyclin is a potent vasodilator and inhibitor of platelet activation and smooth muscle proliferation. Three prostanoids that have been shown to improve exercise capacity, quality of life, functional class, and hemodynamics are epoprostenol, treprostinil, and iloprost. Regimens proven effective include continuous intravenous epoprostenol therapy; inhaled, subcutaneous, and intravenous treprostinil therapy; and inhaled iloprost. Epoprostenol also has been shown to improve survival. Their respective delivery systems are complex and require collaboration with a clinical center with appropriate expertise.

Expert consensus recommends intravenous epoprostenol therapy as first-line treatment for patients with WHO class IV disease and those with class III disease in whom treatment with other disease-targeting therapies has failed to effect improvement. The main drawbacks to intravenous therapy with epoprostenol are its short half-life (approximately 2 to 5 minutes), invasive mode of delivery, expense, and side effects, which include jaw pain, flushing, diarrhea, headache, backache, leg pain, and hypotension. Catheter-related adverse effects include infection, thrombosis, pump failure, and rebound PAH.

Compared with epoprostenol, treprostinil has a longer half-life (approximately 4 hours), so it can be administered by continuous subcutaneous infusion or intravenously. Treprostinil has a side effect profile similar to that for epoprostenol, with two notable differences: The subcutaneous route is associated with significant pain at the infusion site, often resulting in discontinuation of therapy, and the intravenous route is associated with an increased risk of bloodstream infections, particularly gram-negative infections.

Iloprost is a stable prostacyclin analogue that can be given by inhalation but has a relatively short duration of action and must be inhaled between six and nine times per day, whereas treprostinil can be inhaled four times daily. Both inhaled prostanoids require unique devices for drug delivery and are associated with cough.

Rehabilitation

Data on which to base recommendations regarding exercise are limited; nevertheless, experts recommend low-level aerobic exercise and supervised pulmonary rehabilitation. Patients should be advised to avoid heavy physical exertion or isometric exercise, because such effort may evoke exertional syncope.

Surgical Options

Atrial Septostomy

The use of atrial septostomy should be limited to patients who have signs of right-sided heart failure and syncope and who are on maximal medical therapy. It often is viewed as a bridge to transplantation. Atrial septostomy creates a left-to-right intracardiac shunt that decompresses the right side of the heart, increases left ventricular preload, and augments systemic cardiac output. Thus, despite significant arterial oxygen desaturation, oxygen delivery to the tissues can be improved. The procedure is associated with significant mortality and should be performed only in specialized centers.

Lung Transplantation

Lung transplantation should be considered for patients who fail to improve on prostanoid therapy and those who remain in functional class III or IV. Little difference in efficacy between single lung, bilateral sequential lung, and heart-lung transplantation has been noted, with survival rates of 70% to 80% at 1 year and 50% to 60% at 4 years regardless of the procedure performed. Single-lung transplantation is more complicated in the immediate postoperative period because of reperfusion edema in the transplanted lung. Because of the limited availability of organ transplants, heart-lung blocks are reserved for patients with left-sided heart disease or congenital heart disease coexistent with Eisenmenger syndrome.

Pulmonary Thromboendarterectomy

Pulmonary thromboendarterectomy (PTE) is the treatment of choice for patients with proximal CTEPH and offers a potential cure in carefully selected patients. This procedure is performed in just a few specialized centers. During PTE, organized thromboembolic material is carefully removed from the affected pulmonary arteries under hypothermic circulatory arrest, attempting to restore pulmonary hemodynamics to normal or near normal levels. Those patients with a disproportionately higher PVR than would be expected from the segmental obstruction seen on imaging have a higher mortality and benefit less from PTE. With advances in both surgical technique and postoperative intensive care, the procedure-associated mortality rate has progressively diminished to approximately 6% to 8%. More than 90% of survivors return to functional class I or II. Patients with CTEPH caused by distal disease are not amenable to such treatment, and evidence is emerging for PAH-specific mediations in this group.

SURVIVAL AND OUTLOOK

The natural history of IPAH has been well characterized, with an estimated mean survival period of 2.8 years and 1-, 3-, and 5-year survival rates of 68%, 48%, and 34%. Prognostic indicators generally are related to right ventricular function and include clinical and echocardiographic evidence of right ventricular failure or dysfunction, poor exercise tolerance, advanced functional class, elevated serum concentrations of BNP, and poor hemodynamics (elevated right atrial pressure, decreased cardiac index). Patients with these risk factors should be considered for early initiation of prostanoid therapy.

Different survival curves have emerged for the different types of PAH. For example, survival typically is better in patients with congenital heart disease than in patients with IPAH, but worse in patients with connective tissue disease (reported rate of 40% at 2 years). This difference highlights another limitation of the classification scheme: Although the different types of PAH share similar pathobiologic features, key differences are recognized: different responses of the right ventricle (congenital heart disease), differences in the pathologic lesions (absence or reduced presence of the plexiform lesion seen in the connective tissue diseases), presence or absence of concomitant left ventricular diastolic dysfunction and/or pulmonary fibrosis (commonly seen in scleroderma), and differing responses to vasodilatation, hyperdynamic or high-flow states (congenital heart disease, portopulmonary hypertension, and chronic hemolysis), and other comorbid conditions seen in all of the “associated” forms of PAH. Fortunately, data suggest that mortality is decreasing in today’s era of expanding PAH therapy.

The past decade has brought a more thorough understanding of the pathogenesis of PAH, improved methods of detection, and better treatment options, which together have resulted in improved exercise tolerance and quality of life along with increased time to clinical worsening and survival.

CONTROVERSIES AND PITFALLS

- *Combination therapy*: Combination therapy that uses drugs with different therapeutic mechanisms is an attractive option for patients who fail to improve or deteriorate with first-line treatment (monotherapy), but trials to confirm the value of this approach are ongoing and may be limited by the expense of these therapies. Many experts are interested in the concept of induction therapy followed by tailoring to a maintenance regimen.
- *Out-of-proportion magnitude of pulmonary hypertension*: Most patients present with features of more than one WHO group. Unfortunately, clinical trials are lacking in patients with PH that is out of proportion to their parenchymal lung disease or left heart dysfunction. Decisions on how to treat these patients are limited to anecdotal reports and the clinician’s own experience.
- *Peripheral/nonoperable CTEPH:* Data on use of PAH therapies for patients with peripheral or nonoperable CTEPH are evolving, but large clinical trials showing a benefit in this population also are lacking
- *Exercise-induced pulmonary hypertension*: Convincing data show that patients should be treated early for their PH; however the exercise definition (greater than 30 mm Hg) for PH was removed at the most recent symposium in Dana Point. Further studies regarding exercise hemodynamics are sorely needed to allow for earlier detection and treatment, with consequent better prognosis.
- *Associated PAH*: Most of what is known about PAH comes from IPAH; likewise, clinical trials largely comprise patients with IPAH, with a minority of patients with scleroderma spectrum of disease and occasionally diet drugs–related PAH or congenital heart disease. Caution should be taken before applying these data to all forms of PAH.

PULMONARY VASCULAR DISORDERS, VASCULITIDES, AND HEMORRHAGE

Chapter 59

Pulmonary Vasculitis and Hemorrhage

Ulrich Specks

PULMONARY VASCULITIS

Pulmonary vasculitis is defined as inflammation of vessels in the lung of different sizes—pulmonary arteries, veins, and capillaries, as well as bronchial arteries. It usually is only one manifestation of a systemic disorder caused by any of a variety of immunologic mechanisms. Moreover, not all respiratory symptoms occurring in patients with vasculitis are caused by inflammation of pulmonary vessels.

Primary vasculitis is separated from secondary vasculitis. The primary systemic vasculitides are a heterogeneous group of syndromes, of unknown etiology, that share a clinical response to immunosuppressive therapy. Their wide spectrum of frequently overlapping clinical manifestations is defined by the size and location of the affected vessels as well as by the nature of the inflammatory infiltrate. Secondary vasculitis may occur in the context of a well-defined underlying disorder or may be attributable to a specific cause such as collagen vascular disease, infection, or therapeutic or illicit drug use.

Most classification schemes and definitions of the vasculitides are based on the size of the most prominently affected vessels. Definitions, nomenclature, and classification schemes have been and remain subject to change. The terms used in this chapter adhere to the nomenclature and definitions put forth by the Chapel Hill consensus conference in 1992.

SMALL VESSEL VASCULITIS

Antineutrophil Cytoplasmic Autoantibody–Associated Vasculitis

The primary systemic small vessel vasculitides are granulomatosis with polyangiitis (GPA) (i.e., Wegener granulomatosis), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA) (i.e., Churg-Strauss syndrome). In contrast with the other forms of systemic vasculitis with a predilection for larger vessels, most patients with active GPA and MPA and more than half of the patients with active EGPA have antineutrophil cytoplasmic autoantibodies (ANCA). Of all systemic vasculitides, the ANCA-associated vasculitides are most likely to cause respiratory manifestations. GPA and MPA are discussed together here, because the same diagnostic and therapeutic principles apply; EGPA is considered separately.

Granulomatosis with Polyangiitis and Microscopic Polyangiitis

Definitions and Nomenclature

GPA is characterized by necrotizing granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels. The most commonly affected vessels are capillaries, venules, arterioles, and arteries, but the wall of the aorta also may rarely be affected by necrotizing granulomatous inflammation—hence the term *polyangiitis.* Histopathologic documentation of granulomatous involvement of the respiratory tract is not explicitly required. Radiologic evidence or clinical examination findings highly predictive of granulomatous pathology are sufficient. Consequently, the diagnosis of GPA depends on a correlation of clinical, histopathologic, and serologic features. MPA is defined as necrotizing vasculitis with few or no immune deposits, affecting small vessels including capillaries, venules, or arterioles (polyangiitis). Necrotizing arteritis involving small and medium-sized arteries may be present. Necrotizing glomerulonephritis is very common; pulmonary capillaritis resulting in alveolar hemorrhage occurs frequently. The vasculitis of MPA is indistinguishable from that of GPA, and substantial clinical overlap has been observed. For these reasons, the therapeutic approach to patients with GPA and to those with MPA is governed by the same principles, and most clinical studies and therapeutic trials have combined both diseases.

Histopathologic features that define GPA and separate it from MPA include discrete or confluent necrotizing granulomatous inflammation with vasculitis. Fibrinoid necrosis, microabscesses, focal vasculitis, thrombosis, and fibrous obliteration of the vascular lumen also may be seen. Giant cells are a hallmark of the necrotizing granulomatous inflammation of GPA. Atypical and rare histopathologic features of GPA include organizing pneumonia, bronchocentric inflammation, and a marked number of eosinophils in the inflammatory infiltrates.

For treatment stratification, clinical disease activity is categorized as "limited disease" or "severe disease." *Severe disease* is either life-threatening or associated with involvement of an organ with potentially irreversible loss of function. Consequently, patients with any of the following disease manifestations should be labeled as having severe disease: alveolar hemorrhage, glomerulonephritis, eye involvement (except mere episcleritis), or nervous system involvement including sensorineural hearing loss. *Limited disease* includes essentially all patients who have nonsevere disease. The designation limited disease as used in the United States comprises what European investigators have referred to as "early-systemic disease" and "localized disease." Even though this separation is not based on well-defined biologic distinctions, most disease manifestations leading to the categorization as severe disease are caused by capillaritis. By contrast, most symptoms leading to the classification as limited disease are the result of necrotizing granulomatous inflammation. Patients with limited GPA have a more protracted disease course, a greater likelihood of experiencing a disease relapse after a period of remission, and a higher prevalence of destructive upper respiratory tract disorders (e.g., saddle nose deformity). Tracheobronchial disease involvement also is a feature of GPA not shared with MPA; it may present unique treatment challenges (as discussed later on).

Etiology and Pathogenesis

The etiology of ANCA-associated vasculitis remains unknown. Occupational exposures have been suggested as possible etiologic factors, including inhalation of silica-containing compounds, grain dust, and heavy metals. Infection has been linked to the onset of the disease as well as to relapses. A multifactorial genetic predisposition also may contribute to the development of ANCA-associated vasculitis. Last but not least, ANCA seem to play a pathogenic role for the development of vasculitis.

Clinical Presentation

The median age of patients at diagnosis is 45 years, but children as well as octogenarians may be affected. The average age at onset of GPA is about 10 years younger than for MPA. Men and women are affected equally. More than 90% of patients with GPA are white. The clinical presentation of GPA varies, ranging from subacute nonspecific respiratory illness to rapidly progressive alveolar hemorrhage syndrome. The characteristic disease manifestations of GPA affecting the respiratory tract are caused by necrotizing granulomatous inflammation. Ear, nose, and throat symptoms, initially noted by more than 85% of patients, may include rhinorrhea, purulent or bloody nasal discharge, nasal mucosal drying and crust formation, epistaxis, and otitis media. Paranasal sinus involvement manifesting as deep facial pain, nasal septal perforation, and ulceration of the vomer are important clinical signs. *Staphylococcus aureus* frequently is detected in the nose and sinuses and has been linked to relapses of the disease. Other signs include aphthous lesions of the nasal and oral mucosa and inflammation and destruction of the nasal cartilage leading to the so-called saddle nose deformity. Ulcerated lesions of the larynx and trachea are present in 30% of untreated cases and may cause hemoptysis.

Diagnostic Evaluation

The diagnostic evaluation of patients suspected of having GPA or MPA should include imaging of the chest, pulmonary function testing if the patient has any respiratory symptoms or abnormalities on the chest radiograph, measurements of erythrocyte sedimentation rate, C-reactive protein, complete blood count, serum chemistry panel, urine analysis and microscopy, and testing for ANCA.

Respiratory symptoms usually are associated with unilateral or bilateral radiographic abnormalities including infiltrates, nodules, or mass lesions, which may or may not cavitate. The nodules range in size from a few millimeters to several centimeters across. Solitary nodules also may occur. Unusual manifestations include lymphadenopathy, lobar consolidation, and large pleural effusions.

Tracheobronchial lesions are common and may be asymptomatic or mistaken for evidence of asthma. Pulmonary function testing including inspiratory and expiratory flow-volume loops may provide important clues to the presence of airway narrowing and should be part of the initial evaluation. Bronchoscopic inspection of the tracheobronchial tree is recommended for patients with unexplained respiratory symptoms, abnormalities on pulmonary function tests, or radiographic abnormalities.

Patients with GPA or MPA exhibit variable degrees of elevation of erythrocyte sedimentation rate or C-reactive protein levels. If GPA or MPA is suspected, urine analysis and microscopy and serum creatinine determination are crucial, because early renal involvement may be clinically silent yet can progress rapidly.

In GPA and MPA, ANCA that cause a cytoplasmic immunofluorescence pattern (c-ANCA) on ethanol-fixed neutrophils are caused by the reaction of antibodies with proteinase 3 (PR3) (i.e., PR3-ANCA). By contrast, a variety of antibodies can cause a perinuclear immunofluorescence pattern (p-ANCA) on ethanol-fixed neutrophils. Only those that also react with myeloperoxidase (MPO) are of interest in the context of ANCA-associated vasculitis. Maximal diagnostic accuracy of ANCA testing requires corroboration of a positive target antigen–specific test result (PR3-ANCA or MPO-ANCA) by immunofluorescence assay, or vice versa. Only the PR3-ANCA with c-ANCA combination and the MPO-ANCA with p-ANCA combination are sensitive and specific for ANCA-associated vasculitis.

The clinical utility—as reflected in positive and negative predictive values—of ANCA testing for GPA and MPA is critically dependent on the pretest probability of the disease in the patient tested, as well as on the analytic accuracy of the test method. If applied in patients with clinical features indicating a high pretest probability of GPA or MPA, ANCA testing has a very high positive predictive value. However, occasional false-positive ANCA test results have been reported in a variety of infections. Particularly, subacute bacterial endocarditis may represent a diagnostic dilemma as it may mimic small-vessel vasculitis clinically and has been reported with c-ANCA/PR3-ANCA. With other infections reported with ANCA, either the right pairing of immunofluorescence test results with its corresponding antigen specificity is lacking or their clinical features are distinct from those of GPA or MPA. In patients undergoing evaluation for necrotizing glomerulonephritis with or without alveolar hemorrhage, ANCA may occur in conjunction with anti–glomerular basement membrane (anti-GBM) antibodies. These ANCA usually are of the MPO-ANCA variety. The presence of anti-GBM antibodies seems to determine the prognosis in such double-positive patients.

Most patients with severe GPA or MPA demonstrate a positive result on ANCA testing (for a sensitivity greater than 95%), but up to 30% of patients with limited GPA may not have detectable ANCA. Despite the recognized association between ANCA titers and disease activity, changes in ANCA levels do not reliably predict the disease activity in individual patients. Therefore, serial titers of ANCA should not be used to plan long-term therapy.

Therapy

Standard therapy for GPA and MPA currently follows the same basic principles. Methotrexate (MTX) at a dose of up to 25 mg once a week in combination with oral prednisone is considered the standard of care for patients with limited GPA. However, only one prospective randomized trial has compared MTX and cyclophosphamide (CYC) for remission induction in such patients (Table 59-1). The trial, conducted by the European Vasculitis Study Group (EUVAS), showed that MTX is noninferior to CYC for remission induction, but the side effects were less frequent and less severe. The trial also documented that early discontinuation of immunosuppression in patients with ANCA-associated vasculitis is fraught with a high relapse rate. The largest reported group of patients with limited Wegener's

Table 59-1 Randomized Controlled Trials Informing the Standard of Care in ANCA-Associated Vasculitis

Treatment Investigated	Trial Design	No. of Patients	Main Conclusion	Published Study/Name of Trial
TMP-SMX for remission maintenance in GPA	Randomized (1 : 1), placebo-controlled	81	TMP-SMX reduces incidence of relapses in WG.	Stegeman et al, 1996/(N/A)
AZA versus CYC for remission maintenance in severe GPA and MPA	Randomized (1 : 1), controlled, open-label	144	AZA is as effective for remission maintenance as continuation of CYC in severe AAV.	Jayne et al, 2003/ CYCAZAREM
MTX versus CYC for remission induction in early-systemic GPA and MPA	Randomized (1 : 1), controlled, open-label	100	MTX is not inferior to CYC in early-systemic AAV.	De Groot et al, 2005/ NORAM
PLEX versus intravenous methylprednisolone for GPA and MPA with severe renal disease	Randomized (1 : 1), controlled, open-label	137	PLEX improves renal survival of methylprednisolone in patients with AAV with severe renal disease.	Jayne et al, 2007/ MEPEX
AZA versus MTX for remission maintenance in severe GPA and MPA	Randomized (1 : 1), controlled, open-label	126	There is no difference in efficacy (relapse rate) or adverse events rate between AZA and MTX.	Pagnoux et al, 2008/ WEGENT
Etanercept versus placebo added to standard therapy for limited and severe GPA	Randomized (1 : 1), placebo-controlled, double-blind	180	Etanercept has no benefit in addition to standard therapy.	Wegener's Granulomatosis Etanercept Trial (WGET) Research Group, 2005/WGET
Pulse CYC versus oral daily CYC	Randomized, controlled, open-label	149	Pulse CYC is as effective as oral daily CYC for severe AAV.	De Groot et al, 2009/ CYCLOPS
AZA versus MMF for remission maintenance in GPA and MPA	Randomized, controlled, open-label	156	MMF is inferior to AZA for remission maintenance in GPA and MPA.	Hiemstra et al, 2010/ IMPROVE
RTX versus daily oral CYC, followed by AZA, for remission induction in severe newly diagnosed or relapsing GPA and MPA	Randomized (1 : 1), double dummy-controlled, double blind	197	RTX is noninferior to CYC for remission induction in severe GPA and MPA. For severe relapses, RTX is superior to CYC. Trial results led to FDA approval of RTX for this indication.	Stone et al, 2010/RAVE
RTX plus 2 pulses of CYC versus intravenous pulse CYC, followed by AZA, for remission induction in severe newly diagnosed GPA and MPA	Randomized (3 : 1), controlled, open-label	44	RTX is noninferior to CYC followed by AZA for induction of sustained remission (>6 months) in severe GPA and MPA.	Jones et al, 2010/RITUXVAS

AAV, ANCA-associated vasculitis; ANCA, antineutrophil cytoplasmic antibodies; *AZA*, azathioprine; *CYC*, cyclophosphamide; *FDA*, U.S. Food and Drug Administration; *GPA*, granulomatosis with polyangiitis; *MMF*, mycophenolate mofetil; *MPA*, microscopic polyangiitis; *MTX*, methotrexate; *PLEX*, plasma exchange; *RTX*, rituximab; *TMP-SMX*, trimethoprim-sulfamethoxazole; *WG*, Wegener granulomatosis.

Data from de Groot K, Harper L, Jayne DR, et al: Pulse versus daily oral cyclophosphamide for induction of remission in antineutrophil cytoplasmic antibody–associated vasculitis: a randomized trial, *Ann Intern Med* 150:670, 2009; de Groot K, Rasmussen N, Bacon PA, et al: Randomized trial of cyclophosphamide versus methotrexate for induction of remission in early systemic antineutrophil cytoplasmic antibody-associated vasculitis, *Arthritis Rheum* 52:2461, 2005; Hiemstra TF, Walsh MW, Mahr A, et al: Mycophenolate mofetil versus azathioprine for remission maintenance in antineutrophil cytoplasmic antibody-associated vasculitis (IMPROVE), *JAMA* 304:2381, 2010; Jayne D, Rasmussen N, Andrassy K, et al: A randomized trial of maintenance therapy for vasculitis associated with antineutrophil cytoplasmic autoantibodies, *N Engl J Med* 349:36, 2003; Jayne DR, Gaskin G, Rasmussen N, et al: Randomized trial of plasma exchange or high-dosage methylprednisolone as adjunctive therapy for severe renal vasculitis, *J Am Soc Nephrol* 18:2180, 2007; Jones RB, Tervaert JW, Hauser T, et al: Rituximab versus cyclophosphamide in ANCA-associated renal vasculitis, *N Engl J Med* 363:211, 2010; Pagnoux C, Mahr A, Hamidou MA, et al: Azathioprine or methotrexate maintenance for ANCA-associated vasculitis, *N Engl J Med* 359:2790, 2008; Stegeman CA, Tervaert JW, de Jong PE, Kallenberg CG: Trimethoprim-sulfamethoxazole (co-trimoxazole) for the prevention of relapses of Wegener's granulomatosis. granulomatosis (WG) was treated with MTX for remission induction in the context of the Wegener's Granulomatosis Trial (WGET). More than 90% of patients achieved remission with this regimen, and more than 70% achieved a sustained remission (lasting longer than 6 months). These rates are equivalent to those achieved with CYC in severe disease, as discussed next.

CYC at a dose of 2 mg/kg/day in combination with prednisone has been the standard of care for patients with severe GPA or MPA until recently. In contrast with the original regimen introduced by Fauci 40 years ago, the current consensus is to limit the duration of CYC therapy to the first 3 to 6 months of remission induction.

Once remission has been induced and the prednisone taper is well under way, CYC should be switched to either azathioprine (AZA), preferred in patients with renal involvement and any degree of renal insufficiency, or MTX. The first option is supported by the results of a randomized trial showing that AZA is as good as CYC for remission maintenance to 18 months. Another randomized controlled trial has shown that MTX and AZA are equivalent for remission maintenance. By contrast, a recent randomized controlled trial that compared mycophenolate mofetil (MMF) with AZA for remission maintenance has shown that MMF is inferior to AZA for this purpose. Thus, the use of MMF for remission maintenance can be supported only for patients who have failed MTX and AZA, or who have contraindications to both agents. The WGET study, in which MTX was used for remission maintenance, confirmed that long-term remission remains an elusive goal for many patients, because remission was maintained in less than half of the patients.

Whenever CYC is used for remission induction, consideration should be given to the patient's fertility. Young men should be offered sperm banking before therapy is initiated. If time allows, ovarian protection should be offered to young women, in addition to minimizing the cumulative exposure as much as possible.

One randomized controlled trial has evaluated a regimen of intravenous pulse application of CYC compared with daily oral use. The pulse regimen was noninferior to the oral application of CYC for remission, and the frequency of leukopenia, but not infection, was lower. Even though the trial was not powered to detect a difference in relapses, however, the relapse rate was higher after remission induction with the intermittent pulse regimen than with the oral application of CYC.

A metaanalysis of earlier cohort studies had also indicated that intravenous pulse CYC therapy may be safer because of a lower cumulative dose, but a higher relapse rate also was observed after discontinuation. In my own experience, intravenous CYC is best avoided in the intensive care unit setting. However, its use is preferred over oral CYC in patients with questionable compliance, in young women with fertility issues, and in patients who have gastrointestinal problems with oral CYC application.

The four-decade-old standard use of CYC for remission induction in patients with severe GPA and MPA recently has been challenged by the results of two randomized controlled trials. The RAVE (rituximab for ANCA-associated vasculitis) trial was a randomized double-blind, double-placebo-controlled, multicenter trial that compared oral CYC (2 mg/kg/day) to rituximab (RTX) (375 mg/m^2 body surface area/week for 4 weeks) for remission induction in severe GPA or MPA in 197 patients. Once remission was achieved between 3 and 6 months, patients randomized to receive CYC were switched to AZA for remission maintenance for 18 months, whereas patients in the original RTX group then received placebo. No difference was observed in rates of achieving remission at the end of 6 months and maintaining remission at 18 months between the two treatment arms. Among the 101 patients who entered the trial with severe relapsing disease, however, RTX proved superior to CYC. The results of the RAVE trial led to approval by the U.S. Food and Drug Administration (FDA) of RTX for remission induction in severe GPA and MPA.

Another randomized controlled open-label trial conducted in 44 patients with newly diagnosed severe ANCA-associated vasculitis with active renal disease, RITUXVAS (Rituximab versus Cyclophosphamide for ANCA-Associated Renal Vasculitis), showed results complementary to those of the RAVE trial. In the RITUXVAS trial, patients were randomized 3 : 1 to receive RTX (together with two pulses of CYC) compared with standard intravenous pulse CYC therapy followed by oral AZA. The primary outcome was sustained remission (of more than 6 months' duration) at month 12. No difference between the treatment groups was found (RTX 76% versus CYC 82%).

Mycophenolate mofetil (MMF) may represent an alternative to CYC (and RTX) for patients with MPA who have MPO-ANCA and mild renal disease (as defined by creatinine levels less than 3.5 mg/day) and no other life- or organ-threatening disease manifestation. This claim is supported by data from a randomized controlled trial in 35 patients from China comparing oral MMF (1.5 to 2 g/day) with intravenous CYC (0.75 to 1.0 g/m^2 once monthly). In addition, all patients received intravenous methylprednisolone bolus therapy (0.5 g/day for 3 days) followed by oral prednisone (0.6 to 0.8 mg/kg for 4 weeks tapered by 5 mg every week to reach 10 mg/day). These regimens demonstrated equivalent efficacy, but MMF was better tolerated than CYC. A prospective pilot trial in 17 patients conducted at the Mayo Clinic achieved similar results.

For some patients with Wegener granulomatosis (WG) and MPA, the combination of glucocorticoids and cyclophosphamide may not be sufficient to induce a remission quickly. Plasma exchange should be considered early in patients who present with rapidly progressive glomerulonephritis and renal failure, as well as in patients who present with diffuse alveolar hemorrhage (DAH). The use of plasma exchange currently is supported by two studies: The MEPEX (Methylprednisolone Versus Plasma Exchange) trial in 156 patients who presented with a serum creatinine level of 5.5 mg/dL or greater was conducted to compare three pulses of intravenous methylprednisolone with 2 weeks of plasma exchange (seven exchanges at rate of 60 mL/kg) in addition to standard therapy for severe disease (oral prednisone and CYC). Plasma exchange was superior to methylprednisolone with respect to renal recovery. A single-center cohort study of 20 patients presenting with alveolar hemorrhage described 100% survival when plasma exchange was added to standard immunosuppressive therapy. If alveolar hemorrhage is uncontrolled despite aggressive immunosuppressive therapy and plasma exchange, the use of recombinant activated factor VII may be considered.

The term *refractory disease* commonly is used to describe persistent disease activity in patients on the maximal tolerated dose of CYC or in those with contraindications to the use of CYC. A variety of agents have been proposed for use in addition to or instead of the failing regimen in such patients. Over the past decade, RTX has emerged as the agent of choice for treatment of refractory disease, based on over 20 case series and cohort studies comprising more than 200 patients.

Infliximab also has been used in small case series and uncontrolled trials. Of note, however, infliximab therapy was associated with a high frequency of infections with bad outcomes. The WGET showed that etanercept had no effect on remission induction or maintenance when used in addition to standard therapy. Moreover, significantly more malignancies were observed among patients who had received CYC in the etanercept treatment group. Accordingly, the use of etanercept in patients who have received or are receiving CYC is contraindicated. Consequently, no convincing rationale has emerged for the use of antitumor necrosis factor-α (anti-TNF) therapy in patients with GPA.

Several reports have described the use of other agents in patients with refractory disease. Antithymoglobulin has some efficacy but significant side effects. Dispergualine is an agent available in Japan and Europe but not in the United States.

The management of large airway involvement in GPA may present unique challenges. Subglottic stenosis may necessitate dilation procedures paired with local injection of long-acting glucocorticoids with or without mitomycin C, and stenosis of the large airways may warrant bronchoscopic interventions, including dilation by rigid bronchoscopy, yttrium-aluminum-garnet (YAG) laser treatment, and placement of silicone airway stents.

In patients with GPA and MPA, significant morbidity and mortality related to organ damage is not only caused by the disease itself but also attributable to treatment toxicities. Permanent complications have been reported to occur in 86% of patients from GPA itself, including end-stage renal disease, chronic pulmonary dysfunction, diminished hearing, destructive sinus disease, saddle nose deformities, proptosis, and blindness. Among the treated patients, 42% experienced permanent treatment-related problems including chemical (drug-induced) cystitis, osteoporotic fracture, bladder cancer, myelodysplasia, and avascular necrosis. In the 180 patients in the WGET, which reflects more recent standard practice, damage that occurred despite (or because of) therapy included visual impairment, hearing loss, nasal blockage, pulmonary fibrosis, hypertension, renal insufficiency, peripheral neuropathy, gonadal failure, and diabetes mellitus. Only 11% of the enrolled patients did not exhibit a single point on the vascular damage index (which was developed from 61 various items) after 1 year of study enrollment. The WGET investigators also concluded that patients with limited GPA are at a higher risk for GPA-related damage than are those with severe disease.

In the same cohort of 180 patients with GPA, the incidence rate of venous thromboembolism was found to be high in comparison with reported rates in the general population, patients with lupus, and patients with rheumatoid arthritis. This increased risk for thromboembolic disease also has been documented for the other ANCA-associated vasculitides. A high frequency of echocardiographic abnormalities attributable to GPA and associated with an increased mortality was observed in a study of 85 patients with confirmed GPA. Lesions directly related to GPA included regional wall motion abnormalities not matching coronary distributions, left ventricular systolic dysfunction with decreased ejection fraction, pericardial effusions, valvulitis, left ventricular aneurysm, and a large intracardiac mass. Evaluation of unexplained dyspnea in patients with GPA should therefore include echocardiography.

Eosinophilic Granulomatosis With Polyangiitis (Churg-Strauss Syndrome)

The Chapel Hill Consensus definition for EGPA is "eosinophil-rich and granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels, and associated with asthma and eosinophilia." EGPA is included among the ANCA-associated vasculitides, but only 40% to 70% of patients with active EGPA have detectable ANCA. EGPA is distinguished from GPA and MPA primarily by a high prevalence of asthma and peripheral blood and tissue eosinophilia.

Three distinct phases of the disease have been described: The first is a *prodromal allergic phase* with asthma. This phase may last for a number of years. Second is an *eosinophilic phase* with prominent peripheral and tissue eosinophilia. This phase also may last a number of years, and the manifestations may remit and recur over this period. The differential diagnosis in this phase of the disease includes parasitic infection and chronic eosinophilic pneumonia. The third *vasculitic phase* consists of systemic vasculitis and may be life-threatening. The three phases are not seen in all patients, do not necessarily occur in this order, and may even be concurrent. However, asthma usually predates vasculitic symptoms by a mean of 7 years (range, 0 to 61 years). "Formes frustes" of EGPA also have been described with eosinophilic vasculitis and/or eosinophilic granulomas in isolated organs without evidence of systemic disease.

Pulmonary parenchymal involvement occurs in 38% of patients. Transient alveolar-type infiltrates are most common. These have a predominantly peripheral distribution and are indistinguishable from infiltrates seen in chronic eosinophilic pneumonia. Occasionally, nodular lesions may be seen in EGPA. In contrast with GPA and MPA, alveolar hemorrhage is exceedingly rare in EGPA. Renal involvement is less prominent than in GPA or MPA and does not generally lead to renal failure. By contrast, peripheral nerve involvement, typically in the form of mononeuritis multiplex, is more frequent. Skin, heart, central nervous system, and abdominal viscera also may be involved.

The classic histopathologic picture consists of necrotizing vasculitis, eosinophilic tissue infiltration, and extravascular granulomas. Not all features are found in every case, however, and they are not pathognomonic for the condition. In particular, the finding of a "Churg-Strauss granuloma" on skin biopsy should not lead to confusion with the diagnosis of EGPA. This type of necrotizing extravascular granuloma may be seen in EGPA as well as in other systemic autoimmune diseases including GPA and rheumatoid arthritis.

If ANCA are present, they usually are p-ANCA reacting with MPO. The ANCA status appears to correlate with disease activity. Recent evidence points to a more vasculitic disease phenotype in the presence of ANCA, but this association was not confirmed by all studies. Substantial overlap of organ manifestations between patients with EGPA who are ANCA-positive and those who are ANCA-negative is characteristic.

In recent years, significant attention has been devoted to EGPA detected in patients taking leukotriene receptor antagonists. Available case studies and limited population-based incidence estimates suggest that these agents may lead to unmasking of vasculitic symptoms in asthmatic persons by allowing dose reductions or discontinuation of oral glucocorticoid therapy. There is no evidence suggesting that these agents directly cause the disease.

The prognosis with EGPA is better than that with GPA or MPA, because the overall mortality is lower and not significantly different from that for the normal population. Most deaths are secondary to cardiac involvement.

Systemic glucocorticoids remain the mainstay of therapy. No clinical trials have been conducted to provide clear guidance for therapy for EGPA. It seems most appropriate to treat EGPA according to the principles applied to the management of ANCA-associated vasculitis. Accordingly, CYC should be added to glucocorticoids for remission induction in all patients with disease manifestations that threaten either life or function of a vital organ—particularly those with central or peripheral nerve involvement, glomerulonephritis, heart involvement, or alveolar hemorrhage. MTX, AZA, and MMF have been used as glucocorticoid-sparing agents in less severe disease and for remission maintenance. Refractory disease and that dominated by difficult-to-control eosinophilic inflammation have been reported to respond to interferon-α therapy. Of note, however, continued long-term interferon-α therapy may be necessary, and this treatment carries the risk of substantial toxicity. RTX also has been used successfully in EGPA, particularly ANCA-positive patients with renal disease, but the data are still limited, and use of RTX instead of CYC for patients with severe EGPA cannot be recommended. Anti-interleukin 5 (IL-5) also has recently been reported as a promising agent for treatment of EGPA. The glucocorticoid-sparing effect of anti-IL5 in EGPA has been documented in two separate prospective pilot studies.

Idiopathic Pauciimmune Pulmonary Capillaritis

Occasionally patients present with isolated DAH caused by capillaritis. Despite extensive searching, no evidence of other organ involvement or specific autoantibodies can be detected.

Direct immunofluorescence studies of the lung tissue reveal no immune deposits. This clinicopathologic presentation has been referred to as *idiopathic pauciimmune pulmonary capillaritis* and represents a diagnosis of exclusion. This form of isolated pulmonary capillaritis is histopathologically indistinguishable from that of ANCA-associated vasculitis. Affected patients are best treated with an immunosuppressive regimen selected according to the guidelines for severe GPA and MPA.

MEDIUM-SIZE VESSEL VASCULITIS

Classic Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is not associated with ANCA and does not affect capillaries. Therefore, it does not cause glomerulonephritis or alveolar hemorrhage. However, classic PAN can on rare occasion affect the bronchial or bronchiolar arteries, causing lung hemorrhage by that mechanism. Most cases of classic PAN diagnosed today are associated with viral infections, specifically, hepatitis B and C. Consequently, antiviral therapy plays a prominent role in the management of such cases, in addition to immunosuppression. With classic PAN, relapse is far less likely than with MPA, so PAN generally can be treated with an immunosuppressive regimen of shorter duration.

LARGE VESSEL VASCULITIS

Giant Cell Arteritis

Giant cell arteritis (GCA), also known as *temporal arteritis*, *cranial arteritis*, and *granulomatous arteritis*, is a generalized inflammatory disorder involving large and medium-sized arteries. It is the most common form of vasculitis in the Northern Hemisphere and affects predominantly elderly patients. The typical features of the disease include new-onset headache, a palpably tender or nodular temporal artery with decreased pulsation, and elevated erythrocyte sedimentation rate (ESR). The clinical illness emerges gradually, with the development of nonspecific systemic signs and symptoms such as low-grade fever, malaise, and weight loss. Headache, variable but often severe, is the most common symptom in GCA. Amaurosis fugax is observed in 20% of patients, and visual loss in 10%. Granulomatous inflammation of the vessel wall is found in 60% of temporal artery biopsy specimens. The aorta also may be affected by the disease, and GCA should be considered as the cause of thoracic aortic aneurysm occurring in elderly patients.

Respiratory symptoms have been reported in up to 25% of patients but rarely require management by a respiratory physician. However, respiratory symptoms may be the initial presentation of giant cell arteritis. Therefore, GCA should be considered in any elderly patient with new-onset cough, hoarseness, or throat pain without other identifiable cause, and the ESR should be measured in such patients. Cough, hoarseness, and throat pain usually resolve promptly with glucocorticoid therapy. Isolated cases of GCA with pleural effusion or multinodular pulmonary lesions also have been reported. Such findings are difficult to interpret in this setting, and GPA should be considered in the differential diagnosis, because it also may involve the temporal artery. Therapy of GCA continues to be based on the use of glucocorticoids without proven alternative. The glucocorticoid-sparing role of MTX for GCA remains controversial.

Takayasu Arteritis

Takayasu arteritis is a large vessel vasculitis affecting predominantly the aorta and its major branches in young patients. Takayasu arteritis also has been called *pulseless disease*, *aortic arch syndrome*, or *reverse coarctation*. The disease affects mostly young adult women. It is not limited to patients of Asian descent. Early disease manifestations include constitutional symptoms, low-grade fever, and arthralgias. Variable pulses of the extremities and claudication of affected vascular territories are typical. Renovascular hypertension, pulmonary hypertension, and ischemia of affected organs may be the more disabling complications of this chronically relapsing disease.

Pulmonary complications are the result of a unique arteriopathy predominantly involving the large and medium-size pulmonary vessels. Progressive defects in the outer media of the arteries and ingrowth of granulation tissue–like capillaries associated with thickened intima and subendothelial smooth muscle proliferation lead to pulmonary artery stenoses and occlusion, as well as pulmonary hypertension, in up to half of all patients. The inflammatory infiltrate of the vessel wall is predominantly lymphoplasmocytic, with variable amounts of giant cells. The involvement of pulmonary arteries is common but often asymptomatic. It is detectable by conventional angiography, perfusion scan, or magnetic resonance angiography (MRA). Chest radiographs often are normal in appearance, but computed tomography (CT) may show areas of low attenuation as a result of regional hypoperfusion, subpleural reticulolinear changes, and pleural thickening. Fistula formation between pulmonary artery branches and bronchial arteries, as well as nonspecific inflammatory interstitial lung disease, also has been reported.

Therapy for Takayasu arteritis consists primarily of immunosuppression with glucocorticoids. Other immunosuppressive agents including MTX are used in conjunction with glucocorticoids for remission induction and as glucocorticoid-sparing agents for remission maintenance. Unfortunately, many patients relapse when the glucocorticoid dose is reduced below 15 mg daily. The use of antitumor necrosis factor-α agents may be beneficial for patients with disease refractory to standard therapy. Vascular bypass procedures may restore perfusion to areas affected by severe arterial stenoses, but the improvement is only temporary.

OTHER VASCULITIS SYNDROMES

Behçet Disease

Behçet disease is a rare, chronically relapsing systemic inflammatory disorder characterized by aphthous oral ulcers and at least two or more of the following: aphthous genital ulcers, uveitis, cutaneous nodules or pustules, and meningoencephalitis. Reported prevalence of the disease is 1 : 16,000 in Japan and 1 : 20,000 in the United States. A strong association with the major histocompatibility complex antigen HLA-B51 has been recognized. The mean age of patients at the onset of Behçet disease is 35 years. Most studies have reported a predominance of men with the disease over women. Respiratory manifestations are common in Behçet disease and include cough, hemoptysis, chest pain, and dyspnea. Hemoptysis often is massive and fatal. The vasculitis of Behçet disease is immune complex–mediated and may involve vessels of all sizes. Secondary thrombosis with major venous occlusion can occur. Thrombosis may not be preventable in Behçet disease by anticoagulation, but aspirin 80 mg/day has been advocated. Destruction of the elastic lamina of pulmonary arteries causing aneurysm formation, secondary erosion of bronchi, and arterial-bronchial fistulas may result in massive hemoptysis. CT or MRA can be used to detect pulmonary artery aneurysms. Recurrent pneumonia as well as bronchial obstruction secondary to mucosal inflammation also has been described.

Therapy of the underlying disease consists of immunosuppression. Prednisone alone may not be sufficient to control the vasculitis. The addition of other drugs, such as colchicine, chlorambucil, MTX, cyclosporine, or AZA, is recommended. The use of biologic agents, in particular anti-TNF agents, also has been reported recently. The addition of AZA or CYC to glucocorticoids may result in resolution of pulmonary aneurysms. Once pulmonary arteritis has been identified, anticoagulation should be avoided. The prognosis of pulmonary involvement is poor. About one third of patients die within 2 years of developing pulmonary involvement, most from fatal pulmonary hemorrhage. Embolization therapy may be used for treatment and prevention of hemorrhage from pulmonary artery aneurysms.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP), also known as *anaphylactoid purpura*, *allergic purpura*, or, as more recently proposed, *IgA-associated disease*, is a syndrome characterized by acute-onset purpura, arthritis, colicky abdominal pain, and nephritis. Histopathologic findings include acute arteriolitis and venulitis in the superficial dermis and the bowel. Proliferative and necrotizing glomerulonephritis usually is mild. A similar type of renal lesion is seen in patients with infective subacute bacterial endocarditis, GPA, MPA, systemic lupus erythematosus (SLE), and anti-GBM disease.

Immunofluorescence microscopy shows large deposits of IgA in the skin and kidney. Although HSP is more common in children (mean age of patients, 17 years), adults also may be affected. Palpable purpuric lesions, which usually are distributed over the buttocks and lower extremities, and fever are generally the first clinical manifestations. The purpura may precede, accompany, or follow onset of arthralgias and abdominal colic. The triad of purpura, arthritis, and abdominal pain is present in approximately 80% of patients. Joint involvement typically is monoarticular and transient, involves the large joints, and causes pain that is out of proportion to the objective evidence of synovitis. Peritonitis and melena are common.

Pulmonary manifestations of HSP are rare. Only 26 cases have been reported to date, and capillaritis has been documented histopathologically only in a minority of them. IgA deposits along the pulmonary capillary walls, analogous to those found in vessels of the skin and glomeruli of affected kidneys, are pathognomonic for HSP.

Secondary Vasculitis

Many of the rheumatologic diseases exhibit a secondary vasculitic process in the organs involved. Infectious processes, particularly those secondary to infection with *Aspergillus* and *Mucor* spp., invade vascular structures and produce secondary vasculitis. Certain drugs and chemicals can induce vasculitis. Other uncommon secondary vasculitic entities include benign lymphocytic angiitis and granulomatosis, bronchocentric granulomatosis, and necrotizing sarcoid angiitis.

ALVEOLAR HEMORRHAGE SYNDROMES

Diffuse hemorrhage into the alveolar spaces often is referred to as *diffuse alveolar hemorrhage (DAH) syndrome*. The clinical course of DAH is unpredictable: It may progress rapidly to respiratory failure, and it is always potentially life-threatening. Consequently, this entity should be considered in the differential diagnostic evaluation of any patient with alveolar infiltrates on chest radiograph. The symptoms of DAH are nonspecific. Patients usually seek care because of dyspnea and cough, possibly associated with fever. Diffuse alveolar infiltrates on the chest radiograph constitute the initial diagnostic hallmark. Depending on the severity of the disease process at the time of evaluation, anemia and hypoxemia may be prominent. Hemoptysis is a common presenting manifestation of DAH but may be absent in up to one third of patients with DAH.

DAH can result from a variety of underlying or associated conditions that cause a disruption of the alveolar-capillary basement membrane integrity. Mechanisms leading to DAH include immunologic inflammatory conditions or agents causing immune complex deposition or capillaritis (e.g., anti-GBM disease or Goodpasture syndrome, SLE, ANCA-associated vasculitis), direct chemical or toxic injury (e.g., from toxic or chemical inhalation, abciximab use, all-*trans*-retinoic acid, trimellitic anhydride, or smoked crack cocaine), physical trauma (e.g., pulmonary contusion), and increased vascular pressure within the capillaries (e.g., mitral stenosis or severe left ventricular failure).

DAH is best confirmed by bronchoalveolar lavage (BAL). Progressively more bloody return fluid indicates alveolar origin of the blood; the presence of greater than 20% hemosiderin-laden macrophages among the total number of alveolar macrophages recovered by BAL is reported to indicate alveolar hemorrhage, even in the absence of ongoing active bleeding. Pulmonary alveolar hemorrhage is significantly associated with the following: thrombocytopenia (less than 50,000 cells/μL), other abnormal coagulation variables, renal failure (creatinine concentration of 2.5 mg/dL or greater), and a history of heavy smoking. The clinical approach to the patient presenting with DAH is aimed at rapid identification of the underlying cause and prompt implementation of appropriate therapy.

Exposure to inhalational toxins such as trimellitic anhydride or pyromellitic dianhydrate, drug abuse including crack cocaine abuse, and tobacco smoke should be identified. The past medical history also will uncover preexisting comorbid conditions, factors, and agents that can cause DAH, including mitral stenosis, coagulation disorders, recent bone marrow or hematopoetic stem cell transplantation, preexisting autoimmune disorders, and various therapeutic drugs. Similarly, the initial physical examination should include a careful search for signs of comorbidity and possible systemic autoimmune disorders.

Initial blood and urine testing should screen for other organ involvement, particularly kidney involvement (complete blood count, blood chemistry profile, urine analysis and microscopy), and determine the current coagulation status (activated partial prothrombin time [aPTT], international normalized ratio [INR]). Baseline markers of inflammation (erythrocyte sedimentation rate and C-reactive protein) are helpful to monitor subsequent responses to therapy. At the same time, specific serologic testing for potential underlying systemic disease processes should be initiated. This includes testing for ANCA, anti-GBM antibodies, antinuclear antibodies, anti–double-stranded DNA antibodies, rheumatoid factor, and antiphospholipid antibodies, as well as determination of complement and creatine kinase levels.

The decision to obtain a biopsy specimen needs to be considered carefully, weighing the risks of the biopsy procedure, the likelihood of obtaining a diagnostic piece of tissue, the likelihood of the biopsy findings to alter the therapeutic approach, and the risks associated with the chosen therapy.

The DAH syndromes can be broadly separated into those in which DAH is caused by or associated with pulmonary capillaritis and those in which pulmonary capillaritis is lacking (bland histologic pattern). Pulmonary capillaritis refers to the specific histopathologic finding of alveolar wall infiltration with inflammatory cells centered on capillary walls and small veins. The inflammatory cells are predominantly neutrophils, but eosinophils or monocytes also may be encountered. Capillaritis usually causes fibrinoid necrosis of alveolar and vessel walls and may culminate in the destruction of the underlying lung architecture. The interstitial infiltration by neutrophils seen in the context of capillaritis needs to be distinguished from the predominant intraalveolar neutrophilic infiltration commonly associated with active infections. Another hallmark of capillaritis is the presence of pyknotic cells and nuclear fragments from neutrophils undergoing apoptosis. This feature, referred to as leukocytoclasis, allows the distinction of true capillaritis from neutrophil margination related to surgical trauma, which can simulate capillaritis.

Most of the syndromes associated with pulmonary capillaritis leading to DAH have been discussed earlier in the chapter. A few unique syndromes or conditions that also may be associated with DAH are described next.

ANTI–GLOMERULAR BASEMENT MEMBRANE ANTIBODY DISEASE (GOODPASTURE SYNDROME)

Anti–glomerular basement membrane antibody (anti-GBM) disease, or Goodpasture syndrome, is a rare autoimmune disease characterized by the presence of autoantibodies directed against the NC1-domain of the alpha-3 chain of basement membrane collagen type IV. This epitope is accessible only to autoantibodies in the basement membranes of kidneys and lungs. DAH occurs in about half of the patients with anti-GBM disease. An additional inhalational injury, particularly smoking, is thought to be required for development of the pulmonary manifestation of this disease. Isolated alveolar hemorrhage in the absence of renal disease is rare in anti-GBM disease. Circulating autoantibodies to basement membrane are detectable in the serum, but the diagnosis of anti-GBM disease hinges on the histopathologic documentation of linear immunoglobulin G (IgG) deposits along the basement membranes in lung or kidney.

Anti-GBM disease is arguably not a vasculitis. Bland pulmonary hemorrhage is the most frequently described histopathologic pattern in DAH associated with anti-GBM disease. Capillaritis occurring as a secondary histopathologic feature, however, has been encountered in some patients. Early implementation of immunosuppressive therapy in conjunction with plasma exchange is the key to a favorable outcome in patients with anti-GBM disease. The pulmonary outcome with anti-GBM disease generally is favorable, but chronic renal failure is common.

VASCULITIDES CAUSING DIFFUSE ALVEOLAR HEMORRHAGE

The various primary vasculitis syndromes that may cause DAH have already been discussed in detail. Worth reiterating here is that the most common cause of the pulmonary-renal syndrome defined as DAH with glomerulonephritis is ANCA-associated vasculitis, either GPA or MPA. By contrast, DAH is rare in the context of EGPA.

SYSTEMIC LUPUS ERYTHEMATOSUS AND OTHER COLLAGEN VASCULAR DISORDERS

The disease manifestations of SLE are highly variable. Pulmonary capillaritis leading to diffuse DAH is rare in SLE, but usually a severe complication of the disease. Direct immunofluorescence microscopy reveals prominent immune complex deposits in the affected tissue of patients with SLE including the lungs. Hence, the development of pulmonary capillaritis in SLE is thought to be immune complex–mediated.

The onset of DAH in patients with SLE usually is abrupt, and it is seldom the first sign of the disease. In the overwhelming majority of patients, the rapid development of pulmonary infiltrates is associated with fever. Hemoptysis may be absent in up to half of the patients. Consequently, the differentiation of DAH from infection may be difficult in SLE and may require diagnostic BAL. Mechanical ventilation, infection, and CYC therapy were identified by univariate analysis as negative prognostic factors in one cohort of patients. The reported mortality rate for DAH in patients with SLE ranges from zero to 90%.

Treatment consists of glucocorticoids and CYC. The use of plasma exchange has been suggested, but its benefit remains unproved.

In all other types of collagen vascular disease or connective tissue disorders, respiratory complications are very common. Pulmonary capillaritis manifesting as DAH is rare, however. Isolated cases have been reported with polymyositis, rheumatoid arthritis, and mixed connective tissue disease. Consequently, serologic testing performed as part of an evaluation of DAH should include studies aimed at the identification of these potential underlying disease entities.

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome (APS) is defined by arterial and venous thromboses, or recurrent miscarriages occurring in patients with antiphospholipid antibodies (anticardiolipin antibodies, lupus anticoagulant, or both). If APS occurs in the context of another autoimmune disease, malignancy, or drug exposure, it is labeled *secondary* APS. In the absence of other coexisting disorders, it is considered *primary*. Hypercoagulability can cause pulmonary embolism and infarction, pulmonary microthrombosis, and pulmonary arterial thrombosis with secondary pulmonary hypertension as a consequence. Of note, however, primary pulmonary hypertension and acute respiratory distress syndrome (ARDS) also have been reported as complications of APS.

Diffuse DAH is rare in APS. The clinical presentation is nonspecific and consists of cough, dyspnea, fever, and bilateral pulmonary infiltrates. DAH also can occur in the context of ARDS, and hemoptysis is absent in more than half of the reported patients with APS and DAH. Therefore, early BAL may help in the differential diagnosis. Tissue necrosis from microthrombosis as well as pulmonary capillaritis has been implicated as a cause of DAH in APS. As in SLE, the capillaritis of APS is immune complex–mediated. Most patients respond to glucocorticoids. Yet the coexistence of thrombosis and capillaritis with DAH represents a therapeutic dilemma, in that anticoagulation may need to be interrupted to control the hemorrhage. Early plasma exchange in addition to immunosuppressive therapy should be considered in patients with APS and DAH.

MITRAL VALVE DISEASE

DAH is a well-known feature of mitral stenosis, even though the possibility is rarely considered in clinical practice. Severe mitral insufficiency also can produce alveolar hemorrhage. Hemoptysis can be the presenting feature. It may be caused by the rupture of dilated and varicose bronchial veins early in the course of mitral stenosis or may be a result of the stress failure of pulmonary capillaries. In patients in whom the valvular problem is not corrected surgically, recurrent episodes of DAH may lead to chronic hemosiderosis of the lungs, fibrosis, and punctate calcification or ossification of the lung parenchyma.

IDIOPATHIC PULMONARY HEMOSIDEROSIS

Idiopathic pulmonary hemosiderosis (IPH) is a rare disorder of unknown cause. It is a diagnosis of exclusion. Many such cases reported before the discovery of ANCA probably represented ANCA-associated vasculitis. Most cases of IPH diagnosed today probably are associated with gluten-sensitive sprue (celiac disease). The combination of alveolar hemorrhage and celiac disease also has been called *Lane-Hamilton syndrome*.

In contrast with DAH of other etiology, the DAH of IPH may be subtle and not necessarily associated with hemoptysis. Iron deficiency anemia is a clinical hallmark of IPH. It is thought to be caused by malabsorption of iron in the gastrointestinal tract, rather than recurrent lung hemorrhage. IPH can occur in children or young adults. Patients suspected of having IPH should be tested for antigliadin antibodies, especially because gastrointestinal symptoms may be absent or very subtle. Most patients with IPH attributable to celiac disease respond to a gluten-free diet and do not need immunosuppressive therapy. Repeated DAH in IPH has been reported to progress to lung fibrosis; early appropriate therapy may prevent this outcome.

TOXIC ALVEOLAR HEMORRHAGE

DAH can result from toxic fume inhalation or from bloodborne toxins. Fumes or dust of trimellitic anhydride (a component of certain plastics, paints, and epoxy resins) cause acute rhinitis and asthmatic symptoms if exposure is minor; with greater exposure, alveolar hemorrhage occurs. The trimellitic anhydride–associated hemoptysis-anemia syndrome occurs after "high-dose exposure" to fumes. Isocyanates have caused lung hemorrhage. Illicit drug use, particularly crack cocaine inhalation has also been linked to DAH.

Many medications have been associated with the development of DAH. These include drugs with antiplatelet or anticoagulant effects, including abciximab; immunosuppressive and chemotherapeutic agents, including D-penicillamine, sirolimus, and all-*trans*-retinoic acid; antithyroid drugs such as propylthiouracil; and epoprostenol given by continuous intravenous infusion for primary pulmonary hypertension.

ALVEOLAR HEMORRHAGE AFTER BONE MARROW TRANSPLANTATION

DAH occurs in both allogeneic and autologous hematopoietic stem cell transplantation recipients—specifically those undergoing bone marrow transplantation (BMT)—usually during the first 30 days, with most episodes occurring around day 12 after BMT. Recipients of autologous marrow transplants are at higher risk than recipients of allogeneic marrow transplants. DAH and diffuse alveolar damage are the two major complications after BMT. The overall incidence of diffuse alveolar damage is 5% to 7%. An autopsy series has found DAH in 24% of recipients of bone marrow transplants. Risk factors for the development of DAH include intensive conditioning chemotherapy and older age (older than 40 years).

Post-BMT alveolar hemorrhage is a form of noninfectious pneumonitis characterized by sudden onset of dyspnea, nonproductive cough, fever, and hypoxemia. Hemoptysis is rare, and its absence may lead to incorrect diagnosis. Many cases are identified only at autopsy. The clinical presentation is nonspecific. Chest imaging shows diffuse but patchy alveolar densities with central predominance of distribution. Lung biopsy is rarely indicated. BAL is important to detect DAH and to exclude infections. DAH is a potentially fatal respiratory complication, with a reported mortality rate in excess of 50%. Data that support use of high-dose parenteral glucocorticoids for BMT-associated DAH as beneficial therapy are not convincing, yet it remains standard practice in this setting.

MISCELLANEOUS CAUSES OF ALVEOLAR HEMORRHAGE

The following rare disease entities also can occasionally manifest with alveolar hemorrhage and therefore should be considered in the differential diagnosis: pulmonary lymphangioleiomyomatosis, pulmonary venoocclusive disease, pulmonary capillary hemangiomatosis, and tumor emboli.

Section 10
SLEEP-DISORDERED BREATHING

Chapter 60
Obstructive Sleep Apnea: Epidemiology, Risk Factors, and Pathophysiology

Ferrán Barbé Illa • Miguel Ángel Martínez-García

Obstructive sleep apnea (OSA) is a disorder characterized by repetitive collapse of the upper airway during sleep, resulting in changes in ventilation and intermittent hypoxemia and arousals, which may result in diurnal sleepiness and may lead to cognitive impairment and cardiovascular morbidity. The OSA syndrome is defined on the basis of recognition of symptoms (especially daytime sleepiness) and the objective measurement of disordered breathing during sleep.

EPIDEMIOLOGY

Although obstructive sleep apnea clearly is a common disorder within the general population, its incidence is hard to establish, because methodologic differences among the various epidemiologic studies have made comparisons difficult. First, different tests have been used to diagnose OSA. Overnight polysomnography (PSG) is considered the "gold standard" diagnostic modality, but assessments have been made using other tests instead, such as unattended in-home PSG or respiratory polygraphy, pulse oximetry, and even clinical questionnaires (see Chapter 61). Second, variability in the definitions of different respiratory events (especially hypopnea) and the apnea-hypopnea index (AHI) cutoff value that defines OSA, or clinically significant OSA, is well recognized. In this sense, the chosen oxyhemoglobin desaturation threshold, typically 3% or 4%, used to define hypopnea can lead to different AHI scores; accordingly, estimates of disease severity will vary. Third, differences in sampling of populations (for example, the percentages of elderly and female subjects included) have been noted. Fourth, disparities in signal processing and a lack of standardization in the quantification of airflow (including thermistor, inductance plethysmography, and nasal cannula–pressure transduction) are common. Finally, the quality of validation of equipment and the conclusions of some studies have been questioned because of methodologic limitations such as small sample sizes or inadequate controls for potential confounding variables.

Apart from these differences, epidemiologic studies have focused on two levels of abnormal sleep quantification: OSA, when defined physiologically as increased obstructive breathing events (apneas or hypopneas) during sleep, usually with an AHI of 5 or more events/hour; and the clinical syndrome (the combination of an AHI of 5 or more events/hour and significant self-reported symptoms, especially daytime sleepiness). The real prevalence of OSA probably is underestimated, because a majority of studies used subjective sleepiness as the sole self-reported symptom for definition, although OSA is well known to be associated with other negative outcomes, such as sleep disruption, deterioration of quality of life, cognitive impairment, or cardiovascular disease, which also should be included in the definition of the syndrome.

MIDDLE-AGED POPULATION

It is estimated that 24% of men and 9% of women have OSA, as defined by an AHI of 5 or greater, and that 15% of men and 5% of women between 30 and 60 years have an AHI of 10 or higher. With use of daytime sleepiness as a clinical syndrome, the prevalence ranges between 3% and 7% in men and 2% and 5% in women in the general population (**Box 60-1**). Until recently, population-based epidemiologic studies of OSA were available only for North America, Europe, and Australia. However, more recent studies undertaken in other countries, including China, India, and Korea, report similar prevalence rates. The overall incidence of moderate to severe OSA (defined by an AHI of 15 or higher) occurring over a 5-year period is 11% and 5% in men and in women, respectively, which persists even after adjustment for confounding variables. This means that, even in the absence of any weight change, approximately 20% of men and 10% of women will develop moderate to severe OSA in that period of time.

Most population-based studies have found a two- to threefold higher prevalence of OSA in males than in females. The ratio is even higher for men treated in sleep centers, with reported ratios between 4 : 1 and 8 : 1 or higher. This higher ratio may be the result of multiple factors: Women do not show the "classic" OSA symptomatology—they typically have more comorbid illnesses, use more psychoactive drugs in the absence of a correct diagnosis, and often present with vague, nonspecific symptoms, which widens the differential diagnosis and leads to a higher level of underdiagnosis or misdiagnosis of OSA. An important finding from epidemiologic studies is that gender disparities in prevalence seem to decrease with age, and when women reach postmenopausal status (and are not receiving hormonal replacement treatment), incidence rates for men and women become similar. **Table 60-1** summarizes the most important sleep apnea prevalence studies in middle-aged populations.

ELDERLY POPULATION

The prevalence of OSA in adults increases with age as a result of greater collapsibility of the upper airway and probably reaches a plateau after the age of 65. It is estimated that 65%

Box 60-1 **Epidemiologic Features of Obstructive Sleep Apnea (OSA)**

- 24% of men and 9% of women have OSA.
- 3% to 7% men and 2% to 5% women have OSA syndrome.
- 65% of older men and 56% of older women have OSA.
- 20% of older men and 15% of older women have OSA syndrome.
- In postmenopausal status, women reach similar incidence rates of OSA than men.
- The overall 5-year incidence of moderate to severe OSA ranges between 5% and 11%.
- Referral to sleep centers for further investigation is four- to eight times more frequent in men than in women.

of older men and 56% of older women between 65 and 95 have OSA as defined by AHI of 10 or greater, and 26% of men and 21% of women between 71 and 100 years have an AHI of 30 or greater. Finally, 20% of older men and 15% of older women have the OSA syndrome (AHI of 10 or higher plus daytime hypersomnia). With age comes an increase in the frequency of both obstructive and central respiratory events. The main problem is to identify the AHI cutoff point that marks the limit of a physiologic and abnormal increase, in order to determine the real prevalence of clinically relevant OSA in the elderly population. In this sense, some investigators state that OSA represents different and distinct clinical entities in middle-aged adults and in older adults, based on morbidity and mortality data, although this position is controversial. Perhaps there is a more complex model of OSA that varies with the patient's age.

In any case, the two proposed types of OSA consist of (1) a pathologic form of OSA that appears in middle age in those patients who usually are diagnosed in sleep laboratories and (2) OSA that appears after the age of 60 years, with some overlap between the two, mainly caused by physiologic changes (increase in pharyngeal collapsibility) associated with aging, and of less clinical importance. Data also suggest that the interaction between body weight and OSA in elderly persons may be different from that in younger adults. Because of the population-wide increase in longevity, the proportion of elderly persons being treated at sleep units also is increasing; currently one in four sleep studies are performed in patients older than 65 years of age. This scenario will present a scientific challenge in the future, in view of the lack of scientific evidence available on OSA in the elderly. Table 60-2 summarizes the most important epidemiologic studies describing the prevalence of OSA in older people.

RISK FACTORS FOR OBSTRUCTIVE SLEEP APNEA

Obesity, aging, and male gender are the main risk factors for the development of OSA. It has been estimated that approximately 30% to 40% of AHI variance can be explained by genetic factors. Other risk factors have been proposed,

Table 60-2 Summary of Important Studies on Prevalence of Obstructive Sleep Apnea in Older People

Study	No. of Subjects	Age Range or Mean (SD)	Population	AHI ≥5	AHI ≥10	AHI ≥20

related to increased anatomic or physiologic upper airway collapsibility.

OBESITY

According to recent estimates, 60% of adults in industrialized nations are overweight (body mass index [BMI] of 25 kg/m^2 or higher) and at least 15% are obese (BMI of 30 kg/m^2 or higher). Obesity is a common clinical finding and is present in more than 60% of patients referred for diagnostic sleep evaluations. Twin studies have shown that up to 70% of the variance in obesity within a population may be attributable to genetic factors. Although candidate genes for obesity are numerous, only a few single-gene mutations causally related to obesity have been convincingly detected, including the leptin receptor gene, the leptin gene, the pro-opiomelanocortin gene, the prohormone convertase 1 gene, and the melanocortin MC4 receptor gene, but very few studies on candidate genes associated with weight loss or weight gain have been performed, and no work in this area has been carried out specifically in the OSA population.

The prevalence of OSA in obese subjects is as high as 45%. Obesity explains 30% to 50% of the variance in AHI and is the only variable that can be modified. Several researchers have speculated that obesity and OSA may share a common genotype, and linkage analysis identified candidate regions at least on chromosomal arms 2p and 19p, but further studies are needed to confirm these results. Some major epidemiologic studies from around the world have consistently identified body weight as the strongest risk factor for OSA and have demonstrated a positive correlation between changes in OSA incidence and changes in weight over time. The Wisconsin Sleep Cohort showed that an increase of one standard deviation in BMI was associated with a four-fold increase in the prevalence of OSA. The longitudinal analysis component of the same study demonstrated that OSA severity changed approximately 3% for every 1% change in weight over a 4-year period. The Sleep Heart Health Study found that the change in AHI with weight changes over a 5-year period was more pronounced in men, and that the change was greater when associated with a weight increase than with a weight decrease. Corroborating this strong association, some studies have shown that dietary or surgical weight loss leads to reduced OSA severity in many patients and that OSA can even be completely cured in some cases. In other words, patients with mild OSA who gain 10% of their baseline weight are at a six-fold increased risk for progression of OSA, and an equivalent weight loss can result in a more than 20% improvement with respect to OSA severity.

Whether OSA predisposes affected persons to the preferential accumulation of visceral fat remains to be determined. More evidence is necessary to determine which specific measure of peripheral or central fat distribution is less compromising for OSA. Some investigators have shown that neck circumference, waist circumference, and BMI are independently associated with OSA severity at all ages, although it seems that neck size is the strongest predictor of sleep-disordered breathing, indicating that upper body obesity (fat deposition around the upper airway or fat deposited in the parapharyngeal fat pads), rather than a more generalized distribution of body fat, is important for the development of OSA. In any case, it is advisable to obtain information from all three measures in clinical practice.

The fundamental mechanisms by which obesity leads to an increase in the number of respiratory events during sleep, and weight loss decreases them, are unknown. It has been postulated that fat deposits surrounding the airway play a role in increasing the critical closing pressure. Other potential contributing factors include the reduction of functional residual capacity, ventilatory control system instability, alterations in neural compensatory mechanisms that maintain airway patency, and functional impairment of the upper airway muscles. Obesity also reduces chest wall compliance and increases whole-body oxygen demand, again predisposing affected persons to development of OSA. The degree to which common conditions associated with obesity, such as diabetes, may cause vascular or neuropathic damage to the dilator pharyngeal muscles and reduced upper airway sensation remains to be fully elucidated.

AGING

Aging in itself is associated with numerous physiologic changes, one of them being an increase in upper airway collapsibility, leading to a higher prevalence of OSA. The critical closing pressure of the upper airway in older people is −8.3 ± 2.3 cm H_2O, whereas in middle-aged people it is −16 ± 6.9 cm H_2O, independent of BMI. This difference may be due to various factors: an age-related decrease in the genioglossus response, an increase in airflow resistance, a decrease in upper airway dilation reflex mechanisms, reduced response to the stimulus of hypoxia, changes in the bony structure surrounding the pharynx, descent of the hyoid bone, increase in soft palate length, or an increase in pharyngeal fat pads. All of these changes lead to a generalized age-related decrease in the size of the upper airway lumen, specifically in men, and a consequent increase in airflow resistance. Age also is associated with an increased incidence of comorbid conditions, postmenopausal hormone status in women, dental disorders, decreased quality of sleep, and intake of psychoactive drugs. All of these factors may increase upper airway collapsibility. Finally, an additional factor that may predispose older persons to development of OSA is the aging-related increase in arousal frequency. Arousals from sleep lead to hyperventilation and relative hypocapnia, which in turn can promote respiratory instability and periodic breathing during subsequent periods of sleep onset.

MALE GENDER

It is not known which mechanisms explain the finding that OSA risk is twice as high in men as in women. Some studies have implicated several factors. First, men have increased fat deposition around the upper airways walls. Although data suggest that, in percentage terms, more women (33.4%) than men (27.5%) have a BMI ≥30 kg/m^2, magnetic resonance imaging (MRI) studies have shown a decreased proportion of pharyngeal fat and soft tissue volume in the neck of obese women in comparison with obese men. Women in general have lower Mallampati scores, suggesting that the fat does not play as large a role in the female tongue as it does in the male tongue. Second, the upper airway in men is more prone to collapse as a result of its greater overall length with a longer vulnerable segment. Third, PSG characteristics of sleep and breathing patterns differ between women and men. Women tend to have a lower AHI in non–rapid eye movement (REM) sleep but have a similar AHI in REM sleep. Moreover, disordered-breathing events in women are of shorter duration and are associated with less oxyhemoglobin desaturation than in men. Finally, several mechanisms have been proposed to explain how male- or female-specific hormones would affect the propensity to develop OSA. One hypothesis is that the different hormones affect the distribution of body fat. Android body fat distribution (in the upper body and trunk) increases with both age and years after onset of menopause, which is a risk factor for the development of OSA. Hormone levels also have been hypothesized to affect central and neural respiratory control mechanisms. In this sense, progesterone has been shown to be a respiratory stimulant, which might protect premenopausal women from OSA; moreover, combined estrogen-progesterone treatment leads to a decrease in the number of apneic and hypopneic episodes during sleep. On the other hand, lower levels of testosterone may be protective against the development of OSA in women. Some researchers have shown that exogenous androgen therapy in men and women can aggravate OSA severity. It is possible that differing levels of hormones, starting from puberty and further modified by later maturational changes, can affect the development of OSA.

GENETIC PREDISPOSITION

Several studies have confirmed the role of inheritance and familial factors in the genesis of OSA. First-degree relatives of persons with the disorder are more likely to be at risk than first-degree relatives of unaffected persons. Genetic factors explain more than 30% to 40% of the variance in disease severity, although confounding factors must be taken into account. Some OSA risk factors have a demonstrated genetic basis, such as craniofacial morphology, the volume of the lateral parapharyngeal walls, tongue form, total volume of soft tissue structures, abnormalities in breathing control, and finally, genetic determinants of obesity.

Recently, Larkin and associates conducted the first candidate gene study of OSA. More than 1500 single-nucleotide polymorphisms (SNPs) were genotyped, covering 53 genes representing intermediate disease pathways implicated in the disorder. These workers identified significant associations between sleep-disordered breathing and genetic variants of C-reactive protein, glial cell–derived growth factor, and serotonin 2A receptor genes independently of BMI. These results highlight the potential role of genetic analysis to better describe the different phenotypes of OSA, the risk of inheritance of each type, and its relationship with other diseases.

OTHER PREDISPOSING FACTORS

Box 60-2 shows other predisposing factors that have been associated with increased risk for OSA. Their mechanisms of action are multiple: anatomic variability (e.g., craniofacial malformations), increased airway inflammation (smoking or infections), physiologic factors (sleep position, REM sleep, pregnancy, or ethnicity-related predilection), and depression of dilator pharyngeal muscle function (alcohol consumption, benzodiazepine or sedative use, stroke, and other comorbid conditions).

Although Asians are less obese than whites, disease prevalence in the East is not less than in the West. For a given age, sex, and BMI, however, Asians demonstrate greater disease severity than whites, which can be explained by differences in craniofacial features (persons of Asian ethnicity have a shorter

cranial base and a more acute cranial base flexure). On the other hand, also in comparison with whites, African Americans show a greater role for soft tissue factors in susceptibility to OSA. The epidemiologic studies related to racial predisposition to OSA have to be interpreted carefully. Confounding variables, such as comorbid conditions, differing socioeconomic status, and health care disadvantages, could explain the differences in OSA prevalence between races, indicating that race may be a surrogate variable for other predisposing factors.

On the other hand, some epidemiologic studies show that both active smoking and second-hand smoke exposure have been independently associated with habitual snoring and even with an increase in OSA prevalence in some subjects, especially in active smokers. It seems that the inflammation and alteration of some mechanical and neural protective properties of the airway due to cigarette smoke increase the collapsibility of the upper airway. Alcohol intake also can promote pharyngeal collapse, even in normal persons, inducing apneic activity and prolonging apnea duration, probably by reducing respiratory motor output to the upper airway, resulting in hypotonia of the pharyngeal muscles.

The frequency and duration of OSA events and the extent of associated desaturation may increase in the supine compared with the side-lying sleep position. Positional OSA is defined as a supine-measured AHI at least double that measured in the lateral position. The prevalence of positional OSA varies in relation to OSA severity. It was recently identified in 50% of mild, 19% of moderate, and 6.5% of severe OSA cases. The main mechanism has been suggested to involve the effects of gravity on the upper airway size through displacement of the soft tissues, by mandibular retropulsion, and indirectly, by upward displacement of abdominal contents, thereby reducing lung volume and compromising airway cross-sectional area or length. Other studies have shown that one of the main mechanisms is change in the shape of the airway from a transversely oriented ellipse when the subject is supine to a more circular shape with assumption of the side-lying position.

Pregnancy also is associated with a higher prevalence of OSA, particularly in the third trimester. Many changes occur in the respiratory system during pregnancy. Factors recognized to contribute to this phenomenon include elevation of the diaphragm secondary to an enlarged uterus, leading to alterations in pulmonary mechanics including reduced functional residual capacity; an increase in Mallampati score secondary to fluid retention and edema; enlargement of neck circumference; reduced nasal patency; changes in hormonal concentrations (estrogen and progesterone); and weight gain. OSA is an important diagnosis to consider in symptomatic pregnant women, especially in view of possible adverse side effects including pregnancy-induced hypertension and intrauterine growth retardation.

PATHOPHYSIOLOGY

OSA is characterized by repetitive collapse of the upper airway during sleep. The most frequent mechanism of collapse is that in which gravity pulls the tongue toward the back wall of the pharynx in a person who has assumed the supine position. Airway resistance increases during collapse, resulting in increased ventilatory effort, intrathoracic pressure swings, and disruption of sleep (arousals). The activation of the upper airway dilator muscles during arousals causes reopening of the airway and restores ventilation (Figure 60-1).

UPPER AIRWAY IN NORMAL SUBJECTS

It has long been recognized that, for what on casual consideration may appear to be a simple tube, the human upper airway is deceptively and enigmatically complex, performing functional tasks such as swallowing and the passage of air for breathing and speech, governed by anatomy and neural controls. Under normal physiologic conditions, the pharynx remains open at all times, except during short closures associated with swallowing, regurgitation, and speech. It is separated into three regions: the *nasopharynx*, extending from the nasal turbinates to the hard palate; the *oropharynx*, composed of the retropalatal region (from the hard palate to the caudal margin of the soft palate) and the retroglossal region (from the caudal margin of the soft palate to the base of the epiglottis); and the *hypopharynx*, extending from the base of the tongue to the larynx. It is composed of more than 20 muscles and soft tissues without rigid or bony support. Pharyngeal muscles can be divided into

three groups: muscles controlling the position of the hyoid bone (geniohyoid and sternohyoid), muscles of the tongue (genioglossus), and palatal muscles (palatopharyngeus, tensor palatini, and levator palatini). The largest of the dilator pharyngeal muscles is the genioglossus, the muscle that forms the major portion of the body of the tongue (Figure 60-2).

Human speech requires pharyngeal mobility, such that the hyoid bone, which is a key anchoring site for pharyngeal muscles, is not firmly attached to the skeleton. Thus, the upper airway has rigid support in its proximal and distal segments but has a collapsible portion extending from the hard palate to the larynx, with the size of its lumen being subject to the influence of surrounding pressures and the activity of dilator muscles. Other well-known biologic examples of mobility in respiratory physiology include intrathoracic airway collapse on forced exhalation, collapse of pulmonary capillaries in the lung apex, and collapse of the alae nasi under high inspiratory flow rates.

One mechanistic physiologic representation of this collapsible model is the Starling resistor (Figure 60-3). According to this model, when air pressure is applied to the upper airway, the collapsible portion of the upper airway is bound by an upstream segment (nasal segment) and a downstream segment (tracheal segment). Nasal and tracheal segments have their corresponding intraluminal pressures and resistances. The nasal segment has atmospheric pressure at the airway opening. In the surrounding collapsible segment, pressure is generated by soft tissues and structures surrounding the pharynx. Occlusion of the collapsible portions occurs when the surrounding pressure (Pout) becomes greater than the intraluminal pressure (Pin) (transmural pressure [Pout − Pin] above 0).

The oropharynx represents the collapsible segment, the critical closing pressure (Pcrit) of which is defined as the pressure inside the airway at which airway collapse occurs. Flow is partially limited when nasal pressure is higher than Pcrit, Pcrit being higher than tracheal pressure, and total occlusion occurs when Pcrit is greater even than nasal pressure. Pcrit in the human upper airway is determined by lowering the nasal pressure until inspiratory airflow ceases. Its measurements have been shown to define a spectrum of upper airway obstruction ranging from normal breathing to total collapse (apnea), depending on the equilibrium between mechanical upper airway loads that provoke collapse and neuromuscular dilator functions that maintain upper airway patency. In general, these measures when applied in sleeping or paralyzed humans have shown that passive Pcrit is below −10 cm H_2O in normal subjects with lower airway resistance and minimal CO_2 retention during non-REM sleep. In sleep-disordered breathing, however, it varies, with reported values of −10 to −5 cm H_2O in snorers, −5 to 0 cm H_2O in those with sufficiently high airway resistance to induce airflow limitation and transient hypopneas, and above 0 cm H_2O in patients with apneas associated with complete airway obstruction (Figure 60-4). Increases in airway resistance or hypercapnia provoke the activation of the muscle through neural control pathways composed of pressure receptors, sleep-wake brain centers, chemoreceptors, and respiratory centers.

Box 60-3 **Factors Contributing to Upper Airway Collapse in Obstructive Sleep Apnea**

- Reduction in upper airway caliber by anatomic factors
- Reduction in upper airway dilator muscle activity
- Ventilatory control instability
- Decrease in lung volume during sleep
- Premature arousals during a respiratory event
- Edema and rostral fluid shifts
- Increased surface tension
- Upper airway inflammation
- Increase in respiratory events during REM sleep
- Reduction in intraluminal pressure due to Bernoulli effect

REM, rapid eye movement.

UPPER AIRWAY IN PATIENTS WITH OBSTRUCTIVE SLEEP APNEA

During sleep, the ventilatory system is under automatic control. Even in normal subjects, airway resistance increases during sleep as a consequence of body position, decreased pharyngeal tone, depression of the respiratory drive, and depression of protective reflexes, leading to an increased probability of upper airway collapse. A number of factors contribute to the pathogenesis of OSA, including the activity of the dilated pharyngeal muscles during sleep, upper airway anatomy, lung volume, ventilatory control stability, sleep state stability, rostral fluid shifts, and others; all of these factors probably are mediated, at least in part, by genetic factors.

The primary site of collapse is in the retropalatal and oropharyngeal area in a majority of patients (up to 75%), with frequent caudal extension to the base of the tongue (25% to 44%) and, less often, to the hypopharynx (0 to 33%). The site of collapse depends on the equilibrium of functions exercised by the skeletal structure, soft tissue, and pharyngeal muscles. In obese patients, the most frequent area of collapse evidently is the velopharynx, whereas in nonobese patients, both the velopharynx and the oropharynx constitute the primary site of collapse. The extent of collapse varies by sleep stage, with caudal collapse being more extensive in REM sleep owing to changes in neuromuscular activation (Box 60-3).

PATHOGENESIS

ANATOMIC FACTORS

Anatomic factors include increased airway length, lateral wall thickness, tongue volume (macroglossia), skeletal structure (retrognathia or micrognathia), and nasal or pharyngeal abnormalities (nasal obstruction, polyps, or enlarged tonsils, adenoids, or uvula) and probably constitute the most important heritable determinants of OSA. Studies of cephalometric and computed tomography scans have demonstrated differences in the craniofacial structure of patients with OSA in comparison with that of normal subjects, including lower facial weight, retroposition of both the maxilla and the mandible, and shorter and medially displaced mandibular rami, all of them correlated with decreased pharyngeal size. The role of enlarged soft tissues has been demonstrated using MRI (Figure 60-5). In patients with OSA, pharyngeal lumen is smaller than normal and tissues are narrowed laterally, rather than in the anteroposterior dimension, especially at the retropalatal level, mainly owing to increased thickness of the muscular pharyngeal wall as well as an increase in tongue and total soft tissue volume. The interaction between the bony and soft tissue structures determines upper airway collapsibility. Nevertheless, increased airway length has been observed in subjects with OSA and has been shown to correlate with severity, especially in men. Usually, the longer the upper airway, the greater the risk of collapse.

Data from early physiologic studies suggest that upper airway narrowing and consequent snoring and apnea can be induced by subatmospheric nasal pressure. In theory, inspiratory nasal obstruction would not provoke continuing collapse of the pharynx: With cessation of flow, upstream resistance becomes irrelevant, intrapharyngeal pressure returns to atmospheric, and the pharynx reopens—a cycle generating snoring but not apneas. It is unlikely, however, that the pharynx does behave as a perfect Starling resistor, partly because of hysteresis and partly as a result of surface tension forces from mucus, which will tend to hold the pharynx closed once collapsed. Various observational and cross-sectional studies have documented a relationship among chronic nasal obstruction, snoring, and OSA.

PHARYNGEAL MUSCLE ACTIVITY

Despite compromised anatomic dimensions of the upper airway, subjects with OSA show upper airway collapse only during sleep, because the upper airway musculature can maintain patency during the awake state but has a reduced ability to do so during sleep. This phenomenon is thought to be related to a reduction in upper airway dilator muscle activity, especially in the transition from wakefulness to sleep. Paradoxically, some studies have shown that during the awake state, genioglossus activity is increased in patients with OSA compared with normal subjects, probably because the drive of the upper airway muscles is increased to compensate for anatomic compromise. During sleep, however, the relative decrease in genioglossus activity is greater in patients with OSA than in control subjects. Various mechanisms may explain the reduction in dilator muscle activity seen in patients with OSA: alterations in the mechanoreceptor reflex related to negative intraluminal pressure; changes in the 5-hydroxytryptamine 2A receptor, which has been shown to be the predominant receptor subtype in hypoglossal motor neurons; altered upper airway neuromechanical function; or even an upper airway denervation neuropathy or muscle denervation. In OSA, upper airway neuromuscular compensatory mechanisms during sleep are attenuated compared with those in control subjects in studies using electromyograms and often fail to restore airway patency in the absence of arousals. Furthermore, impaired upper airway afferent neural function has been described, which could attenuate the transmission of information related to intraluminal pressure. This impairment has been observed in the mechanosensitivity receptor of the oropharynx and thermal sensitivity receptors and sensory receptors in the velopharynx and larynx in persons with OSA. Some of these afferent impairments have been associated with OSA severity.

All of these findings point to the presence of an upper airway neuropathy in OSA, probably due to mechanical trauma associated with snoring and apneas, oxidative stress related to hypoxia-reoxygenation, and inflammation resulting from both of these insults. One of these forms of neuropathies appears in the form of muscle denervation, including fiber type grouping, grouped atrophy, and increased fiber size variability. This airway muscle denervation presumably also may result from damage to brain stem motor neurons, as has been reported in a murine model of intermittent hypoxia.

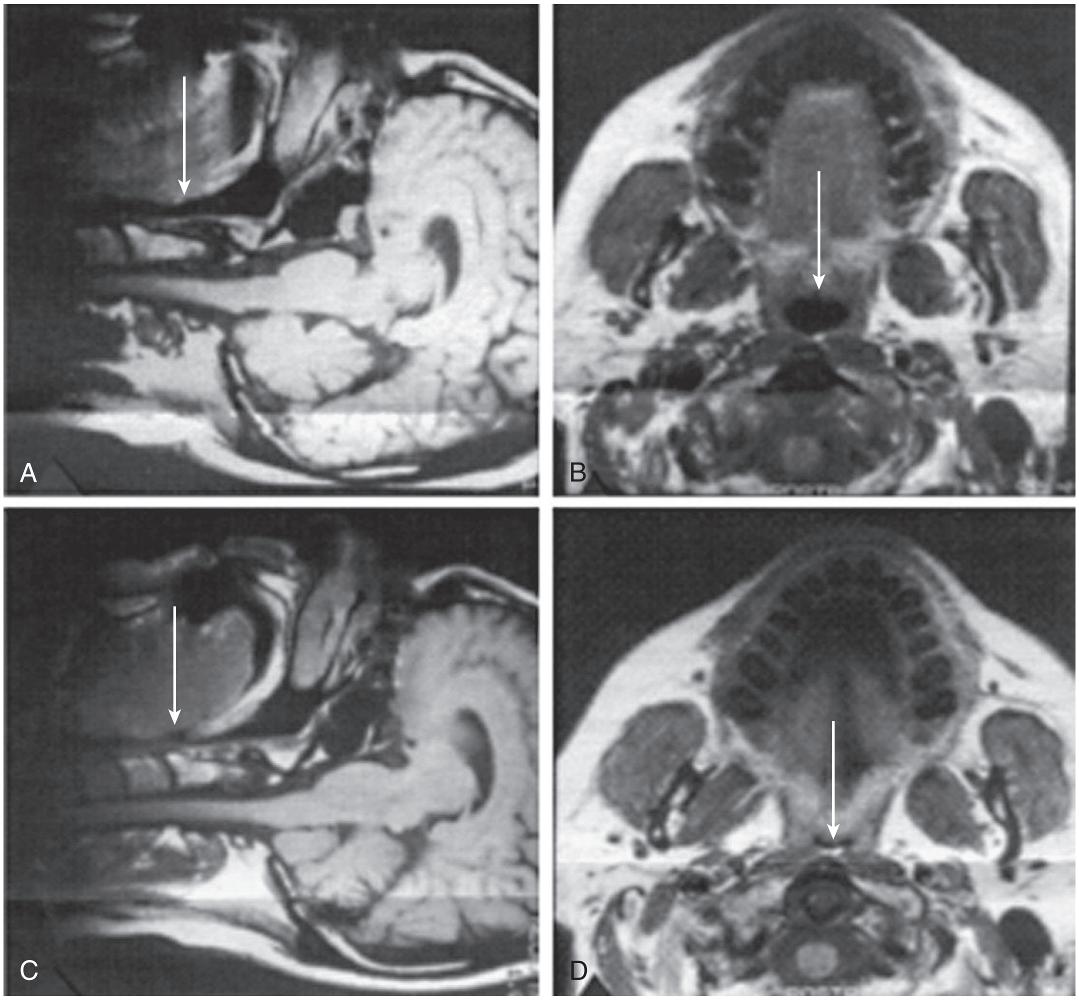

Figure 60-5 Magnetic resonance imaging study of cross-sectional and longitudinal upper airway lumen in a normal subject (*white arrows* in **A** and **B**) and in a patient with obstructive sleep apnea (*white arrows* in **C** and **D**). *(Courtesy J.L. Fernandez, MD.)*

On the other hand, another potential mechanism contributing to altered upper airway muscle function in OSA could be impaired contractile function. In patients with OSA , the upper airway muscle works under considerable load in adverse hypoxic conditions, which could generate some injuries and morphologic changes, increasing force but making the muscle more prone to fatigue. Histologic and biochemical studies have shown an increased proportion of fast-twitch type IIa fibers in the uvula and genioglossus and increased levels of enzymes associated with anaerobic metabolism in patients with OSA, leading to the maintenance of increased muscle contractility at the cost of increased fatigability. Moreover, other factors such as increased airway inflammation and secondary tissue changes could compromise contractile function and alter mechanical coupling of upper airway muscles.

Finally, considerable interest has emerged in the role of some neural pathways and neurotransmitters in the modulation of upper airway muscle activity. Animal studies have shown that the withdrawal of serotoninergic excitation reduces hypoglossal motor output (which drives the major upper airway dilator muscle, i.e., the genioglossus), although human studies using selective serotonin reuptake inhibitors showed only modest effects on OSA severity. Noradrenergic inputs to the hypoglossal motor pool contribute to both the tonic and the phasic components of genioglossus muscle activity in the awake state, and withdrawal of noradrenergic input accounts for some of the reduction in hypoglossal motor activity during non-REM sleep. Glutamatergic inputs seem to play a similar role. The two main inhibitory neurotransmitters in the central nervous system are glycine and gamma-aminobutyric acid (GABA). Stimulation of GABA or glycine receptors suppresses respiration-related genioglossus muscle activity, whereas antagonism of those receptors increases it.

VENTILATORY CONTROL STABILITY

Ventilatory control stability is believed to be an important contributor to OSA pathogenesis, because obstructive events tend to occur during periods of low respiratory drive. One of the most important mechanisms that control the ventilatory system is the hypoxic or hypercapnic ventilatory response (Pa_{CO_2} is maintained at a stable level by negative feedback control). This mechanism has a high degree of heritability. During non-REM sleep, reductions in CO_2 below eupneic levels will produce apnea, although this phenomenon does not occur during wakefulness. The CO_2 level at which this occurs (apneic threshold) typically is 1 to 2 mm Hg below waking eupneic levels. Thus, the sudden increase in ventilation occurring in association with arousal, which typically is seen at the termination of apneic and hypopneic episodes, will lead to hypocapnia, so that on returning to sleep, CO_2 is below the apneic threshold, and another apnea ensues. In this manner, postventilatory overshoot and loss of drive to the upper airway may lead to airway collapse with initiation of a subsequent obstructive event.

Other factors may contribute to reduced drive after postapneic hyperpnea, such as vagal stimuli generated during large inspired volumes and baroreceptor-mediated ventilatory inhibition due to postapneic blood pressure surges. Another important concept is *loop gain*, a term used to describe the stability of the respiratory system as a whole and how responsive the system is to a perturbation in breathing during sleep. The higher the loop gain, the lower the ventilatory stability. Patients with OSA have greater ventilatory control instability and higher loop gain when compared with control subjects. The two principal components of loop gain are *controller gain*, representing chemoreceptor responsiveness to hypoxia and hypercapnia (high controller gain is due to increased hypercapnic responsiveness), and *plant gain*, reflecting the effectiveness of a given level of ventilation to eliminate CO_2. In the context of high plant gain, a small change in ventilation would produce a large change in $PaCO_2$. Because upper airway muscles receive input from respiratory control centers, an unstable ventilatory drive will cause greater fluctuation in the activity of these muscles and promote upper airway collapse when ventilatory drive is at its nadir.

LUNG VOLUME AND PHARYNGEAL PATENCY

The interaction between pharyngeal patency and lung volume is believed to be an important contributor to the pathogenesis of OSA. Across the range from residual volume to total lung capacity, there is a lung volume dependence on upper airway diameter that appears to be more pronounced in subjects with OSA. During sleep, airway resistance increases as lung volume decreases. This combination leads to upward displacement of the diaphragm and thorax, with loss of caudal traction on the upper airway, yielding a more collapsible airway. Central obesity is believed to result in a reduction in lung volume during sleep, promoting pharyngeal collapse.

STABILITY OF SLEEP AND UPPER AIRWAY PATENCY

Arousal from sleep is believed to be an important if not essential mechanism for reestablishing airway patency in OSA. The preeminence of arousal is based on a temporal association between arousal and upper airway opening. Arousal mechanisms and upper airway motor neuron pools receive excitatory input from mechanoreceptors and probably also from chemoreceptors. The amount of excitation required to cause arousal is, on average, the same as that required to activate the upper airway motor neuron pool enough to open independently. Because the two systems are subject to different influences, however, the opportunity exists for either event to occur before the other. If arousal occurs prematurely in the context of a respiratory event during sleep, it may abort compensatory mechanisms such as increased pharyngeal dilator muscle activity, engendering ventilatory instability by stimulating hyperventilation. This can in turn promote upper airway collapse and worsening of OSA. These early arousals also have been associated with prolongation of respiratory events and worsened hypoxemia.

EDEMA AND ROSTRAL FLUID SHIFTS

Fluid shifts from the legs to the neck, caused by lower body positive pressure, have been shown to reduce upper airway size and increase collapsibility and appear to play a role in the pathogenesis of OSA. This mechanism is especially important in patients in whom the upper airway lumen is relatively small, because even a small amount of fluid could further compromise its patency. Some studies in patients with heart failure or superior vena cava syndrome corroborate this finding. In these patients, intensive diuresis was associated with an increase in oropharyngeal caliber and a significant reduction in AHI. Finally, vascular tone also may play a role in pharyngeal collapsibility. Animal studies have shown that vasodilatation increases and vasoconstriction decreases upper airway closing and opening pressures.

SURFACE TENSION OF UPPER AIRWAY FLUID

Upper airway collapsibility is affected by the surface tension of the liquid lining the airway, increasing both reopening and closing pressures. Increased surface tension has been reported in patients with OSA over that in normal subjects, as a consequence of mucosal trauma during apneas and use of the oral breathing route. Instillation of a surfactant has been shown to reduce AHI in persons with OSA as a consequence of improvement of airway collapsibility (reduced Pcrit).

UPPER AIRWAY INFLAMMATION

Substantial evidence has shown that inflammation is increased in the upper airway in OSA based on nasal lavage, induced sputum, exhaled breath condensate, and airway mucosal tissue biopsy specimens and that the level of inflammation is related to the severity of OSA. Factors associated with increased inflammation include mechanical trauma associated with snoring, suction collapse and traction during apneas, intense activation of dilator muscles at airway opening, increases in oxidative stress related to hypoxia-reoxygenation and other external factors such as gastroesophageal reflux, alcohol intake, smoking, allergic inflammation, the effect of systemic inflammation, and upper airway infections. Negative consequences appear in the context of repeated intense inflammation, because this could contribute to tissue injury and fibrosis, disorganization of the elastic tissue fibrillar network in uvular tissue, and changes in the connective tissue content, altering airway dimensions and compliance.

RAPID EYE MOVEMENT SLEEP

Hypopneas and apneas increase in duration and are associated with more pronounced hypoxemia during REM sleep in patients with OSA, because REM sleep is associated with decreased upper airway muscle tone, impaired genioglossus reflex responsiveness to negative pressure, and reduced chemosensitivity. Some patients experience OSA only during REM sleep. Certain protective mechanisms, however, tend to reduce event duration: The arousal threshold seems to be higher during REM sleep than during non-REM sleep in patients with OSA, and Pcrit does not change during REM sleep.

BERNOULLI EFFECT

Two physical phenomena cause a reduction in intraluminal pressure as air flows though the upper airway: loss of energy and the Bernoulli effect. The first phenomenon occurs when air flows through a segment (nasal segment) with high resistance, and potential energy is dissipated in overcoming friction, leading to a decrease in intraluminal pharyngeal pressure. Bernoulli effect is related to the acceleration of the air as it flows through a narrowed segment of the tube, contributing to a decrease in intraluminal pharyngeal pressure.

CONTROVERSIES AND PITFALLS

One of the most controversial issues in the epidemiologic approach to OSA is the difficulty of comparing the results of different studies, because they may use various methodologies and different definitions for the syndrome. Agreement is required on the definition of OSA and the type and applications of diagnostic devices, as well as a global consensus on the definition of hypopnea and what symptoms define OSA, not only in middle-aged men but also in women and elderly persons. More research should be dedicated to specific issues in these two populations: distinguishing between physiologic and pathologic situations in the number and type of respiratory events during sleep in the elderly and, in addition, the clinical presentation of OSA in women, which usually is different from the classical form. On the other hand, although general risk factors for OSA are fairly well known, an additional aspect merits further attention: the analysis of the genomic, proteomic, and metabolomic (metabolite-associated) aspects of the disease. Obstructive events during sleep result in changes in molecular processes that can be assessed, providing a potential molecular signature for the presence and consequences of OSA. Heterogeneity in biologic responses and their changes over time probably explain why some patients with OSA develop hypertension or experience more sleepiness than others, or why some affected persons suffer marked sleep fragmentation and others exhibit more intermittent hypoxia and its consequences. It is possible that developing and validating genetic and molecular signatures for OSA will provide not only diagnostic but also prognostic information, making the goal of personalized sleep medicine a reality in the near future (Figure 60-6).

Obstructive Sleep Apnea: Clinical Features, Diagnosis, and Treatment*

José M. Marin

CLINICAL FEATURES

The clinical presentations of obstructive sleep apnea (OSA) are legion. Common clinical features can be divided into major and minor categories, as summarized in Box 61-1. Patients may present with daytime and/or nocturnal complaints, but commonly, spouses and living companions are the first to push for medical attention.

SNORING

Snoring is the most frequent nocturnal symptom of OSA, occurring in up to 95% of patients with the condition. Snoring has poor predictive value owing to a high prevalence in the general population. In population surveys, the prevalence of snoring increases progressively with age, yet snoring is a hallmark of OSA, and in its absence, the diagnosis of OSA is unlikely. Snoring occurs after sleep onset, although in some patients with OSA it is present even during drowsiness. Its intensity increases with nighttime alcohol consumption and use of sedative drugs. In general, snoring is loudest in the supine position (dorsal recumbency) and decreases in volume in the side-lying position. Periods of silence interrupting loud snoring may reflect occurrence of pathologic apneas.

OTHER NOCTURNAL SIGNS AND SYMPTOMS

Patients with OSA usually fall asleep quickly, although many of them report insomnia and frequent nocturnal awakenings. Insomnia is most likely to reflect the perception of recurrent arousals from sleep and its nonrestorative pattern. Repetitive episodes of airway obstruction can be associated with snorting, gasping, diaphoresis, and restlessness that lead to sleep fragmentation. In severe OSA, choking is reported by more than 30% of patients. Nocturnal awakenings raise a differential diagnosis that should include nocturnal asthma, cardiac failure, and gastroesophageal reflux. Pathologic nocturia (2 episodes or more per night) has a prevalence of 50% among patients with OSA. It is thought to be secondary to hypoxia and atrial stretch, leading to increased atrial natriuretic peptide secretion and subsequent increment in intravascular volume. Effective therapy with continuous positive airway pressure (CPAP) reduces occurrence of these symptoms, thus suggesting a causal relationship between them and OSA.

Bed partners often volunteer witnessing breathing pauses followed by snorting or gasping during sleep, and this is a common reason for referral of the patient to a sleep clinic. Witnessed apneas are considered a good diagnostic predictor of OSA; nevertheless, this finding does not correlate with objective measurements and hence does not predict the severity of the disorder.

EXCESSIVE DAYTIME SLEEPINESS

Sleepiness is difficult to define and is a subjective feeling of impairment of concentration and increased craving for sleep. Excessive daytime sleepiness (EDS) is a nonphysiologic complaint that is not satisfied by a restorative sleep. Sleepiness is reported by 30% to 50% of the general population, so EDS alone is a poor predictor of OSA and requires a differential diagnosis to exclude many other medical conditions associated with this daytime symptom, such as depression, fibromyalgia, chronic insomnia, or hypothyroidism. Patients with OSA sometimes refer to EDS as abnormal daytime tiredness or lack of energy and convey the impression that they must make stringent efforts to remain alert and awake. It is believed that the loss of the restorative function of sleep due to repetitive arousals is the main mechanism to explain the presence of EDS in OSA. The Epworth Sleepiness Scale (Box 61-2) is the most popular tool for subjective evaluation (self-assessment) of EDS. A score above 10 of 24 is considered to be clinically relevant. The relationship between the Epworth score and the apnea-hypopnea index (AHI) (as a surrogate index of OSA severity) is relatively poor. In fact, 35% patients with severe OSA identified within sleep clinics do not complain of EDS. This discrepancy is partly due to underestimation or intentional underreporting the severity of sleepiness for personal gain, such as to avoid job loss. On the other hand, patients scoring high in the Epworth scale could have just mild to moderate OSA. EDS is the most disabling symptom among patients with OSA. One example is drowsiness while driving, which is associated with a three-fold increase in risk of accidents in patients with OSA. Poor school or job performance also is frequently reported.

OTHER DAYTIME SIGNS AND SYMPTOMS

On wakening in the morning, half of sufferers report headaches. Morning headache usually is generalized and lessens as the patient begins the usual activities of the day. This symptom may be due to hypercapnia and associated cerebral vasodilatation with resultant increase in intracranial pressure. Often,

morning headaches disappear after effective treatment of OSA. Symptoms related to cognitive impairment such as memory loss, irritability, personality changes, and depression are frequent but nonspecific. Both sleep fragmentation and nocturnal hypoxemia have been advocated to explain decreased vigilance and psychomotor impairment, respectively. One concern is the observation that OSA treated with CPAP causes only partial resolution of those deficits, suggesting a potentially irreversible anoxic brain damage. In men with OSA, sexual dysfunction including impotence and decreased libido have been reported in 30% to 50% of the cases and appears to be fully reversible with effective treatment of the OSA. Past medical history should be obtained, particularly for those conditions that may occur as a result of OSA, such as hypertension, cardiac failure, myocardial infarction, and motor vehicle crashes.

PHYSICAL EXAMINATION

After a complete history has been obtained, a systematic examination should be performed. In nonobese patients (body mass index [BMI] less than 30 kg/m^2), common physical findings can be observed in the craniofacial, nasal, pharyngeal, and dental areas (Box 61-3). Radiographic cephalometry is indicated if craniofacial abnormalities are suspected or if upper airway surgery is planned to treat the patient. The oropharynx must be examined, and the degree of oropharyngeal crowding can be scored using the Friedman Tongue Position, formerly called the modified Mallampati score. For this assessment, the patient is asked to open the mouth widely without protruding the tongue. The observer can assign scores as indicated in Figure 61-1. Higher scores suggest the presence of OSA.

Obesity frequently is associated with OSA, in both men and women, but up to 30% of newly diagnosed patients are not obese or overweight. Neck circumference greater than 40 cm is considered a reliable clinical predictor of OSA, and the size of the neck correlates with the severity of disease. Peripheral edema should be sought as a sign of possible coexisting heart failure. Careful assessment for the presence of hypertension, thyroid abnormality, and acromegaly is indicated. Blood samples should be obtained routinely for testing thyroid function and to check for any other hormonal abnormality. In children, the clinical assessment should include evaluation for evidence of Down syndrome, craniofacial disorders, and enlarged tonsils.

DIAGNOSIS

Once the diagnosis of OSA is suspected from the clinical or laboratory features, the presence and severity of the sleep-disordered breathing are confirmed and assessed by a sleep study. Patients should be referred for a sleep study as soon as possible if they have problems with work or driving because of daytime sleepiness. The American Academy of Sleep Medicine (AASM) classified four different levels of sleep testing, as summarized in Table 61-1). Inpatient sleep laboratory polysomnography (PSG) remains the “gold standard” modality for the diagnosis of OSA and the initiation of CPAP treatment. Nevertheless, the American Medicare Service recently has turned from full-night attended PSG to portable polygraphy to establish the need for CPAP as a reimbursable therapy for OSA.

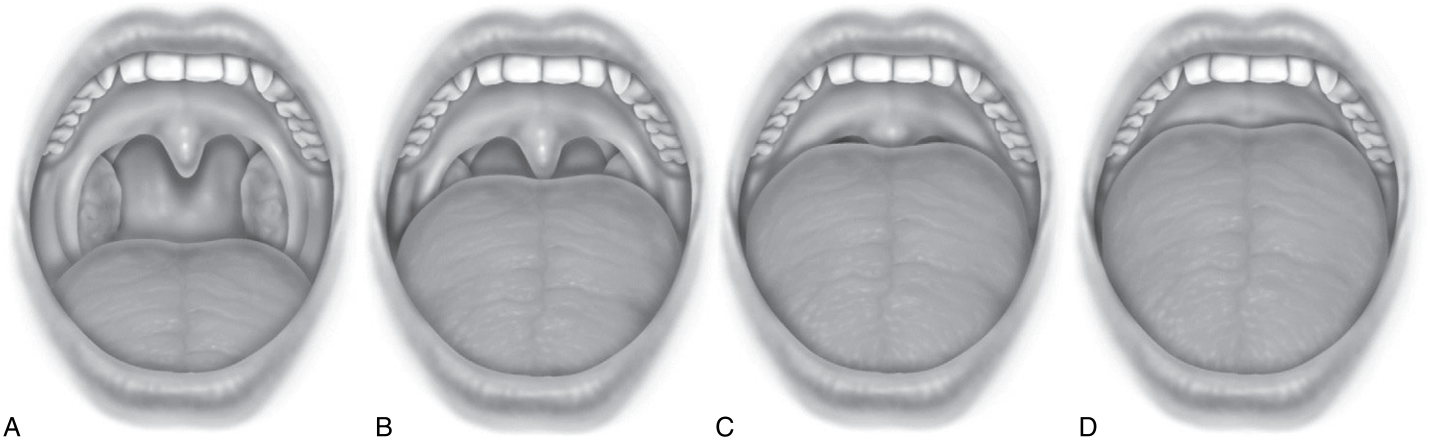

Figure 61-1 Friedman tongue position index for visualization of oral structures. **A,** Score I: all of the structures of the oropharynx are seen (soft palate, uvula, lateral pharyngeal pillars, and tonsils). **B,** Score II: allows visualization of the uvula but not the tonsils. **C,** Score III: allows visualization of the soft palate but not the uvula. **D,** Score IV: only the hard palate is seen. *(From Friedman M, Tanyeri H, La Rosa M, et al: Clinical predictors of obstructive sleep apnea,* Laryngoscope *109:1901–1907, 1999.)*

Table 61-1 AASM Classification of Different Types of Sleep Studies

Sleep Test	Description	Personnel	Minimum Signals Required
Type 1	In-laboratory PSG	Attended	*At least*: EEG, EOG, EMG, ECG, airflow, respiratory effort, and oxygen saturation
Type 2	Portable PSG	Unattended	Same as for type 1
Type 3	Portable monitor	Attended or unattended	*At least*: respiratory movement, airflow, ECG or pulse rate and oxygen saturation
Type 4	Mono-channel	Unattended	Airflow or pulse oximetry

AASM, American Academy of Sleep Medicine; *ECG*, electrocardiogram; *EEG*, electroencephalogram; *EMG*, electromyogram; *EOG*, electrooculogram; *PSG*, polysomnography.

POLYSOMNOGRAPHY

Polysomnography records neurophysiologic and cardiorespiratory signals, to assess sleep stage. Monitoring includes electroencephalography (EEG), electromyography (EMG) of the anterior tibialis, electrocardiography (ECG), oronasal airflow, snoring, thoracic, and abdominal movements, pulse oximetry, and body position (Figure 61-2). The PSG study must be performed in sleep laboratories by trained technicians and is therefore costly and time-consuming but provides the physician with information on both breathing- and non–breathing-related sleep disorders. PSG should be the preferred diagnostic sleep test for snorers with a lower likelihood of OSA, patients with EDS that could be caused by other non–breathing-related disorders during sleep (e.g., narcolepsy, restless legs syndrome), and patients with other medical comorbid conditions (e.g., neuromuscular, cardiac, and respiratory disorders). Apneas and hypopneas are identified, and the number of events per hour of sleep—the apnea-hypopnea index (AHI)—is determined. An AHI of less than 5 is normal. The severity of OSA is classified according to the AHI as mild (5 to 15 events/hour), moderate (15 to 30 events/hour), or severe (more than 30 events/hour). This disease severity classification is correlated with fatal and nonfatal cardiovascular outcomes.

Patients with OSA who are considered candidates for CPAP treatment (see further on) need to have a second attended PSG to determine the optimal level of CPAP to abolish the occurrence of all respiratory events. The so-called split night study combines a diagnostic PSG followed by CPAP titration during the same night. It is an accepted alternative to full-night PSG if the AHI is greater than 40 events/hour during the first two hours of recording.

UNATTENDED SLEEP STUDIES

For hospitalized patients or for persons unable to attend a sleep laboratory, PSG can be performed as an unattended study (type 2 study of the AASM classification). Indications and technical requirements are the same as for type 1 (in-laboratory PSG). Type 3 patient monitors are increasingly used owing to the limited number and capacity of sleep laboratories, as well as the increasing number of persons suspected of having OSA. These devices do not monitor EEG and sleep stages but should record the minimum airflow, respiratory effort, and O_2 saturation (Figure 61-3). They cannot evaluate sleep time or detect respiratory event-related arousals. As a result, they tend to underestimate the AHI. On the other hand, for most patients, home sleep studies offer greater convenience, and the study conditions allow close replication of the usual nighttime sleep pattern. The diagnosis of OSA is confirmed and severity determined using the same criteria as for PSG. Type 4 home monitors record continuous single or dual signals during sleep, including O_2 saturation and/or airflow (Figure 61-4). Baseline values for SaO_2, mean SaO_2, nadir SaO_2, and O_2 desaturation index (number of episodes of desaturation greater than 3% as divided by recording time) can be collected very easily using home oximetry. Airflow recorders also assess the frequency of apneas and hypopneas, but differentiation between obstructive and central or mixed apneas cannot be achieved.

The utility of type 3 and type 4 studies is greater for diagnosis of OSA in patients with high pretest probability of moderate to severe OSA and not combined sleep or major medical disorders. In most sleep units, however, use of a home monitor recording oxygen saturations, pulse rate, and airflow, calculating the number and severity of apneas, is a perfectly adequate screening test. If done before the patient sees the clinician, it may suffice or may indicate that a more sophisticated sleep

study is needed. A negative result with a portable monitor in patients with symptoms or clinical features highly consistent with OSA also warrants in-laboratory PSG.

OTHER EVALUATIONS

Once the diagnosis of OSA is made, collaboration with an ear, nose, and throat (ENT) specialist may be valuable to search for anatomic obstruction and to formulate a personalized therapy for each patient. Further blood sample analysis or imaging techniques may not be necessary if additional medical conditions are not suspected, although thyroid function abnormalities can still be present without clinical symptoms. In addition, the patient's drug history should be reviewed carefully, because many medicines such as opioids, hypnotics, antidepressants, or antihistamines can cause or aggravate sleep apneas.

DIAGNOSIS

After snoring, EDS is the most common presenting complaint in persons with OSA. Bed partners should be asked about the usual pattern of the patient's sleep, and the physician must consider other causes of EDS in the differential diagnosis (Table 61-2). Apart from OSA, sleep can be interrupted by many other medical conditions, all causing EDS. In particular, patients with asthma and COPD frequently wake up owing to increased nocturnal respiratory symptoms. Heart failure and gastroesophageal reflux must be ruled out as potential causes of poor sleep quality and EDS. As noted, a drug history to identify medications that can cause EDS (e.g., psychiatric drugs, antihistamines, beta blockers) also should be part of a complete evaluation of all patients reporting EDS.

TREATMENT

GENERAL MEASURES

Treatment options should be offered in the context of the severity of the patient's OSA, risk factors, associated comorbid conditions, and personal wishes. A flow diagram outlining a treatment algorithm is shown in Figure 61-5. All affected patients should avoid alcohol and sedatives, because these agents reduce upper airway muscle tone and increase severity of OSA.

Weight loss reduces the collapsibility of the upper airway. It has been shown that a 1% reduction in weight is associated with a 3% decrease in AHI in severe OSA. Currently, weight loss is not a primary treatment for OSA but is recommended as an adjunct to other primary therapies and measures such as CPAP. For patients with mild OSA in whom apneas occur only in the supine position and without daytime sleepiness, positional therapy (e.g., with appropriate use of pillows or placement of a tennis ball at the back) may be of benefit. A type 3 or 4 home monitor can evaluate the efficacy of weight loss or positioning measures. No other medical therapies are recommended as primary treatment for OSA of any severity.

SURGICAL TREATMENT

The goal of upper airway surgical procedures is to increase upper airway patency. Surgery remains controversial for the treatment of OSA and is not widely used. A recent Cochrane review concluded that the available evidence does not support the use of surgery for patients with OSA. Nevertheless, it could be indicated if a specific airway abnormality is found. The AASM has identified three potential conditions for the application of upper airway surgery:

1. As a primary therapy for patients with mild OSA who have severe obstructive anatomy that is surgically correctible
2. As secondary treatment for OSA when CPAP or use of an oral appliance (OA) is poorly tolerated or contraindicated or provides inadequate correction or benefit
3. As an adjunctive therapy when obstructive anatomy or functional deficiency compromises other therapies, or to improve tolerance of other OSA treatment

Tonsillectomy or adenoidectomy (or in combination) is the primary treatment for children but does not improve OSA in adults. In patients with craniofacial abnormalities, procedures such as mandibular or genioglossus advancement with tongue and hyoid suspension can be effective when performed by expert surgeons. Uvulopalatopharyngoplasty (UPPP) reduces soft palate redundancy and can be used in patients with mild OSA with retropalatal obstruction. Even in these patients, UPPP reduces AHI to less than 50% of baseline. In patients with hypopharyngeal obstruction or severe OSA, UPPP is not effective at all. Hypopharyngeal procedures such as tongue reduction and tongue advancement or stabilization can be considered in patients with macroglossia or hypopharyngeal obstruction, but again these procedures should be performed by experienced surgeons. Nasal surgery—septoplasty, nasal polypectomy, turbinate reduction, and others—should be considered as adjunctive therapy to increase tolerance to CPAP.

Postsurgical follow-up evaluation should include a sleep study to objectively assess the procedure's success. Further surgical specific outcomes to be evaluated include side effects, complications, anatomic results, patient and spousal satisfaction, and resolution of sleepiness.

ORAL APPLIANCES

The aim with use of OAs is to increase upper airway patency and reduce its collapsibility by improving muscle tone. Most OA devices cover upper and lower teeth and hold the mandible in an advanced position with respect to the resting position. This positioning, in turn, pulls the tongue forward, making pharyngeal collapse with consequent obstruction much less likely to happen. An OA ideally should be custom-made for the patient after a dental consultation (Figure 61-6); when created using this approach, the device is much more likely to be beneficial.

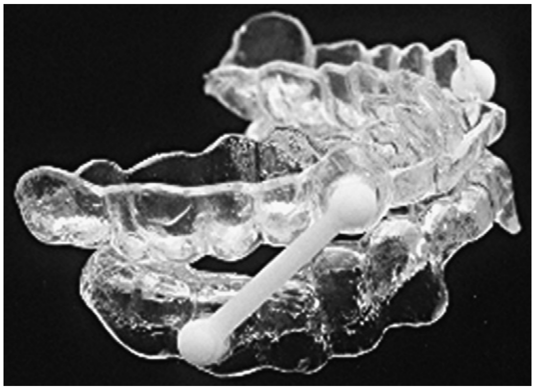

Figure 61-6 Oral appliance. *(From Douglas NJ: Obstructive sleep apnea. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

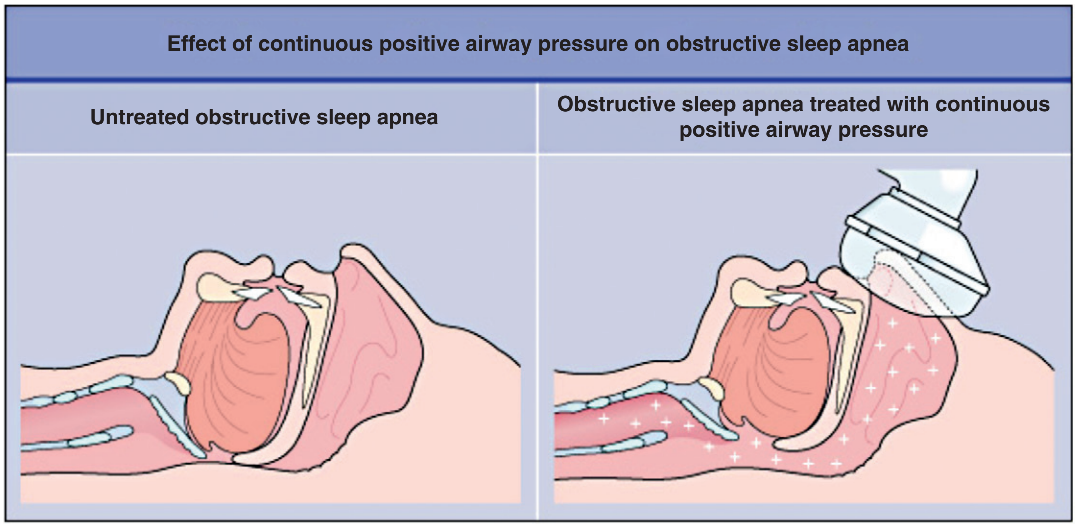
In clinical trials, OAs are less efficacious at reducing AHI but are associated with better compliance than that typical for CPAP. Available data regarding long-term outcomes with use of these appliances in persons with OSA are limited. No variables predictive of success have been identified, although OAs work better in persons with mild to moderate OSA, but not so well in those with big heavy jaws and masseters, which can generate forces sufficient to destroy the appliance. Also many persons with OSA grind their teeth during sleep; this bruxism also can destroy the appliance. Thus, sleep studies (e.g., with a home monitor) after treatment are recommended to document the efficacy of these devices. Currently, OAs are indicated for persons with simple snoring, patients with mild to moderate OSA, and those unable or unwilling to use CPAP.

POSITIVE AIRWAY PRESSURE

Positive airway pressure (PAP) currently is the management modality of choice for patients with OSA. PAP works by providing pneumatic splinting of the upper airway (Figure 61-7). In randomized trials, PAP delivered in continuous mode (i.e., CPAP) has been shown to improve quality of sleep, relieve daytime sleepiness, support maintenance and recovery of neurocognitive and driving abilities, decrease arterial hypertension, and help maximize quality of life in patients with OSA. It also reduces the frequency of cardiovascular events as long-term outcomes in prospective observational studies (Figure 61-8).

To determine optimal PAP level, a full-night attended PSG study is the preferred approach for titration. A split-night sleep study, however, may be indicated when AHI higher than 40 is recorded during the initial two hours of PSG. Auto-CPAP (aCPAP) machines continually adjust the applied pressure depending on the patency of the upper airway. Such devices may be used in an unattended setting to determine a fixed CPAP pressure, but this option is valid only for patients without significant comorbid conditions or other non-OSA sleep disorders. When high PAP pressure is required to avoid obstruction, the patient receiving CPAP or aCPAP therapy may experience difficulty with exhaling or can develop hypoventilation. In such cases, a switch to a bilevel system (BiPAP) will allow independent adjustment of inspiratory and expiratory pressures, potentially improving tolerance to the therapy.



Effect of continuous positive airway pressure on obstructive sleep apnea
Untreated obstructive sleep apnea
Obstructive sleep apnea treated with continuous positive airway pressure

Figure 61-7 Anatomic changes with use of continuous positive airway pressure (CPAP) in obstructive sleep apnea. *Left*, Obstruction of the upper airway at the retrolingual level. *Right*, CPAP works by splinting and dilating the obstructed pharyngeal segment.

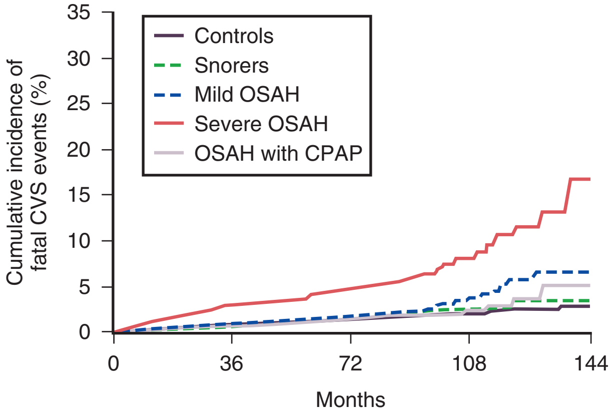


Figure 61-8 Effect of continuous positive airway pressure (CPAP) on mortality. Cumulative incidence of fatal cardiovascular events in patients with untreated obstructive sleep apnea-hypopnea (OSAH) and treated OSAH with CPAP. *(From Marin JM, Carrizo SJ, Vicente E, et al: Long-term cardiovascular outcomes in men with obstructive sleep apnoea/hypopnoea with or without treatment with continuous positive airway pressure: an observational study,* Lancet *365:1046–1053, 2005.)*

PAP usually is delivered by nasal mask. Other interfaces such as nasal pillows or full face masks are alternatives to increase patient comfort, ensure a good seal, and avoid leaks. Long-term adherence is predicted by patient sleepiness, average nightly use within the first weeks of therapy, and the reporting of problems during the titration night. PAP is safe, and adverse events are minor and reversible. The most common side effect of PAP is nasal irritation and dryness, which can be treated with an integral heated humidifier. After initial PAP setup, follow-up evaluation is recommended at least once a year and whenever needed to troubleshoot device problems and to assess the cause of any change in clinical features.

ADJUNCTIVE THERAPIES

In obese patients, bariatric surgery may be an acceptable adjunctive therapy in the management of OSA. This surgical procedure is indicated for subjects with a body mass index (BMI) of 40 kg/m^2 or greater or those with a BMI of 35 kg/m^2 or greater with important comorbid conditions. Data from cohort studies show that AHI decreases with weight loss after surgery. If previously initiated, PAP should be maintained after surgery as long as it is indicated (see further on).

Oxygen therapy alone is not recommended for patients with OSA. Such therapy provided during sleep could be added to PAP treatment if, during PAP titration, O_2 was needed to correct hypoxemia in patients with cardiopulmonary comorbidity. No effective drugs are available for treatment of OSA. Use of topical nasal steroids may be beneficial adjunctive therapy in patients with rhinitis and frequently improves nasal suffusion, which many patients complain of during CPAP therapy. Modafinil can be used to relieve residual sleepiness in patients who remain sleepy despite effective PAP treatment.

EFFECTS OF TREATMENT ON MAJOR OUTCOMES

In patients with moderate to severe OSA, maxillofacial surgery is the only surgical procedure for which the degree of improvement in sleepiness achieved was similar to that obtained with CPAP in a randomized trial. No effect on other major clinical outcomes such as motor vehicle crashes or incident cardiovascular events in patients with sleep apnea has been evaluated after surgical procedures or with the use of OAs.

In short-term randomized studies, CPAP reduced blood pressure in patients with severe OSA. This effect was evident only in patients who used the machine for more than 5 hours per night. In specific hypertensive populations such as patients with OSA plus resistant hypertension, CPAP also is effective, but again, the treatment must be used for more than 5 hours per night. The long-term effect of therapy to reduce new-onset hypertension in previously normotensive patients with OSA has not yet been determined. In population and clinic-based long-term observational studies, treatment with CPAP in patients with severe OSA is associated with reduced risk for development of fatal and nonfatal cardiovascular events (i.e., myocardial infarction, stroke). A reduction in frequency of motor vehicle crashes among persons with severe OSA treated with CPAP also has been noted. Today, however, with respect to assessment and validation of the effect of treatment, good long-term randomized controlled trials with strong end points such as cardiovascular events, traffic accidents, or all-cause mortality are lacking. Attempting these kinds of studies poses ethical problems in patients with significant daytime sleepiness: Because CPAP is very effective in alleviating this symptom, it cannot be denied for a long time in a control group.

WHOM TO TREAT AND HOW

Untreated patients with moderate to severe OSA have an increased risk for involvement in motor vehicle crashes and cardiovascular events. Current evidence indicates that persons with excessive daytime sleepiness (e.g., with an Epworth Sleepiness Scale score higher than 10), or who fall asleep while driving to or at work, should be treated no matter what the AHI is. For these patients, PAP is the primary treatment. For patients with AHI greater than 30, CPAP also is indicated as primary treatment regardless of the degree of sleepiness. For those with mild to moderate OSA (AHI between 5 and 30), therapy with CPAP is effective, but OAs and upper airway surgery should be offered and the risks and expected benefits discussed with the patient. Use of OAs is more suitable for thinner and younger patients with mild OSA. Surgery should be limited to patients with mild to moderate OSA who refuse other forms of therapy or as adjunctive treatment for those with upper airway obstruction to improve tolerance to PAP.

CONTROVERSIES AND PITFALLS

OBSTRUCTIVE SLEEP APNEA IN WOMEN

As in chronic obstructive pulmonary disease (COPD), OSA remains underdiagnosed in women. Physicians have a lower suspicion of OSA in females. On the other hand, they are more reluctant than males to complain of snoring. Finally, women reported more sleep and medical comorbidities such as depression, fibromyalgia, hypothyroidism, or chronic fatigue syndrome that ultimately can be attributed as responsible for daytime sleepiness. Hence, the clinicians need to include OSA in their differential diagnosis when evaluating female patients.

OBSTRUCTIVE SLEEP APNEA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The coincidence of OSA and COPD is termed *overlap syndrome*, and it is present in 1% of adults older than 40 years of age. In patients with OSA alone, daytime hypoxemia is rare, but in patients with COPD, the coexistence of OSA is associated with more profound nocturnal hypoxemia than in patients who have only one disorder. Consequently, patients with the overlap syndrome are at high risk for development of pulmonary hypertension. Recently, these patients have been reported to be at increased risk for severe exacerbations of COPD and all-cause mortality compared with patients with COPD and no coexistent OSA. Moreover, treatment of the OSA component of the overlap syndrome with CPAP decreases COPD exacerbations and improves survival. Accordingly, it is paramount in patients with COPD and daytime sleepiness to evaluate the potential coexistence of OSA.

SLEEP LABORATORY VERSUS OUT-OF-LABORATORY DIAGNOSIS

Full overnight polysomnography remains the "gold standard" modality for the diagnosis of sleep-disordered breathing performed in a staffed laboratory setting. Out-of-laboratory diagnosis is rapidly growing in respiratory medicine. The utility of these studies is greatest among patients with high pretest probability of severe disease, who may benefit from expedited diagnosis and treatment. Nevertheless, uncertainty remains regarding the quality of most devices, and pitfalls in automatic scoring have been recognized. Currently, portable systems for the diagnosis of OSA should be applied only by trained physicians, and their use should be limited to patients with suspected OSA not associated with comorbid conditions or other sleep disorders unlikely to be a cause of symptoms.

NON-CONTINUOUS POSITIVE AIRWAY PRESSURE THERAPY

Despite the efficacy of CPAP for relieving symptoms of OSA, many patients experience discomfort with this therapy and look for a curative option. Evidence supports the use of OAs in persons with mild to moderate OSA and weight loss in obese patients. Nevertheless, most surgical therapies lack robust scientific evidence and cannot be recommended as treatment for severe OSA. Controversies exist on when and what procedure to perform on an individual basis. Success depends mainly on the experience of the surgeon.

SLEEP-DISORDERED BREATHING

Chapter 62

Obesity Hypoventilation Syndrome

Gimbada B. Mwenge • Daniel Rodenstein

Obesity hypoventilation syndrome is a disorder characterized by the presence of daytime compensated respiratory acidosis (i.e., hypercapnia with normal pH and increased serum bicarbonate), in patients in whom no cause of ventilatory failure can be identified. These patients cannot ensure a normal minute ventilation even in the resting state, although clinical evaluation will rule out disorders associated with decreased muscle force (neuromuscular diseases), abnormal muscle geometry (e.g., kyphoscoliosis), severe airway obstruction and abnormal ventilation-perfusion relationships (e.g., chronic obstructive pulmonary disease [COPD], emphysema), or parenchymal abnormalities (e.g., interstitial lung diseases). In these patients, with performance of a respiratory maneuver consisting of serial deep inspirations, subsequently the arterial carbon dioxide tension ($PaCO_2$) normalizes, and in those in whom hypoxia is present, oxygen saturation (SaO_2) rises by 4% to 6% in less than 2 minutes. Of note, however, they do not sustain adequate minute ventilation and remain hypercapnic, with the kidneys compensating to maintain a normal pH. Another clinical element quite evident is that such persons are obese, frequently morbidly obese, with body mass index (BMI) values in excess of 35 kg/m^2. It is the association of pathologic obesity and daytime hypercapnia that defines the obesity hypoventilation syndrome.

When these patients are studied in a sleep laboratory, it becomes clear that they are afflicted with some form of sleep-disordered breathing pattern. The vast majority of patients have a moderate to severe form of obstructive sleep apnea (OSA), with a minority showing no obstructed breathing but simply sleep-related hypoxia and hypercapnia (long periods of SaO_2 below 90% and an increase in $PaCO_2$ of about 10 mm Hg developing overnight). The diagnosis of obesity hypoventilation syndrome can be reached with certainty only when other causes of daytime hypercapnia have been excluded.

EPIDEMIOLOGY

The prevalence of obesity hypoventilation syndrome in the general population remains unknown. In the United States, it has been estimated to be between 0.15% and 0.3%. A study conducted in obese hospitalized patients with a BMI greater than 35 kg/m^2 found a prevalence of 31%. Among patients with OSA, previous European studies (France, Italy, Greece, and Spain) found occurrence rates for obesity hypoventilation syndrome of 9% to 17%. Studies from the United States found a prevalence of greater than 20% in this patient group.

The gender ratio for obesity hypoventilation syndrome remains uncertain: Even if the prevalence seems to be higher in men, some studies found a higher proportion of the cases in women. All reported data come from selected cohorts of hospitalized patients or from sleep laboratories.

RISK FACTORS

Several conditions seem to predispose an obese person to development of the obesity hypoventilation syndrome. Undisputedly, in comparison with patients with OSA, patients diagnosed with this syndrome seem to be more obese, and they have more severe OSA. The main cause of obesity is well recognized to be an excess of food intake in relation to the energy expenditure requirements of the organism, resulting in the constitution of an energy stock essentially in the form of fat deposits. According to worldwide epidemiologic data, the prevalence of obesity is increasing everywhere, and this trend seems to be related essentially to a rapid change in eating habits, themselves influenced by technologic changes and food industry policies. Whether this reflects an improvement in the standard of living is a matter of debate.

The health consequences of obesity should prompt implementation of educational strategies to promote adequate behavioral changes in eating habits. Nevertheless, at the individual level, genetic factors may have an influence on the development of obesity, depending on the balance between what can be termed "catabolic" and "anabolic" genes. More than 250 genes have been identified that have a more or less important influence on the final handling of the energetic balance. The clinical importance of each genetic variant, however, is not yet well appreciated. Only a few monogenetic causes of obesity have been described in humans, the best example being mutations in the gene coding for the melanocortin 4 receptor. It has to be stressed, however, that obesity will not develop if access to food is compromised, or if energy expenditure exceeds energy absorption.

An apnea-hypopnea index (AHI) greater than 50, as measured by the number of apneic or hypopneic episodes per hour of sleep, also seems to be a risk factor for obesity hypoventilation syndrome, because 25% of patients with such AHIs in several studies had the syndrome. Oxygen saturation nadir levels below 60% during polysomnography and moderate to severe restriction found on pulmonary function testing also are predictors for the syndrome, with odds ratios of 4 and 10, respectively. Finally, some studies found that patients with obesity hypoventilation syndrome had greater neck, waist, and hip circumferences and a larger waist-to-hip ratio than their counterparts with OSA.

PATHOPHYSIOLOGY

Obese patients, both eucapnic and hypercapnic, have significant reductions in functional residual capacity and expiratory reserve volume with preservation of inspiratory capacity and often normal or slightly reduced total lung capacity. But obesity is not, however, the only determinant of hypoventilation, because only a third of morbidly obese persons develop hypercapnia. Some differences between eucapnic obese and hypercapnic subjects have been recognized and are summarized next.

Reduced Muscle Strength

The maximal inspiratory and expiratory pressures are normal in eucapnic morbidly obese patients but may be reduced in patients with obesity hypoventilation syndrome, although this is not a universal finding.

Central Respiratory Drive

Many studies found that patients with obesity hypoventilation syndrome do not hyperventilate to the same degree as morbidly obese patients without the syndrome when rebreathing CO_2. This deficit corrects in most patients after normalization of $Paco_2$. In patients with severe OSA but without hypercapnia, the hypercapnic ventilatory response does not change with continuous positive airway therapy (CPAP). The reversibility of the blunted central drive suggests that this is a secondary phenomenon of the syndrome (and necessary for its persistence), but not the origin of it.

Obstructive Sleep Apnea

OSA may play a role in the pathogenesis of chronic hypercapnia in those patients, because in most cases, treatment of OSA corrects the hypercapnia. Indeed, to compensate for the effect of intermittent periodic breathing and resultant acute hypercapnia, normal subjects as well as patients with OSA will increase their tidal volume in the first breath after an apnea (hyperventilation). With physiologic differences in ventilatory responses between subjects, however, an overload in CO_2 could result. The duration of the apneas also could contribute: When apneic episode duration becomes three times longer than the breathing interval, CO_2 tends to accumulate despite maximal tidal volume, because there is insufficient time for adequate hyperventilation events (**Figure 62-1**). In addition, hypercapnia could blunt the ventilatory responses: The initial ventilation after an apneic episode is directly related to the volume of CO_2 loaded during the preceding respiratory event and thus represents an index of CO_2 ventilatory response. Hypercapnic patients demonstrated depression of this index of ventilatory compensation compared with that in eucapnic patients. It has been shown that the apnea-to-interapnea duration ratio is greater in hypercapnic patients than in eucapnic patients.

One study also has shown impaired CO_2 homeostasis after respiratory events may be mediated by opioids or opioid receptors, because endorphin blockade changed this pattern. Increased cerebrospinal fluid beta-endorphin activity with return to normal values has been reported in subjects with OSA. This finding could explain hypercapnia on awakening after a night full of apneic episodes. To understand why in a period of wakefulness free of apnea the $Paco_2$ does not normalize, the role of the renal system has to be considered. Hypercapnia leads to respiratory acidosis, which activates the process of renal compensation.

To elucidate the mechanisms that are involved in the development of hypercapnia in patients with OSA, Norman and co-workers have proposed, using a computer model, some hints for prediction of the transition from acute hypercapnia during sleep-disordered breathing (apnea, hypopnea, and hypoventilation) to chronic daytime hypercapnia. In their model, when the ventilatory CO_2 response and renal HCO_3^- excretion were normal, increases in $Paco_2$ and HCO_3^- did not develop. The bicarbonate excretion during the day compensated for that retained during the night. When CO_2 ventilatory response was very low, however, the model demonstrated a modest rise in $Paco_2$ and HCO_3^- measured during the awake state over multiple days. Similarly, when renal HCO_3^- excretion rate was lowered to simulate chloride deficiency, the model

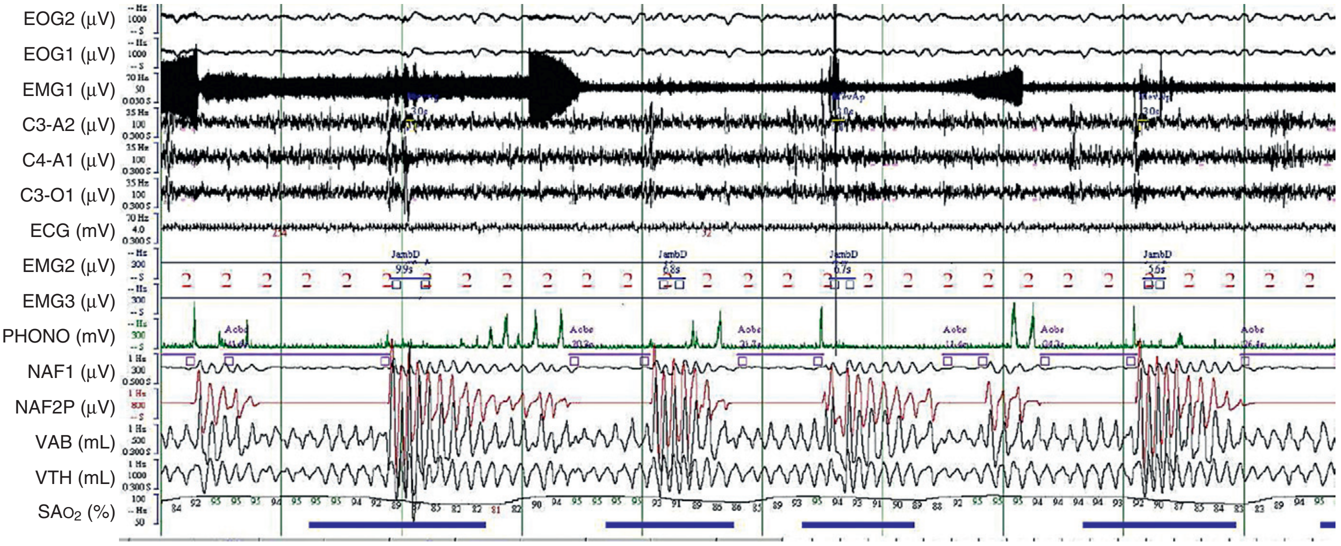

Figure 62-1 Five-minute tracing from a diagnostic polysomnography study. *Top to bottom*: Two electrooculograms (*EOG*); chin electromyogram (*EMG1*); three electroencephalograms (*C3-A2*, *C4-A1*, *C3-O1*); electrocardiogram (*ECG*); leg movement electromyograms (*EMG2*, *EMG3*); snoring recordings (*PHONO*); oronasal flow with a thermocouple (*NAF1*); nasal flow (*NAF2P*); abdominal and thoracic movement from inductive plethysmographic bands (*VAB*, *VTH*); and oxygen saturation measurement with pulse oximetry (Sao_2). The subject is in stage 2 non-REM sleep. Note the absence of nasal flow and persistent abdominal and thoracic movements with falls in oxygen saturation, with successive obstructive apneas ending with loud snoring and leg movements (with one exception). *REM*, rapid eye movement.

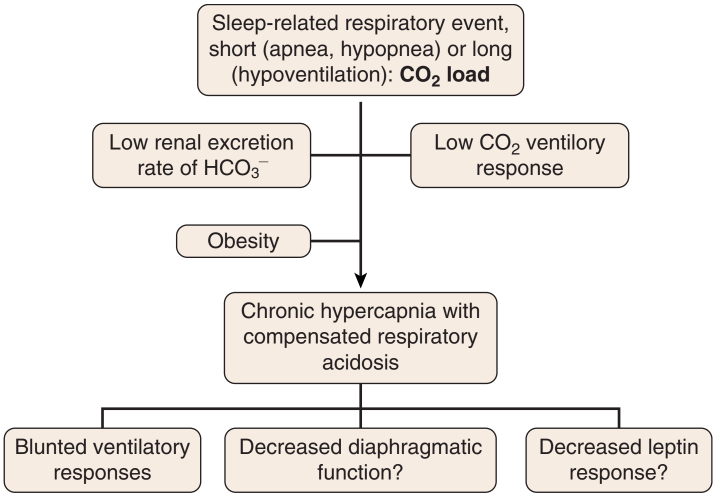

Sleep-related respiratory event, short (apnea, hypopnea) or long (hypoventilation): CO_2 load
Low renal excretion rate of HCO_3^-
Low CO_2 ventilory response
Obesity
Chronic hypercapnia with compensated respiratory acidosis
Blunted ventilatory responses
Decreased diaphragmatic function?
Decreased leptin response?

Figure 62-2 Schematic representations of the physiopathology of obesity hypoventilation syndrome. Respiratory events with the combination of low CO_2 ventilatory response and low renal HCO_3^- excretion rate produce a synergistic effect on the degree of elevation of daytime $PaCO_2$. Chronic hypercapnia will then lead to blunted ventilatory responses, possibly decreased diaphragmatic function, and decreased leptin response.

demonstrated a modest rise in daytime $PaCO_2$ and HCO_3^-. The combination of low CO_2 response and low renal HCO_3^- excretion rate produced a synergistic effect on the degree of elevation of daytime $PaCO_2$. These workers suggested that hypercapnia results from an imbalance between the period of CO_2 loading (short = apnea or hypopnea; long = hypoventilation) and inadequate compensation both during sleep and during the awake state. This pulmonary-renal interaction may contribute to the development and perpetuation of chronic daytime hypercapnia, which will lead to a blunted respiratory drive for the next sleep cycle (Figure 62-2).

There is clearly a link between the pathogenesis of OSA and pure hypoventilation in patients with obesity hypoventilation syndrome. In their study, De Miguel Díez and colleagues provided ventilatory support to 12 patients with pure obesity hypoventilation syndrome (without sleep apnea), using noninvasive ventilation (NIV), for a minimum period of 1 year. After 3 months subsequent to discontinuation of NIV and disappearance of hypercapnia, 7 patients had developed obstructive sleep apnea syndrome. These data suggest that impairment of the ventilatory drive caused by compensated respiratory acidosis may potentially lead the switch from apnea-hypopnea syndrome to pure obesity hypoventilation syndrome.

Neurohormonal Response (Leptin Resistance)

Leptin is a protein released by adipose tissue. Its functions are to reduce appetite and increase energy expenditure. In obesity, some studies have found high blood levels of leptin but without the expected physiologic effects, suggesting the presence of so-called leptin resistance. Animal studies have shown that this protein is a potent stimulus of ventilation, and absence of or reduction in its action may result in hypoventilation. Serum levels of leptin are decreased or normal after CPAP treatment in patients with OSA. A hypothesis for this association is that the apnea and hypopnea could be the *cause* of the elevation of leptin, rather than the result. Leptin levels are twice as high in patients with obesity hypoventilation syndrome as in patients with similar degrees of obesity and similar AHI values. Leptin levels can be reduced with NIV or weight loss. All of these observations have led to the idea that resistance to leptin may be the cause of obesity hypoventilation syndrome. A recent study, however, found opposite results: Those patients with the syndrome not associated with a significant number of apneic and hypopneic episodes have lower leptin levels than those obese patients with the same number of obstructive events without daytime hypercapnia and obesity, and leptin levels increased with treatment with NIV. More studies have to be performed to clarify those findings. Clearly, as yet, no comprehensive picture of the neurohumoral interactions in obesity hypoventilation syndrome has emerged.

CLINICAL FEATURES

The following clinical features have been found in a systematic review of the literature including a significant number of patients. Patients typically are diagnosed in the sixth decade of life and prevalence is slightly higher in men (60%). Compared with patients with OSA, patients with obesity hypoventilation syndrome are severely obese (mean, 44 kg/m^2; range, 35 to 56 kg/m^2). Up to 90% of these patients have OSA, with an AHI in the severe range (mean, 66; range, 20 to 100). Subjects with obesity hypoventilation syndrome are sleepier than those with OSA (on the Epworth sleepiness scale, a score of 14.6 ± 4.9, versus 12.5 ± 4.6). The impact of this excessive sleepiness has the same consequences, with decrements in work performance, concentration lapses, inattention, and increased reaction time. Nocturnal and daytime hypoxemia also characterize obesity hypoventilation syndrome. Depending on the studies, the mean reported daytime PaO_2 is 53 mm Hg (47 to 74 mm Hg). Finally, the nadir of oximetry-measured oxygen saturation (SpO_2) during sleep often is below 60%.

DIAGNOSIS

HISTORY

Most patients with obesity hypoventilation syndrome will have some daytime respiratory complaints (dyspnea) and some degree of excessive daytime sleepiness. They often have comorbid illnesses at the time of diagnosis, such as diabetes and hypertension. All other complaints also are seen in typical eucapnic patients with OSA, including loud snoring, nocturnal choking episodes with witnessed apneas, and excessive daytime sleepiness, nycturia, mood disturbance, and morning headaches. The diagnosis usually is made by a sleep specialist or a respiratory physician. Alternatively, in patients previously treated for OSA successfully, recurrence of symptoms can suggest a shift toward obesity hypoventilation syndrome. Frequently, patients are diagnosed after an episode of acute respiratory failure with admission to intensive care unit.

PHYSICAL EXAMINATION

Physical examination in both eucapnic and hypercapnic patients with obesity hypoventilation syndrome usually reveals a BMI higher than 40 kg/m^2 and a neck circumference greater than 42 cm in men and 40 in women. The oral examination shows a large tongue with a crowded oropharynx (Mallampati score IV; Friedman tongue position index of 3 or 4). Few specific findings have been recognized to distinguish obesity hypoventilation syndrome from OSA: Abnormal oxygen saturation (SpO_2) detected by finger pulse oximetry during the awake state also should lead clinicians to exclude the syndrome in patients with OSA, because hypoxemia during the awake state is not common in these patients.

Patients with obesity hypoventilation syndrome may present with signs of cor pulmonale: a prominent pulmonic component of the second heart sound on cardiac auscultation, lower extremity edema, injected sclera (thought to be related to elevated $Pa\text{CO}_2$ and cerebral vasodilatation), hepatomegaly, and prominent jugular veins.

BLOOD GAS ANALYSIS AND SERUM BLOOD CHEMISTRY

Elevated serum venous bicarbonate level has been suggested as an effective screening tool. Of patients with serum bicarbonate levels greater than 27 mmol/L and clinical obesity (BMI higher than 30 kg/m^2), 38% had obesity hypoventilation syndrome in one study. If obesity was severe and lung function showed restriction and severe OSA, the prevalence of obesity hypoventilation syndrome jumped to 56%.

Hypothyroidism is a rare occurrence, but it may be worth excluding with a thyroid-stimulating hormone (TSH) challenge test.

"Awake" (daytime) hypercapnia ($Pa\text{CO}_2$ greater than 45 mm Hg) in arterial blood is a defining criterion for the diagnosis and frequently is accompanied by daytime hypoxia.

SLEEP LABORATORY DIAGNOSIS

Sleep-disordered breathing can take either of two forms; the most common type is OSA, and the second one is central hypoventilation. Polysomnographic evaluation shows either a typical OSA pattern or periods of fall in $Sa\text{O}_2$ in REM stages alone (**Figure 62-3**) or throughout the entire sleep period (**Figure 62-4**). In many cases, sleep-disordered breathing is seen throughout sleep, with steep falls in saturation in non-REM sleep and much steeper falls in the REM stage (see Figure 62-4).

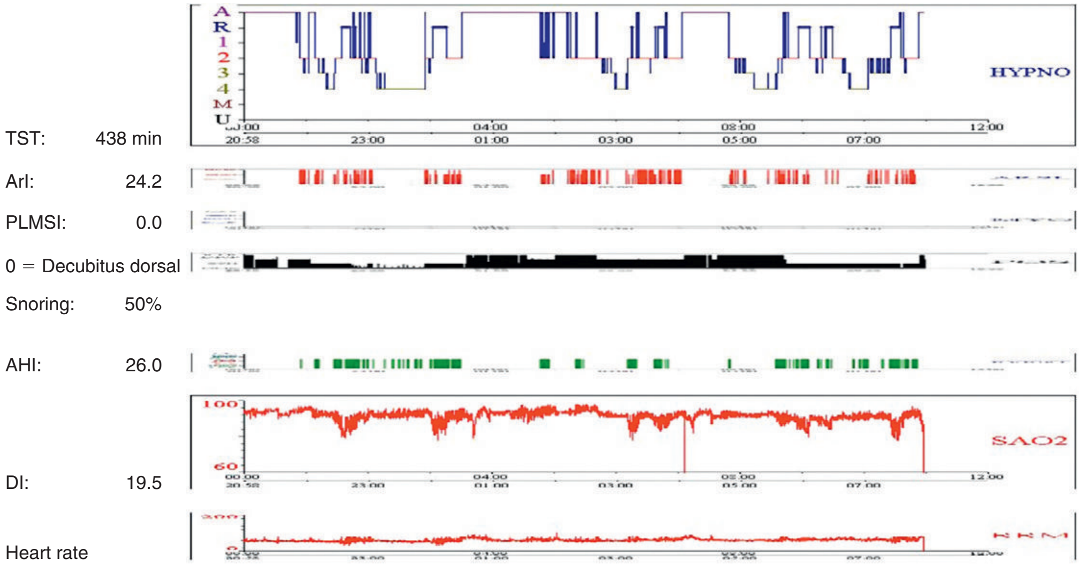

Figure 62-3 *Top to bottom*: The first horizontal panel shows a graph of the wake and sleep data: *A*, awake state; *R*, REM sleep; *1*, *2*, *3*, *4*, non-REM sleep stages; *U*, unknown stage; *M*, movement. The next panels show arousal index (*ArI*), index of periodic leg movements (*PLMSI*), body position (with the supine position indicated as 0), snoring as a percentage of sleep time, apnea-hypopnea index (*AHI*), desaturation index (*DI*) (defined as the number of 4% or greater falls in oxygen saturation [$Sa\text{O}_2$] per hour of sleep), and heart rate. Of note, apneas and hypopneas lead to falls in oxygen saturation, but these falls are much steeper during REM sleep. *REM*, rapid eye movement; *TST*, total sleep time.

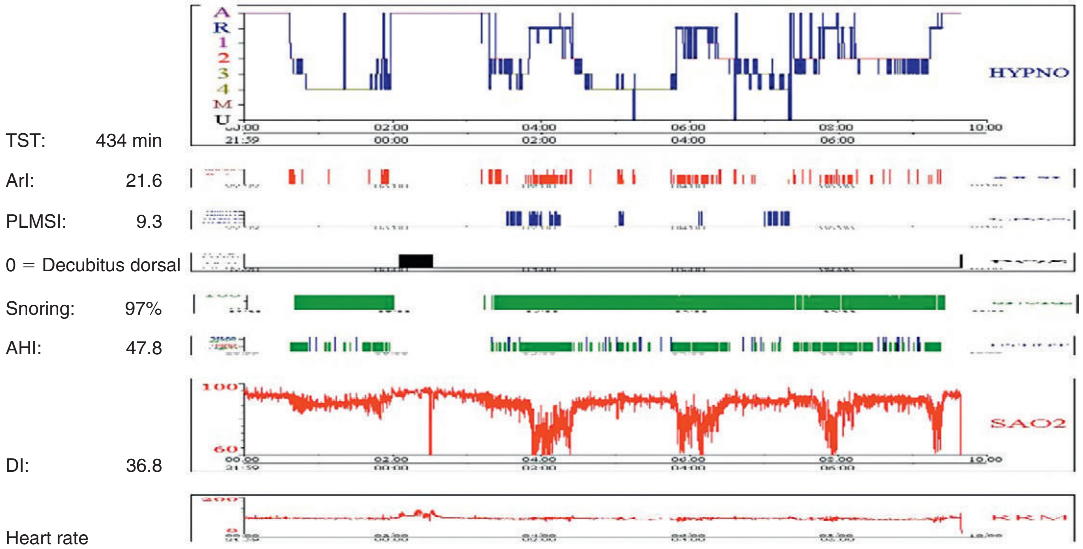

Figure 62-4 Note low $Sa\text{O}_2$ throughout the night and deeper falls in $Sa\text{O}_2$ related to the period of REM sleep. For abbreviations, see Figure 62-3.

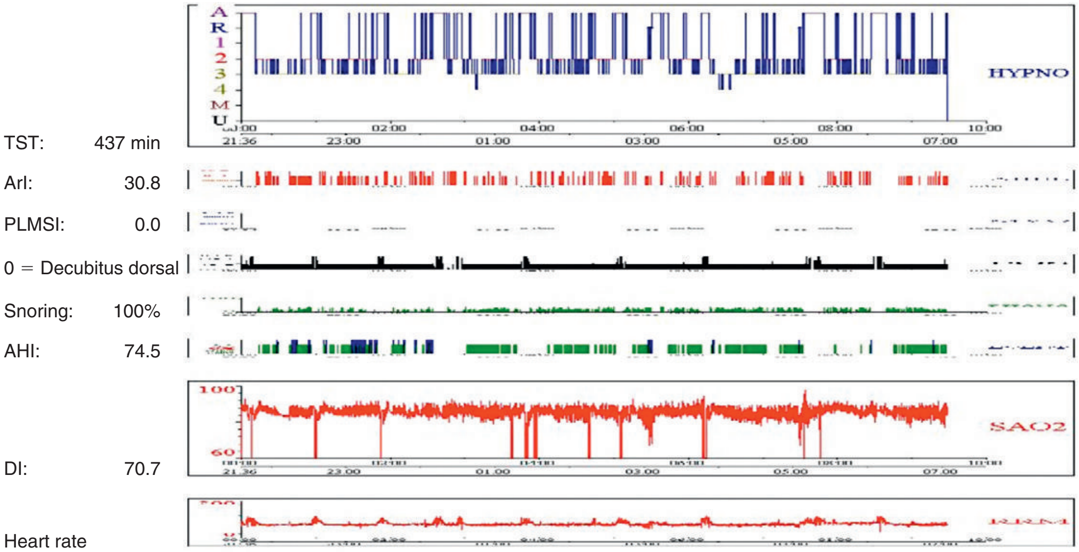

Figure 62-5 Note low SaO_2 throughout the night, with cyclic falls and recoveries, and the almost complete absence of REM sleep. For abbreviations, see Figure 62-3.

In some patients, REM sleep may even be completely absent (**Figure 62-5**).

SPIROMETRY

The most predictable and pronounced effects of obesity on lung function are decrease in functional residual capacity (FRC) and in expiratory reserve volume (ERV) associated with the closure of peripheral lung units and ventilation-to-perfusion ratio abnormalities that appear when the subject is lying down. When obese persons achieve significant weight loss, FRC increases. In patients with obesity hypoventilation syndrome, total lung capacity (TLC) is normal or mildly decreased, whereas ERV and FRC are reduced, compared with values in eucapnic patients, and these changes are more evident in patients with obesity hypoventilation syndrome than in eucapnic patients, even at similar BMI.

CHEST RADIOGRAPHY

Plain chest radiography shows no special features. Nevertheless, this imaging study is recommended to exclude interstitial lung disease and chest wall deformities (severe kyphoscoliosis), or diaphragmatic paralysis.

CARDIAC ECHOGRAPHY

In cases of cor pulmonale, echocardiography may confirm the diagnosis and is useful for follow-up evaluation.

CLINICAL COURSE: MORBIDITY AND MORTALITY

Obesity in itself does not result in a higher rate of morbidity and mortality in intensive care units (ICUs). This has been demonstrated in a matched-patient study that found that BMI did not have a significant impact on mortality in this sample.

Patients with obesity hypoventilation syndrome are heavy users of health care resources for several years before the evaluation and treatment of their sleep-related breathing disorder, and a substantial reduction in days hospitalized is achieved once treatment is instituted. Nowbar and associates showed a clear increase in mortality after hospital discharge in the follow-up evaluation for obesity hypoventilation syndrome compared with simple obesity.

The most common consequences in obesity hypoventilation syndrome include polycythemia, hypothyroidism, pulmonary hypertension, right-sided heart failure, and acute respiratory failure.

MacGregor and associates reported a high level of mortality, including sudden death, in patients with obesity hypoventilation syndrome and a subsequent reduction in mortality with the institution of mechanical ventilation. These findings were reinforced by the study by Budweiser and colleagues that demonstrated improvement of gas exchange and lung function in obesity hypoventilation syndrome after initiation of NIV. These workers also underlined the relationship between a poor survival and the presence of hypoxemia, low pH and elevated inflammation markers.

TREATMENT

WEIGHT REDUCTION

The ideal treatment is weight loss. Restoration of a normal weight reverses respiratory failure, pulmonary hypertension, and sleep-related disordered breathing. The problem is that it is difficult to achieve and maintain significant weight loss in these patients. Bariatric surgery appears to be the most effective means to achieve long-term reduction in body weight. This is a treatment reserved for a minority of subjects, however, owing to increased surgical morbidity and mortality of patients with obesity hypoventilation syndrome. The perioperative mortality rate for this procedure is between 0.5% and 1.5%. The independent risk factors associated with mortality are intestinal leaks and pulmonary embolism. Ideally, patients with obesity hypoventilation syndrome should be supported with CPAP therapy or NIV before undergoing surgical intervention, in order to decrease perioperative morbidity and mortality. Moreover, CPAP or NIV therapy should be reinitiated immediately after extubation, to avoid postoperative respiratory failure.

REVERSAL OF SLEEP-DISORDERED BREATHING

Noninvasive Ventilation

The efficiency of NIV has been extensively studied. It can be expected to produce a successful clinical response, as has been shown in many diseases and conditions associated with hypercapnia (kyphoscoliosis, central alveolar hypoventilation). NIV provides significant long-term improvement in $\mathrm{PaO_2}$ and $\mathrm{PaCO_2}$ and relief of subjective sleepiness and dyspnea.

NIV often is used as second-line treatment after a trial with CPAP, which may be warranted owing to lack of adherence to CPAP therapy, lack of improvement in hypercapnia, or the persistence of hypoxemia despite CPAP. It also should be considered in patients with obesity hypoventilation syndrome who experience an episode of acute-on-chronic respiratory failure and in patients who have obesity hypoventilation syndrome without OSA.

Continuous Positive Airway Pressure

CPAP treatment improves AHI, REM duration, arousal indices, and nocturnal oxygen saturation. In some subjects, however, nocturnal desaturation continues despite the treatment. When evaluated in various cohorts of selected patients without severe hypoxia, CPAP alone produced a satisfactory response in 80% of patients, the others needing NIV. Although CPAP and NIV are widely used for treatment of obesity hypoventilation syndrome, no randomized controlled trial has been conducted in unselected patients, to determine if one of these treatments is more effective or efficient, or for any comparison with weight loss. Also lacking are studies systematically evaluating longer-term response (6 months) of patients with obesity hypoventilation syndrome placed on CPAP, so it is unclear what impact this therapy has on outcomes such as hospitalization and survival.

Thus far, no study has yielded a valid method for predicting success or failure with CPAP, thereby predicting the need for NIV. Until good data allow a reasoned choice, the best option appears to be a trial of CPAP. If sleep-disordered breathing and respiratory acidosis are not corrected, a change to NIV is warranted.

Tracheostomy

Performance of a tracheostomy bypasses the upper airway, with consequent reduction in risk for obstructive events. In patients with OSA, tracheostomy was shown to be an effective treatment alternative despite the presence of hypercapnia. For various reasons, however, it is not recommended in most patients with obesity hypoventilation syndrome. Tracheostomy is challenging in the morbidly obese. Complications have occurred with use of both the surgical and percutaneous approaches. Complications most frequently reported with percutaneous tracheostomy are need to abort the procedure, accidental extubation, need for conversion to surgical tracheostomy, paratracheal placement, development of pneumothorax, major bleeding (requiring blood product transfusion or surgical intervention), hypoxia, minor bleeding (requiring pressure dressing or suturing), subcutaneous emphysema, transient hypotension, tube obstruction, malpositioning of the tracheostomy tube after being dislodged, and death. Because CPAP and NIV are effective in most cases, tracheostomy is certainly not a first choice for management of obesity hypoventilation syndrome.

PHARMACOTHERAPY

Very few drug trials have been conducted in patients with obesity hypoventilation syndrome. A recent study by Raurich and co-workers in Spain, performed in 25 patients with obesity hypoventilation syndrome, investigated the relationship between $\mathrm{CO_2}$ response, BMI, and plasma bicarbonate concentration and the effect of acetazolamide on bicarbonate concentration and $\mathrm{CO_2}$ response in ventilated patients with acute respiratory failure. These workers found that the addition of acetazolamide decreased bicarbonate concentration and increased $\mathrm{CO_2}$ response. They suggest that this treatment could be used as a complement in ventilation.

CONCLUSIONS

Obesity hypoventilation syndrome seems to develop only in the presence of massive obesity and represents one of the most serious respiratory complications of obesity. This syndrome is both preventable and treatable, and the treatment apparently is independent of the maintenance or the loss of the excessive weight. If left undiagnosed and untreated, obesity hypoventilation syndrome leads to severe health consequences. Unfortunately, this clinical entity is underdiagnosed—it remains primarily a subject of interest to a small number of physicians puzzled by the interrelation between sleep and breathing, whereas it remains hidden behind obesity for the vast majority of physicians. The increase in the worldwide prevalence of obesity will require a dedicated educational effort by health care professionals to make this disease better known. Otherwise, patients will continue being diagnosed in the ICU setting, once a first episode or several episodes of acute respiratory failure have precipitated a life-threatening crisis necessitating emergency care.

CONTROVERSIES AND PITFALLS

Although considerable advances have added to the current understanding of how the obesity hypoventilation syndrome develops and becomes established, a vast amount of uncertainty remains regarding its clinical presentation and consequences. Some of the unresolved issues are as follows:

- Is the obesity hypoventilation syndrome just a particular form of obesity, so that losing weight would be enough to cure it?
- Does the obesity hypoventilation syndrome prevent weight loss via excessive daytime sleepiness, decrease in energy consumption, and exacerbated hunger sensation?
- What is the simpler and best screening method to identify patients at risk and to prompt an adequate diagnostic process?
- Is polysomnography necessary to manage patients with obesity hypoventilation syndrome?
- Is the respiratory treatment of the sleep-related causes of obesity hypoventilation syndrome (i.e., CPAP for the apnea-hypopnea syndrome or NIV for sleep-related hypoventilation) enough to protect the patient's health, or is weight loss still a mandatory component of management?
- CPAP is an efficient therapy in many patients. A sizable number, however, do not respond to this intervention. What are the predictive factors that could rapidly identify such nonresponders?
- In patients needing NIV, how many can revert to a simpler CPAP treatment?

- In patients needing NIV, when is a shift to CPAP advisable?
- What is the cost-utility ratio of CPAP and NIV in OHS?
- CPAP or NIV treatment seems to decrease mortality, but this has been assessed in a limited number of patients. Long-term follow-up studies in larger cohorts are needed to confirm this major outcome and to determine the confounding effect of persistent obesity on survival.

CHEST WALL DISORDERS

Chapter 63
Scoliosis and Kyphoscoliosis

Anita K. Simonds

Scoliosis refers to lateral curvature of the spine (Figure 63-1), a well-recognized clinical entity that was described by Hippocrates as early as 500 BCE. *Kyphosis* indicates backward and *lordosis* forward curvature in an anteroposterior (medial) plane. Many patients who have a thoracic scoliosis are mistakenly described as having a kyphoscoliosis, because the rib angle prominence is misinterpreted as a kyphotic component. In fact, most instances of idiopathic thoracic scoliosis incorporate a lordotic and a rotatory element. The degree of lateral curvature is expressed by the *Cobb angle*, which is calculated from radiograph-based measurements, as shown in Figure 63-2.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOPHYSIOLOGY

Spinal curvature is the most common cause of chest wall deformity. The causes of chest wall deformity are shown in Box 63-1. By far, the most frequently found scoliosis is the idiopathic variety, which accounts for approximately 80% of cases. *Idiopathic* scoliosis is defined as lateral curvature for which no cause can be identified; *congenital* forms of scoliosis are related to a developmental abnormality of the spine, as in failure of segmentation (e.g., fused vertebrae), failure of formation (e.g., hemivertebrae), or genetic syndromes (e.g., spondylocostal dysostosis or Klippel-Feil or Goldenhar syndrome).

Scoliotic curves of more than 35 degrees are present in 1 in 1000 population, and those that exceed 70 degrees are estimated to occur at a rate of 0.1 in 1000. A gender predilection for more pronounced deformity has been recognized: Females are at greater risk for severe curvature. It has been estimated that approximately 500,000 persons with a scoliotic curve of greater than 30 degrees are living in the United States. Approximately 3 or 4 children per 1000 will require specialist supervision for their spinal curvature, and a third of these will require intervention (e.g., corrective surgery or bracing). Idiopathic scoliosis occurs more often with increasing maternal age and in higher socioeconomic groups, but no association has been found between the incidence of scoliosis and birth order or season of birth. A subclassification of idiopathic scoliosis is based on age at onset of the spinal changes resulting in curvature—infantile (birth to age 3 years), juvenile (3 to 11 years), and adolescent (11 years and older).

Scoliosis is associated with a variety of congenital syndromes. Marfan syndrome affects 1 in 5000 of the population, and approximately 70% of these patients develop a spinal deformity. Diagnosis can be confirmed by linkage to the Marfan syndrome gene *MFS1*, the protein product of which produces fibrillin. Marfan genotype-phenotype correlations show association with severe mutations in 25% of persons with the syndrome, with 50% of those in the latter half of the exon (exons 33 to 63). Related syndromes may result from mutations in microfibrils that interact with fibrillin in the extracellular matrix. Congenital contractual arachnodactyly (Beals syndrome), in which scoliosis is common, also has been shown to be caused by fibrillin deficiency.

Neurofibromatosis type 1 (NF) is a multisystem disease, with scoliosis being the most common bone manifestation, occurring in 10% to 30% of patients. Genome-wide scans have identified the likely chromosomal locus on 17q11.

GENETICS OF IDIOPATHIC SCOLIOSIS

The genetic basis of idiopathic scoliosis remains unclear, and causation may be multifactorial in that particular growth patterns may exacerbate a genetic predisposition. Support for an underlying genetic cause comes from data showing an incidence of idiopathic scoliosis in 6.94%, 3.69%, and 1.55% in first-, second-, and third-degree relatives, respectively, of 114 affected persons. These findings are consistent with either an autosomal dominant or a multifactorial mode of inheritance. A large kindred with autosomal dominant idiopathic scoliosis has been identified with a chromosomal locus on 17p11. By contrast, congenital scoliosis is relatively common among congenital malformations and is associated with congenital heart and renal tract anomalies. An autosomal recessive form of congenital scoliosis has been found in male and female sibships with consanguineous parents, associated with lack of vertebral segmentation and fused ribs. Mouse models for idiopathic scoliosis have been developed, and the list of candidate genes continues to grow, indicating the underlying etiologic complexity and probable interaction of genetic, environmental, and developmental factors.

Spinal curvature is acquired in neuromuscular disorders (Figure 63-3) that involve the chest wall and thoracic musculature before skeletal maturity occurs. Scoliosis develops in more than 50% of boys with Duchenne muscular dystrophy (DMD), and spinal curvature is common in many of the other congenital muscular dystrophies, myopathies, and conditions such as type I and type II spinal muscular atrophy. The introduction of steroid therapy in childhood in DMD may lessen the severity of scoliosis by reducing the rate of loss of muscle strength, such that wheelchair dependency occurs later in adolescence and peak vital capacity is increased, although the number of prospective randomized controlled trials has been limited.

A scoliotic deformity often develops as a sequela of thoracotomy carried out in childhood or young adulthood.

Box 63-1 Classification of Spinal Deformity

Idiopathic Deformities
Idiopathic scoliosis
Idiopathic kyphosis

Congenital Deformities
Bone
Scoliosis
Kyphosis

Cord
Myelodysplasia

Syndromes in Which Scoliosis Is Common
Neurofibromatosis
Marfan syndrome
Osteogenesis imperfecta
Klippel-Feil syndrome
Mucopolysaccharidoses
Treacher Collins syndrome
Goldenhar syndrome
Apert syndrome
Ehlers-Danlos syndrome
Vertebral and epiphyseal dysplasias
Arthrogryposis

Deformity Associated With Neuromuscular Disease
Cerebral palsy
Poliomyelitis
Muscular dystrophies
Myopathies
Hereditary sensory motor neuropathies
Friedreich ataxia
Syringomyelia

Acquired Deformity Secondary to Insult or Disease
Surgery/trauma
Infection
  Pyogenic
  Tuberculosis (Pott kyphosis)
Radiotherapy
Tumor
  Neuroblastoma
  Osteoma
  Hemangioma
  Chordoma
  Eosinophilic granuloma

KYPHOSIS

Idiopathic kyphosis is rare. An increase in thoracic kyphosis occurs with age and is exacerbated by factors that increase a tendency to osteoporosis, such as oral corticosteroid therapy. Pott's disease, or tuberculosis (TB) of the spine, is still a common cause of acquired kyphosis in TB-endemic geographic regions.

EFFECTS OF CHEST WALL DEFORMITY ON RESPIRATORY AND CARDIAC FUNCTION

Chest wall disorders affect respiratory function and cause a restrictive ventilatory defect. Any significant scoliosis or kyphosis results in a loss of height, so arm span can be used to predict normal lung volumes. As a general rule, patients who have a thoracic curve of greater than 70 degrees are subject to significant ventilatory limitation.

Lung Volumes

Although both scoliosis and kyphosis diminish lung volumes, which results in a restrictive ventilatory defect, lateral curvature has a more profound effect on chest wall mechanics. Total lung capacity is reduced in all chest wall disorders. In a pure scoliosis, both vital capacity (VC) and expiratory reserve volume are decreased, with relative preservation of residual volume (Table 63-1). An obstructive ventilatory defect is rare in scoliosis and kyphosis, unless the individual is a smoker, has coexistent asthma, or the scoliosis results in bronchial torsion.

The relationship between pulmonary impairment and the deformity is complex and cannot be predicted accurately from the Cobb angle alone. The four major determinants of a reduced VC are the number of vertebrae involved in the curve, position of the curve closer to the head, Cobb angle, and the degree of loss of normal thoracic kyphosis.

Table 63-1 Typical Results on Pulmonary Function Testing in Patients With Idiopathic Thoracic Scoliosis

Parameter	Effect
Forced expiratory volume in 1 second (FEV_1)	Reduced
Forced vital capacity (FVC)	Reduced
FEV_1/FVC	Normal
Residual volume	Normal
Total lung capacity	Reduced
Transfer factor for carbon monoxide—diffusion capacity (DLCO)	Reduced
Transfer coefficient (*K*CO)—DLCO/accessible alveolar volume	Supranormal*

*Transfer coefficient usually is supranormal, but it is reduced in the presence of pulmonary hypertension.

In paralytic scoliosis, lung volumes are reduced not only by chest wall restriction but also by inspiratory muscle weakness.

Chest Wall Mechanics

Chest wall compliance (CCW) is an important determinant of lung volumes and the work of breathing. Patients with a Cobb angle of less than 50 degrees experience a minimal reduction in CCW, whereas CCW is likely to be significantly reduced if the Cobb angle is greater than 100 degrees. A direct relationship between Cobb angle and CCW is not seen in patients with neuromuscular disorders, because respiratory muscle weakness contributes independently to chest wall stiffness. Alteration in chest wall properties cannot be attributed solely to the mechanical deformity of scoliosis, because a decrease in CCW has been found in patients affected by chronic respiratory muscle weakness in the absence of a scoliosis.

Lung Compliance

Although lung expansion is compromised by chest wall properties, primary pulmonary pathology is unusual in patients who have idiopathic scoliosis. Lung compliance is reduced, however, because of a shift in the pressure-volume curve to the right. These changes in pulmonary characteristics arise largely from an alteration in alveolar forces caused by chronic hypoventilation. In patients with neuromuscular disease, microatelectasis and macroatelectasis may complicate the picture. Microatelectasis seems relatively rare, however, because fine-section (thin-slice) CT scans have shown areas of atelectasis in only a minority of patients affected by respiratory muscle weakness. Patients with neuromuscular disease who exhibit bulbar weakness or an ineffectual cough are at increased risk for recurrent pneumonia. Severe lateral curvature of the spine in a minority of patients can produce bronchial torsion, and obstruction of the bronchus by this mechanism may lead to recurrent distal infection. Pulmonary fibrosis also is a histopathologic feature in patients who have “old” TB, in whom areas of bronchiectasis may be seen. Cystic lung changes may be noted in some patients with neurofibromatosis.

Gas transfer coefficient tends to be raised in patients with scoliosis in the presence of a low transfer factor (see Table 63-1), because extrathoracic compression squeezes more air than blood out of the lungs, thereby decreasing accessible alveolar volume.

Respiratory Muscles/Thoracic Pump During Sleep

Impaired respiratory muscle function might be expected in idiopathic scoliosis, because the respiratory muscles work at a mechanical disadvantage when chest wall shape is altered. A reduction in transdiaphragmatic pressure and static respiratory mouth pressures have been demonstrated in patients who have scoliosis or a thoracoplasty. These findings tend to support the contention that the efficiency of the respiratory muscles may be affected by relatively small degrees of chest wall deformity. Respiratory muscle action is further reduced by the loss of intercostal muscle tone during rapid eye movement (REM) sleep and a reduced ability to compensate for added respiratory load. The effect of these changes explains why early features of ventilatory failure during sleep predate the development of daytime ventilatory failure.

Control of Breathing

Impaired hypercapnic ventilatory drive usually is secondary to chronic CO_2 retention in patients with scoliosis. However, primary drive disorders may complicate some neuromuscular conditions (e.g., myotonic dystrophy) and may be acquired in patients in whom poliomyelitis has compromised brain stem control mechanisms. Generally, however, ventilatory drive is increased in patients with neuromuscular disease, to compensate for respiratory muscle insufficiency.

Pulmonary and Cardiac Hemodynamics

Cor pulmonale is the end-stage result of severe, untreated chest wall deformity. Pulmonary artery pressure becomes elevated at rest with an inverse correlation between pulmonary artery pressure and arterial oxygen tension. In some patients with severe scoliosis, a disproportionate rise in pulmonary artery pressure on exercise can be seen in the absence of hypoxemia, because the restricted thorax is unable to accommodate the increase in cardiac output on exertion.

An additional stress on hemodynamics is the effect of nocturnal hypoventilation on pulmonary artery pressure. The exact level of nocturnal hypoxemia that generates pulmonary hypertension is unknown, but if it is severe, nocturnal arterial blood gas disturbances inevitably lead to daytime problems if the condition is left untreated.

Impact of Adolescent Idiopathic Scoliosis on Exercise Capacity

In a recent case-control study, the relationship among pulmonary function, muscle strength, and exercise ability was explored in 60 patients with adolescent-onset scoliosis (AIS) and Cobb angles greater than 40 degrees, and the findings were compared with data for 25 control subjects. The patients with AIS had mild to moderate ventilatory limitation (FVC of 86% predicted), but both respiratory muscle and limb muscle strength together with exercise capacity were reduced in comparison with those in control subjects. In the AIS group exercise capacity was 58% predicted with a maximum oxygen uptake of 60% predicted. Arterial oxygen saturation values on exercise remained normal. Of note, no relationship was found between the Cobb angle and lung function, muscle function, or exercise capacity. Exercise ability, however, was correlated with inspiratory, expiratory, and limb muscle function, with the main contributor on multiple regression analysis found to be limb muscle function. This finding suggests that generalized muscle dysfunction is key to explaining exercise limitation *in the absence of severe ventilatory impairment* and underscores the point that AIS may be a systemic disease process.

CLINICAL FEATURES

Spinal abnormalities are best evaluated by ascertaining the age at onset, etiology, and location of the curve (e.g., adolescent onset, idiopathic thoracic scoliosis). During physical examination, accompanying features should be sought, such as café-au-lait spots and neurofibromas. Marfan syndrome is a clinical diagnosis that requires the involvement of two of three main systems—ocular, cardiac, and skeletal. A careful search for cardiac lesions is mandatory in patients with early-onset scoliosis, which is associated with an increased incidence of congenital heart disease. Skeletal lesions demonstrated radiologically, such as hemivertebrae and rib fusion, suggest the presence of a congenital scoliosis.

Patients are observed in the standing position and then viewed bending forward, to obtain an indication of the degree of lateral rib hump deformity. Assessment of shoulder and pelvic symmetry, leg length, and gait is helpful. The lower back should be examined for hairy tufts and other cutaneous stigmata of spinal dysraphism, and a full neurologic examination should be performed.

PROGRESSION OF CURVATURE

Detailed studies of the natural history of untreated idiopathic scoliosis are rare, but the younger the age at presentation, the greater the potential for progression, because more of the growth spurt needs to be accommodated, and spinal growth continues until at least the age of 25 years. High and low thoracic curves, together with thoracolumbar curves, seem to be more unstable than lumbar deformities. Curves most likely to progress include those caused by congenital failure of segmentation, infantile idiopathic scoliosis, the angular curve of neurofibromatosis, pronounced paralytic curves, and scoliosis associated with progressive childhood neuromuscular conditions.

In AIS, key determinants of progression are the growth potential of the child at presentation and the magnitude of the curve. On evaluation using standard indices of skeletal maturity, skeletally immature children with a more pronounced curve (20 to 29 degrees) at initial diagnosis had a 68% risk of curve progression, whereas more mature teenagers with similar curves showed a 23% risk of curve progression. Conversely, immature children with lesser curves (5 to 19 degrees) had a 22% chance of curve progression, whereas mature children had only a 1.6% chance of progression. It also has been shown that children with curves of less than 30 degrees at skeletal maturity did not experience curve progression in adulthood, whereas a majority of curves greater than 50 degrees progressed at a rate of approximately 1 degree per year.

DIAGNOSIS

CARDIOPULMONARY DECOMPENSATION: IDENTIFICATION OF HIGH-RISK CASES

Most patients who have a thoracic spinal curvature do not develop cardiorespiratory problems and therefore do not require long-term respiratory follow-up evaluations. It is important to identify the minority at risk for such problems, however, so that appropriate monitoring and therapeutic intervention can be carried out.

Cor pulmonale was the primary cause of death in a series of 102 untreated patients with idiopathic thoracic scoliosis. Age at onset of the scoliosis is crucial to ascertain. Branthwaite showed that in patients in whom cardiorespiratory problems attributable to their scoliosis developed, 90% had an early-onset curvature (i.e., onset before the age of 5 years).

A VC of 50% predicted is an important cutoff value, because respiratory decompensation is much more likely to develop in patients with a VC of less than 50% predicted at presentation than in those with initially larger lung volumes.

In a study by Braithwaite, the mean age of patients in respiratory failure who presented for ventilatory support was 49 years for those with idiopathic scoliosis, 51 years for those with previous poliomyelitis, and 62 years for those who had sequelae of pulmonary TB. Pehrsson and co-workers followed lung function over a period of 20 years in patients with idiopathic scoliosis. Respiratory failure occurred in 25%, all of whom had a VC of less than 45% predicted and a thoracic Cobb angle greater than 110 degrees.

MONITORING HIGH-RISK PATIENTS

Monitoring high-risk patients should include the following:

- Assessment for breathlessness, exercise intolerance and associated limiting factors, frequency of chest infections, and symptoms of nocturnal hypoventilation
- Clinical examination
- Pulmonary function testing
- Arterial blood gas analysis
- Measurement of respiratory muscle strength (e.g., mouth pressures, sniff inspiratory pressure)
- Spinal and chest radiology

Additional investigations may be indicated:

- MRI scanning may be required to delineate spinal cord and vertebral anomalies, and computed tomography may be needed to investigate abnormalities such as pulmonary hypoplasia or bronchial torsion.
- Echocardiography (ECG) is mandatory in all patients with congenital or early-onset scoliosis.

A fall in VC of more than 15% predicted on assuming the supine position indicates significant diaphragm weakness. Daytime hypercapnia is associated with an inspiratory mouth pressure of less than 30% predicted.

As noted, in addition to detecting breathlessness and exercise tolerance, the assessment should identify any symptoms of nocturnal hypoventilation (morning headache, poor sleep quality, frequent arousals, nocturnal confusion, and morning anorexia); if any of these is present, the patient should undergo monitoring of respiration during sleep. A characteristic picture of nocturnal hypoventilation, with episodes of desaturation and CO_2 retention most pronounced in REM sleep, usually is revealed (Figure 63-4).

TREATMENT

MANAGEMENT OF SPINAL DEFORMITY

Conservative Management

The success of a conservative approach depends on the age of the patient, the severity of the curvature at presentation, and its propensity to progression. For example, an infantile idiopathic scoliosis may spontaneously regress, whereas a juvenile-onset scoliosis is more likely to progress.

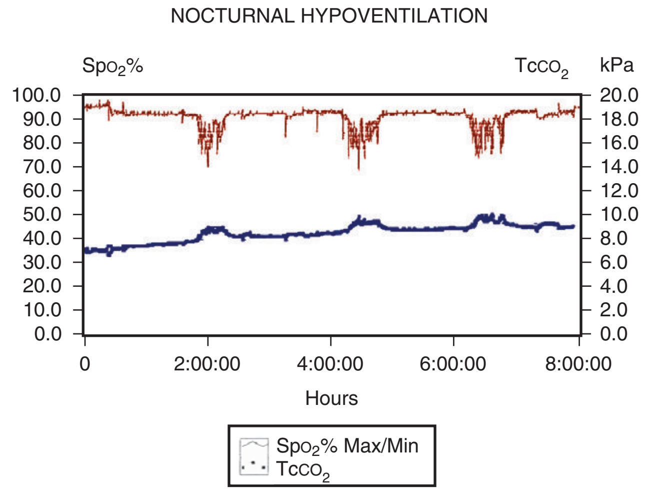

Figure 63-4 Overnight recording of oximetry-determined oxygen saturation ($Sp{O_2}$) and transcutaneous carbon dioxide tension ($Tc{CO_2}$) in a patient with early-onset scoliosis. The initial clinical presentation was one of sleep disturbance and morning headaches. The tracings show three periods of dips in $Sp{O_2}$ and peaks of $Tc{CO_2}$ in rapid eye movement sleep.

Bracing

Devices such as the Milwaukee and Cotrell braces have been used extensively, and these continue to evolve. The mechanical aim of the brace is to re-create a normal thoracic kyphosis, hyperextend the spine, and limit forward flexion, all of which will act to derotate the scoliosis. Bracing probably works more effectively with a kyphosis than with a scoliosis. In paralytic disorders, a circumferential brace can support the trunk, thereby making sitting more comfortable. Vital capacity should always be measured with and without the brace in place.

Surgery for Scoliosis

In general, surgery is performed to correct unacceptable deformity and to prevent progression. It is not carried out to improve ventilatory function.

Thoracic scolioses with curves of more than 45 degrees usually are judged to be unacceptable. A lesser curve associated with a greater degree of rotation, however, may create a rib hump, which is just as concerning to the patient. It is a surgical maxim that even the best operative technique does not completely straighten a spine. An approximately 50% correction of the Cobb angle in smaller curves can be expected from an instrumentation procedure. The best guide to a successful result is the initial amount of spinal flexibility. Also, the greater the degree of rotation, the greater the inflexibility of the curve.

Spinal fusion followed by casting has now been superseded in many situations by rod instrumentation (Figure 63-5). The system provides distraction to the concave side of the spine and compression to the convex side, which enhances stabilization and reduces any rotational tendency. Instrumentation is used to stabilize the curve and spinal fusion to prevent growth. A posterior approach is used, but with a severe deformity or very rigid curvature, an anterior approach may be required to release the disk space. The combined anterior and posterior approach carries greater anesthetic and surgical risk. In patients with AIS, surgical complication rates are around 5% to 6%, with wound infections being more common after posterior fusion and pulmonary complications more frequent with use of an anterior approach. Weiss and colleagues have recently debated the pros and cons of surgical correction in AIS.

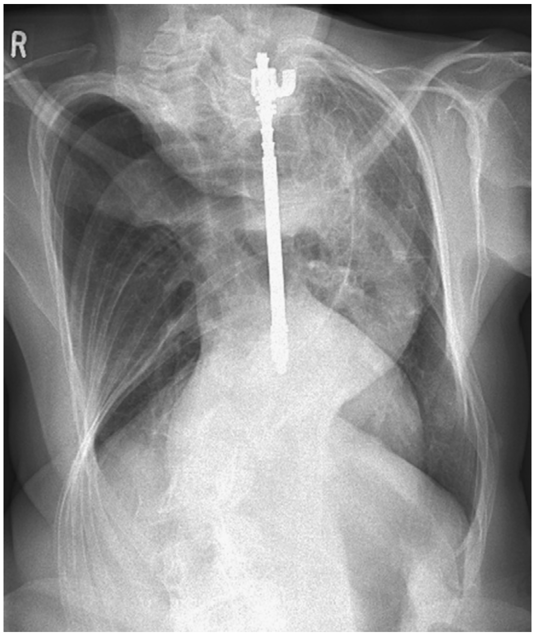

Figure 63-5 Radiograph showing instrumentation in place in a patient with scoliosis treated with a Harrington rod.

Preoperative assessment should include the investigations listed previously. In persons with a VC less than 50% predicted, a sleep study should be considered. If there is evidence of nocturnal hypoventilation, use of noninvasive ventilation (NIV) in the perioperative period may be helpful.

A recent consensus conference of scoliosis surgery in patients with Duchenne muscular dystrophy (DMD) highlighted the fact that scoliosis surgery should be carried out in centers with full access to multidisciplinary respiratory and cardiac input. The key aim of scoliosis surgery in these neuromuscular conditions is *not* to improve lung function, because most studies show no major impact on postoperative lung volumes, but to prevent further progression of the curve and to improve comfort and sitting position in a wheelchair. Surgery should optimally be performed in DMD and other neuromuscular conditions when pulmonary function is not too compromised (as reflected in an FVC greater than 30% predicted) but has been carried out safely in patients with VC between 20% and 30% predicted as supportive care such as NIV in the postoperative period and cough assistance with a mechanical insufflator-exsufflator has become available. All patients with DMD are at risk for development of cardiomyopathy, and left ventricular function and ECG should be monitored closely. Surgery-associated risks are likely to increase if left ventricular fractional shortening is less than 25%, and these risks should be carefully balanced against the overall prognosis.

MANAGEMENT OF VENTILATORY IMPAIRMENT

Optimization of Respiratory Function

Individuals should be advised of the adverse effects of smoking and obesity and encouraged to enroll in appropriate intervention programs. The influenza and pneumococcal vaccines are recommended for persons who have ventilatory limitations.

Bisphosphonate therapy reduces the risk of osteoporosis in postmenopausal women and also in men. Care should be taken not to miss the reactivation of TB in patients with a thoracoplasty. Patients who have Marfan syndrome may require β-adrenergic blocker therapy to reduce the risk of aortic dissection.

Exercise should be encouraged, other than for persons with pulmonary hypertension and patients with Marfan syndrome. Pulmonary rehabilitation programs suggest that exercise and a reduction in deconditioning is just as valuable in restrictive disorders as in chronic obstructive pulmonary disease.

Ventilatory Failure

The evidence now clearly shows that ventilatory failure in patients who have chest wall disease can be successfully treated by use of NIV at night. Negative-pressure devices are effective but have been supplanted by noninvasive positive-pressure ventilation systems. In patients with scoliosis who receive NIV, the 5-year survival rate is approximately 80%, with rates of 100% in patients with previous poliomyelitis and greater than 90% in those with post-TB conditions. It seems increasingly likely that persons who have nonprogressive disorders may live a normal or near-normal life span, provided that NIV is introduced before the development of intractable pulmonary hypertension. Patients report good quality of life with use of NIV, and many are able to return to work.

Of note, NIV produces a more favorable outcome than that achieved with long-term oxygen therapy (LTOT) in patients with scoliosis. In a retrospective analysis of consecutive patients with kyphoscoliosis who started LTOT alone or NIV in Belgium, 1-year survival was higher in the NIV treatment group (100% versus 66%), and NIV-managed patients demonstrated a greater improvement in $\mathrm{Pa{O_2}}$ and $\mathrm{Pa{CO_2}}$. More recently, these results have been confirmed in a larger Swedish cohort, for which the reported survival rate was three times higher in NIV users than in those receiving LTOT alone, and this was unrelated to baseline arterial blood gas tensions, gender, or respiratory comorbidity. In general, oxygen usually is combined with NIV at night if mean $\mathrm{Sa{O_2}}$ on NIV alone is not above 90%, despite adequate control of $\mathrm{Pa{CO_2}}$. Evidence that any one type of ventilator is superior in patients with scoliosis is lacking, although some patients with congenital or idiopathic scoliosis may require relatively high inflation pressures.

NIV also can be used to palliate symptoms of breathlessness and cor pulmonale in patients who have progressive disorders and will alter the natural history of these conditions. A 5-year survival as high as 73% can be achieved in DMD, and many patients with DMD are now surviving into their 30s and early 40s.

CONTROVERSIES AND PITFALLS

CLINICAL SIGNS IN SCOLIOSIS

In patients with severe scoliosis in whom asthma subsequently develops, an important consideration is that a characteristic wheeze may not be heard because of low airflow. Measurement of spirometry and home peak flow monitoring are useful in these cases.

An isolated unifocal wheeze may indicate bronchial torsion or kinking, which can occur in patients with severe scoliosis and may be associated with bronchiectasis or hyperinflation in the distal lung lobe. Bronchial stenting has been successfully used in this situation. In the case shown in Figure 63-6, the right bronchus intermedius was partially obstructed by torsion and compression against the spine. The clinical consequence was development of a staphylococcal pneumonia with cystic changes affecting the right lower lobe.

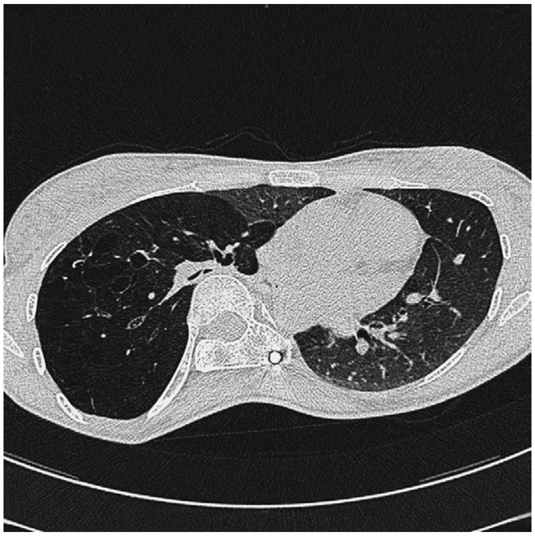

Figure 63-6 Computed tomography scan showing compression of right bronchial tree and hyperinflated right lower lobe with cystic change. The patient had a staphylococcal pneumonia that resulted from the ventilatory obstruction. *(Courtesy P. Rafferty.)*

PREGNANCY AND SCOLIOSIS

A successful outcome from pregnancy is usual in most patients who have adolescent-onset idiopathic scoliosis. In a survey of 118 pregnancies in 64 women who had thoracic scoliosis, no serious medical problems were encountered, with a cesarean rate of 17% for obstetric reasons. More recently, in a study of 142 pregnancies in women who had been treated with Harrington rod surgery, the proportion of cases requiring cesarean section was slightly higher than in the general population, but the rates of complications in pregnancy and delivery did not exceed those in the general population, and the offspring were healthy. About 40% of mothers developed low back pain during pregnancy, but this had resolved by 3 months after delivery in a majority. Likewise, a 2010 survey of cases of mostly idiopathic scoliosis in India shows a higher cesarean rate than for women without scoliosis, and no major problems with maternal health were reported.

However, cardiorespiratory complications can be expected in women with a VC less than 1.0 L. Stable curves are unlikely to progress during pregnancy. Prepregnancy counseling and assessment are sensible in patients with scoliosis, particularly those with congenital or early-onset curves or a VC less than 50% predicted. Assessment should include full pulmonary and cardiologic evaluation and genetic counselling. Pregnancy is contraindicated in the presence of pulmonary hypertension and hypoxemia. If ventilatory problems arise in pregnancy, the situation may be successfully managed by use of NIV.

Section 11
CHEST WALL DISORDERS

Chapter 64
Diseases of the Thoracic Cage and Respiratory Muscles

Michelle Ramsay • Michael I. Polkey • Nicholas Hart

Dyspnea and alveolar hypoventilation occur in patients with restrictive lung disease as a consequence of an imbalance between the respiratory muscle load and respiratory muscle capacity. Subsequent modification of the neural respiratory drive occurs, which directly reflects this imbalance. This chapter begins with an overview of the anatomy of the respiratory muscle pump and includes a detailed explanation of the pathophysiology of chronic respiratory failure. It provides a comprehensive guide to the physician of how best to assess and investigate a patient with suspected respiratory compromise from respiratory muscle weakness, chest wall disease, or obesity. The second part of the chapter focuses on specific neurologic/neuromuscular and chest wall diseases associated with respiratory impairment.

RESPIRATORY MUSCLE PUMP

The respiratory system is made up of two main components: the respiratory muscle pump, which facilitates airflow, thereby enabling ventilation, and the lungs, which support pulmonary gas exchange (see Chapter 6 for more detailed explanations and for respiratory muscle testing). The respiratory muscle pump itself is made up of the inspiratory muscles, the diaphragm and extradiaphragmatic accessory muscles, and the expiratory muscles, principally the abdominal wall muscles. Inspiration is an active process in which contraction of the diaphragm forces the abdominal contents in an anterocaudal direction to allow the volume of the chest cavity to increase. This expansion, in turn, generates a negative subatmospheric pressure to form a pressure gradient that drives air into the lungs. At rest, expiration is a passive process with the elastic properties of the chest wall and lungs providing the recoil forces that allow the lung volume to return to the functional residual capacity. During exercise and forced expiratory maneuvers (e.g., coughing), however, contraction of the abdominal muscles occurs, pushing the diaphragm upward in the absence of flow limitation.

CLINICAL CONSEQUENCES OF RESPIRATORY MUSCLE PUMP IMBALANCE

Breathlessness, alveolar hypoventilation and hypercapnic respiratory failure result from an imbalance between the respiratory muscle load, capacity, and neural respiratory drive (**Figure 64-1**). By using this model the physician can develop a simple clinical tool to assess the breathless patient and the patient in chronic respiratory failure. More commonly, in patients with restrictive lung disease, the reduction in capacity occurs as a consequence of intrinsic muscle weakness. On occasion, however, capacity may be relatively preserved, but in the context of a significant respiratory muscle load or poor orientation of the inspiratory muscles (e.g., kyphoscoliosis), this may limit the pressure-generating capacity, so that dyspnea and alveolar hypoventilation can develop subsequently. In critically ill patients, the respiratory muscle weakness may be transient and reversible, such as occurs in respiratory acidosis, hypokalemia, and hypophosphatemia (**Box 64-1**).

An increase in respiratory muscle load occurs in patients with increased airway resistance, chest wall deformity, or obesity. Any of these conditions will accelerate the onset of dyspnea and alveolar hypoventilation in patients with respiratory muscle weakness (**Figure 64-2**).

In healthy subjects, a significant reduction in neural respiratory drive to skeletal muscle, including the respiratory muscles, occurs during sleep. Despite the complete loss of skeletal muscle activity during rapid eye movement (REM) sleep, in normal subjects significant nocturnal hypoxia and hypercapnia are avoided because the activation of the diaphragm to maintain ventilation is preserved. By contrast, in patients with respiratory muscle weakness, especially diaphragmatic weakness and paralysis, hypoventilation during REM sleep often is the first sign of declining respiratory function. Of interest, in patients with idiopathic diaphragmatic paralysis, hypoventilation is prevented by a neuroadaptive mechanism with cyclic activation of the sternocleidomastoid muscle during REM sleep, which maintains ventilation. Also, there is substantial reserve in the respiratory muscle pump such that inspiratory muscle strength must fall to one third of normal before the onset of respiratory failure. Furthermore, clinical deterioration is observed at an earlier stage if an increased load is applied to the system, such as in pneumonia, or if the neural respiratory drive is modified with drugs such as benzodiazepines, opiates, and other anesthetic agents used during routine anesthesia.

ASSESSMENT OF THE RESPIRATORY MUSCLE PUMP

The respiratory muscle pump is essential for effective ventilation and to maintain gas exchange. In addition to a directed clinical history and examination, the physician can use simple bedside tests as well as more advanced measurements of respiratory muscle function to perform a detailed assessment of the patient with restrictive respiratory muscle and chest wall disease.

Box 64-1 Causes of Respiratory Muscle Weakness

Neurogenic
Motor neuron disease
Polyneuropathy (e.g., Guillain-Barré syndrome)
Critical illness neuromyopathy
Neuralgic amyotrophy
Poliomyelitis
Spinal cord injury
Trauma of phrenic nerves (e.g., from radiotherapy or coronary artery bypass grafting)

Neuromuscular Junction
Myasthenia gravis
Eaton-Lambert syndrome

Muscular
Muscular dystrophies
Inflammatory myopathies (e.g., polymyositis, dermatomyositis)
Acid maltase deficiency
Thyroid myopathy
Biochemical abnormalities (e.g., acidosis, hypophosphatemia, hypokalemia)
Malnutrition myopathy

Table 64-1 Important Clinical Features in Diseases of the Thoracic Cage and Respiratory Muscles

Disorder	Clinical Manifestations
Sleep-disordered breathing	Morning headache, daytime sleepiness, disrupted sleep pattern, impaired intellectual function, generalized fatigue, loss of appetite and weight
Respiratory muscle weakness	Orthopnea, breathlessness on immersion in water, breathlessness on leaning forward, breathlessness on exertion, poor cough, poor chest expansion, paradoxical abdominal motion during inspiration (inward motion of the anterior abdominal wall due to diaphragm weakness), abdominal muscle recruitment in expiration
Bulbar dysfunction	Low volume voice, difficulty swallowing, drooling, difficulty clearing secretions, poor cough, staccato/slurred speech, coughing on swallowing

Clinical Features

As always, a detailed history will facilitate making a correct diagnosis (Table 64-1). Of particular importance is the rate of onset of symptoms. Acute respiratory muscle weakness tends to progress rapidly, culminating in a medical emergency requiring intubation and mechanical ventilation. Some causes of acute respiratory muscle weakness, such as an acute myasthenic crisis or Guillain-Barré disease, may be reversible, and it is important to facilitate invasive respiratory support in the acute setting until a diagnosis can be made and appropriate therapies initiated. In chronic respiratory failure, the onset may not be clear, but clues to the course of events can be gained from the history. Often patients will describe dyspnea on exertion, but if peripheral muscle weakness precedes respiratory muscle weakness, the consequent loss of significant locomotor function will not permit exertion of sufficient degree to produce dyspnea. Classic features of diaphragm weakness are not always present in patients with generalized neuromuscular disease but may include dyspnea on lying supine, on bending forward, or on immersion in water above the midchest level. If respiratory weakness is severe, patients also may describe symptoms of nocturnal hypoventilation, such as extensive daytime somnolence, reduced concentration, and morning headaches that typically resolve within 30 minutes of waking. Specifically, in the pediatric and adolescent populations, clinicians should be alerted to more subtle clinical features such as failing school performance, recurrent episodes of chest sepsis, reduction in appetite, and weight loss.

In all cases of respiratory muscle weakness, an important aspect of the evaluation is to identify any symptoms that may suggest generalized neuromuscular weakness—in particular, decrements in the patient's speech and swallowing function, as well as weakness of the arms and legs. Weakness of the abdominal muscles may result in difficulty achieving an effective cough to clear secretions and debris from the airways. This impairment leads to issues with sputum retention and increases the risk of chest infection. In the case of chest wall disease, the common causes kyphoscoliosis and obesity usually are self-evident. As highlighted earlier, certain drugs have effects that can accelerate respiratory decline, so attention should be given to the common offenders, such as benzodiazepines, opiates, and corticosteroids. More recently, in particular, in the Duchenne muscular dystrophy (DMD) population, corticosteroids are increasingly being used to maintain locomotor muscle function, and these agents are associated with substantial weight gain and consequent upper airway obstruction. Clinicians must be aware of this potential problem in this younger patient population.

Physical examination requires a careful and considered approach, which must include a thorough neurologic examination to observe for signs of tongue and peripheral muscle fasciculation, peripheral muscle wasting and weakness, and peripheral sensory loss. Other signs, such as pseudohypertrophy of the calf muscles, are observed in patients with muscular dystrophies. Scars of previous operations may indicate possible trauma to underlying neuromuscular structures or an imposed restrictive chest wall deformity, such as from a phrenic nerve crush, thoracoplasty, coronary artery bypass grafting, thyroidectomy, or thymoma resection. With severe diaphragm weakness, abdominal inspiratory paradox is observed: The anterior abdominal wall moves inward as a result of the failure of a weak or paralyzed diaphragm to descend against the force exerted by the abdominal contents. With more generalized weakness, global loss of thoracic expansion on inspiration is observed.

Arterial Blood Gas Analysis

Although arterial blood gas analysis is one of the most common first-line investigations to diagnose chronic respiratory failure, limitations associated with this technique have been recognized. In particular, the daytime partial pressure of carbon dioxide (PaCO_2) may be normal despite the presence of substantial inspiratory muscle weakness, nocturnal hypoventilation, and nocturnal hypercapnia. Measurement of arterial blood gas partial pressures is essential, however, to define the severity of respiratory failure. Most commonly, hypoventilation caused by neuromuscular respiratory weakness and chest wall disease manifests with a mild hypoxia, with a partial pressure of oxygen (PaO_2) less than 60 mm Hg, and hypercapnia, with a PaCO_2 greater than 45 mm Hg.

The respiratory failure associated with many neurologic and chest wall conditions frequently manifests insidiously, with hypercapnia triggering metabolic compensation and renal retention of bicarbonate to maintain the hydrogen ions and, consequently, arterial pH within the normal range.

In the event of rapid onset of neurologic symptoms, such as in Guillain-Barré syndrome and myasthenic syndrome, or with acute deterioration of chronic respiratory failure, there is less time for renal buffering, so hypercapnic respiratory acidosis will occur.

Pulmonary Function Tests

Patients with respiratory neuromuscular weakness and those with chest wall disease both are characterized by a reduced ability to expand the thoracic rib cage. In turn, this failure to expand the rib cage results in a lack of generation of sufficient negative intrathoracic pressure to facilitate adequate inspiratory airflow. As a result, these patients present with clinical features of a restrictive lung function pattern characterized by a reduced forced vital capacity (FVC) and an elevated ratio of forced expiratory volume in 1 second (FEV_1) to FVC (FEV_1/FVC greater than 80%). Although vital capacity (VC) is in widespread use and is relatively simple to determine, its utility is limited because it has low sensitivity. In particular, significant inspiratory muscle weakness is required before a significant fall in VC is observed. A fall in VC on adoption of the supine position is specific for respiratory muscle weakness, and a fall in VC of more than 20% suggests bilateral diaphragmatic weakness. Of importance, the VC can be preserved in persons with a moderate degree of global respiratory muscle weakness or hemidiaphragm weakness.

The pattern of respiratory muscle weakness must be considered in interpreting results of pulmonary function tests in patients with chest wall disease and respiratory muscle weakness. Although total lung capacity (TLC) and VC are reduced in patients with predominantly inspiratory muscle weakness and combined inspiratory and expiratory muscle weakness, the pattern of weakness influences functional residual capacity (FRC), residual volume (RV), overall gas transfer (DLco), and gas transfer corrected for alveolar volume (Table 64-2).

Table 64-2 Pulmonary Function Tests for Patients with Predominantly Inspiratory Muscle Weakness and Combined Inspiratory/Expiratory Muscle Weakness

Inspiratory Muscle Weakness	Combined Inspiratory/ Expiratory Muscle Weakness
Reduced VC	Reduced VC
Fall in supine VC >20%	N/A
FEV_1/FVC ratio >80%	FEV_1/FVC ratio >80%
Reduced TLC	Reduced TLC
Normal RV	Increased RV
Reduced FRC	Increased FRC
Reduced TLco	Reduced TLco
"Supranormal" *K*co	Reduced *K*co

FEV_1, forced expiratory volume in 1 second FRC, functional residual capacity; FVC, forced vital capacity; *K*co, gas transfer coefficient corrected for alveolar volume; N/A, not available; RV, residual volume; TLC, total lung capacity; TLco, overall gas transfer; VC, vital capacity.

Tests of Respiratory Muscle Function

Because respiratory muscle contraction generates tension, the consequent pressure change that occurs can serve as an in vivo measure for the quantification of respiratory muscle strength. In addition, recent developments have expanded the current understanding of the mechanical actions and interactions of the respiratory muscles. A greater emphasis has been placed on assessing and quantifying respiratory muscle strength and pulmonary mechanics in a variety of patient groups, including children, adolescents, and adults (see Chapter 6 for a more detailed discussion).

Maximal Inspiratory and Expiratory Pressures

Maximal inspiratory and expiratory pressure measurements are clinically useful noninvasive tests with established reference ranges. As with any volitional test, however, results will be dependent on subject motivation and maximal effort, which explains in part the wide range of normal values. Furthermore, the observed pressure depends on mouthpiece design and patient posture, and it often is difficult to distinguish between mild weakness and normal strength on an individual basis. Nevertheless, maximum inspiratory mouth pressure (PImax) can provide a simple rapid estimation of global inspiratory muscle strength (in men, below −80 cm H_2O; in women, below −70 cm H_2O), but it does not allow specific conclusions to be drawn about the function of the diaphragm. If the maneuver is performed from FRC, PImax reflects the strength of the inspiratory muscles, whereas with performance from RV, the test will be influenced by the elastic recoil of the chest wall. In clinical practice, patients find it easier to perform the test from FRC rather than RV, and previous data have shown little difference between the peak or plateau values measured from either RV or FRC.

The strength of the expiratory muscles, principally the abdominal muscles, is assessed by measuring the static expiratory pressure generated at the mouth (PEmax). As with the PImax, the range of the normal values is wide (in men, above +130 cm H_2O; in women, above +100 cm H_2O) and some patients can find this maneuver difficult to perform, particularly those patients with weakness of the orofacial muscles. Thus, as with PImax, although a high value of PEmax excludes expiratory muscle weakness, a low value can be difficult to interpret. PEmax are can be measured from either TLC or FRC. PImax and PEmax measurements are reduced in females and decline with age.

Sniff Inspiratory Pressure

The rapid inspiratory effort of a sniff maneuver (see Chapter 6) is accompanied by momentary equilibration of intrathoracic and upper airway pressures. This equilibration occurs above a pressure of 10 to 12 cm H_2O, so employing sniff nasal pressure (Pn_{sn}) allows noninvasive measurement of inspiratory muscle strength. Pn_{sn} is a particularly useful additional investigation in patients with a low or equivocal PImax to confirm or exclude the presence of inspiratory muscle weakness.

A study of 241 patients with moderate to severe neuromuscular disorders showed a positive correlation between Pn_{sn} and PImax, but with a relatively poor agreement observed between Pn_{sn} and PImax. However, the findings of this study differ from those in earlier studies in that the value of PImax was at least the same as or even greater than Pn_{sn}, particularly in those patients with severe ventilatory restriction, which highlights the potential limitation of Pn_{sn} in this particular patient population. These findings add support to the idea that Pn_{sn} can underestimate inspiratory muscle strength in patients with moderate to severe neuromuscular disease (VC less than 40% of predicted), as demonstrated previously in smaller studies of patients with chronic stable inspiratory muscle weakness and acute respiratory failure. Specifically, as VC falls, a greater decrease occurs in Pn_{sn} than in PImax. Strictly speaking, PImax and Pn_{sn} are not interchangeable measurements but are complementary tests, and they should be used in combination with VC for a complete sequential assessment of inspiratory muscle strength in patients with neuromuscular and chest wall disease. In clinical practice, Pn_{sn} is usually measured through occlusion of one of the nasal passages with a nasal bung fitted with a small piece of tubing that connects to a handheld pressure transducer. Normal Pn_{sn} values are below −70 cm H_2O in men and below −60 cm H_2O in women with the measurement made from FRC.

Cough Gastric Pressure

As with sniffing, patients find coughing a natural maneuver. Although assessment of the cough gastric pressure ($Pgas_{cough}$) requires the insertion of a gastric balloon, the measurement is easy to learn and more reproducible than with PEmax. Although normal values for $Pgas_{cough}$ have been reported, previous studies using $Pgas_{cough}$ as a marker for expiratory muscle strength are described in the literature. Normal $Pgas_{cough}$ values are above +215 cm H_2O in men and above +165 cm H_2O in women.

Cough Peak Flow

Cough peak flow is a simple noninvasive measure of expiratory muscle function, which is considered to be a useful marker of cough function and a reflection of the patient's ability to clear respiratory secretions. Values of less than 160 L/min are reported to be the cutoff level for increased risk of developing chest sepsis. A cough peak flow less than 160 L/min can be augmented by the mechanical insufflator-exsufflator device used with a face mask.

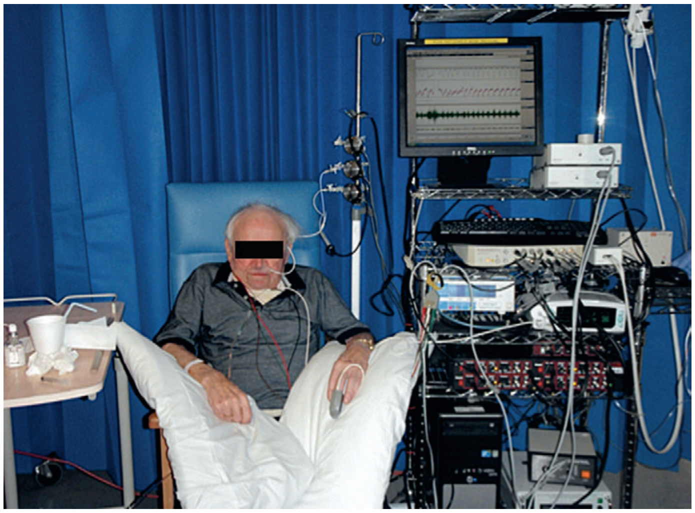

Figure 64-3 Equipment required to measure transdiaphragmatic pressure. *(Courtesy of the patient.)*

Maximum Transdiaphragmatic Pressure Measurements

The previously described tests provide data only on global respiratory muscle function, rather than on diaphragm function itself. To specifically assess diaphragm function, transdiaphragmatic pressure (Pdi) is measured by placement of a pressure-monitoring catheter in both the esophagus and stomach, to provide measurement of the esophageal and gastric pressures (**Figure 64-3**).

Although transdiaphragmatic pressure during a maximal static maneuver (Pdi_{max}) has been reported, this maneuver gives a wide normal range in naive (i.e., previously untested) subjects. An alternative is to obtain maximal sniff transdiaphragmatic pressure (Pdi_{sn}), which has gained recognition in clinical practice not only because it is a familiar maneuver but because it measures both Pes_{sn} and Pdi_{sn}, providing data on global inspiratory muscle and diaphragm strength (**Figure 64-4**).

Twitch Transdiaphragmatic Pressure

Faraday's law states that in a conducting material, a changing magnetic field will induce an electric current. Magnetic stimulation stores electrical energy in a capacitor and then discharges this energy by way of a coil to generate a rapidly changing magnetic field. This magnetic field has advantages over the electrical stimulus in that it is less attenuated by distance and therefore can more easily penetrate the deep structures in the neck and stimulate the phrenic nerve. This stimulation produces a single "twitch" of the diaphragm that is well tolerated by patients.

Clinical magnetic stimulation to allow bilateral stimulation of the roots supplying the phrenic nerves was first reported in 1989. Subsequent work has demonstrated its clinical usefulness, and this technique provides a nonvolitional assessment of diaphragm strength in a number of patient groups, including children and adolescents, as well as critically ill patients in intensive care in whom motivation and cooperation to perform maximal volitional maneuvers are difficult to achieve. In addition to improved tolerability, magnetic stimulation has advantages over electrical stimulation in that it is easier to stimulate

the phrenic nerves and reduces the technical difficulties involved in isolation of the nerve (Figure 64-5). Further details can be found in the recommended reading section.

Pulmonary Mechanics

The measurement of lung and chest wall compliance can be assessed in restrictive lung disease but requires the placement of an esophageal pressure catheter balloon. Moreover, static compliance requires the patient to be able to relax the respiratory musculature against a closed airway, which most patients with respiratory neuromuscular and chest wall disease find difficult. On the other hand, if an esophageal catheter has been passed to accurately measure global inspiratory muscle strength, dynamic lung compliance (measured as the ratio of change in volume to change in pressure between points of zero flow) is easily measured, providing a useful clinical evaluation of the load on the respiratory system.

Role of Imaging in Respiratory Muscle Weakness and Chest Wall Disease

An elevated hemidiaphragm on a plain chest radiograph often is considered to indicate diaphragmatic weakness or paralysis, but in fact this finding is confirmed by diaphragmatic testing in only approximately 24% of cases. The most recent data indicate that hemidiaphragm elevation on the chest radiograph has a 93% sensitivity but only a 44% specificity for predicting diaphragmatic weakness. Thus, elevation of the hemidiaphragm on the chest radiograph is likely to represent hemidiaphragmatic weakness; however, a normally positioned hemidiaphragm does not exclude weakness on that side.

The contraction of the diaphragm can be directly visualized by other techniques such as fluoroscopic screening, ultrasonography, and dynamic magnetic resonance imaging. Of these, ultrasonography has the advantage of being cheap and radiation-free; however, false positives may occur in approximately 6%

of subjects, and even when correctly identifying weakness, this technique gives no functional information with regard to diaphragm strength. Accordingly, ultrasound imaging should not routinely be used in the assessment of patients with suspected hemidiaphragm or bilateral diaphragm weakness. For these purposes, unilateral and bilateral magnetic phrenic nerve stimulation should be used. Although computed tomography (CT) cross-sectional imaging may have particular value in the assessment of pleural causes of lung restriction, it is relatively unhelpful in obese patients, except to exclude coexisting thromboembolic disease and parenchymal lung disease.

Sleep Studies

Overnight oximetry and capnometry constitute an essential part of the assessment for the early detection of nocturnal hypoventilation. These are recommended investigations in patients with neuromuscular and chest wall disease who report symptoms of sleep-disordered breathing (see Table 64-1). Although some investigators advocate the use of polysomnography, including an electroencephalogram, to confirm and quantify arousals during respiratory events, this study is not necessary in the routine clinical management of these patients. Nocturnal hypoventilation can be managed simply with overnight titration of ventilatory support to a defined level of hypercapnia, irrespective of the sleep stage of the patient.

RESPIRATORY PRESENTATIONS OF NEUROLOGIC AND CHEST WALL DISEASE

The remainder of this chapter describes specific neurologic/neuromuscular disorders and chest wall diseases, as well as obesity, recognized to be associated with restrictive lung disease. These conditions are divided into acute and chronic presentations (**Table 64-3**), and the neuromuscular conditions are discussed in the context of the disease and grouped according to their impact on the relevant portion of the anatomic pathway from the central cortex to the peripheral muscle (**Figure 64-6**).

ACUTE DISORDERS AFFECTING THE CENTRAL NERVOUS SYSTEM

Stroke

Stroke (cerebrovascular accident) is one of the most common causes of acute neurologic deterioration. It is the third leading cause of death in both the United Kingdom and the United States affecting 150,000 and 795,000 patients, respectively, each year. The diaphragm has bilateral cortical representation, whereas the expiratory muscles have contralateral representation, similar to that in the limb muscles. Although hypercapnic respiratory failure is uncommon in stroke patients, chest infection is relatively frequent, and it is likely that impaired voluntary cough coupled with poor glottic coordination as well as swallowing difficulties contribute to the episodes of chest sepsis.

Cheyne-Stokes respiration breathing pattern often is observed as a feature associated with many different types of stroke. This pattern consists of a regular crescendo and decrescendo in breathing interspersed with periods of total apnea that cycles approximately every 30 seconds to 2 minutes. It commonly is observed in chronic heart failure and as a preterminal breathing pattern but also may be seen in healthy subjects at altitude.

Certain classic breathing patterns (**Figure 64-7**) are considered to reflect aspects of central nervous system pathology, though these are relatively rare in mainstream respiratory clinical practice. These include (1) *central neurogenic hyperventilation* resulting from a pontine lesion with hyperventilation present throughout both sleep and wakefulness; (2) *cluster breathing* caused by a mid–brain stem lesion, with periods of hyperventilation alternating with distinct periods of apnea; (3) *apneustic breathing* as a consequence of damage to the caudal pons with prolonged pauses after each inspiratory breath resulting in hypoventilation; and (4) *ataxic breathing* observed in patients with cortical lesions of the medulla, which is characterized by an erratic breathing pattern, which differs from the other breathing patterns in having no clear-cut cyclic nature.

Table 64-3 Acute and Chronic Presentations of Neuromuscular Disorders From Central Cortex to Peripheral Muscle

Central Nervous System	Anterior Horn Cell	Peripheral Nerve Disease	Neuromuscular Junction	Muscle
Acute				
Stroke Spinal injury Tetanus	Rabies Poliomyelitis	Guillain-Barré syndrome Critical illness neuromyopathy Phrenic nerve injury	Botulism Shellfish poison Drugs with neuromuscular blocking effects (e.g., aminoglycosides)	Corticosteroid myopathy Hypo/hyperkalemia Hypo/hyperthyroidism Vitamin deficiency (e.g., vitamins D and E)
Chronic				
Multiple sclerosis Arnold-Chiari malformation Parkinson disease	Motor neuron disease Spinal muscular atrophy	Neuralgic amyotrophy Hereditary sensorimotor neuropathy Chronic inflammatory demyelinating polyneuropathy Toxins (lead) Vasculitis Porphyria	Myasthenia gravis Lambert-Eaton syndrome	Duchenne/Becker muscular dystrophy Myotonic dystrophy Congenital myopathies Metabolic myopathies (e.g., glycogen storage diseases, acid maltase deficiency) Inflammatory myopathy (e.g., polymyositis, dermatomyositis)

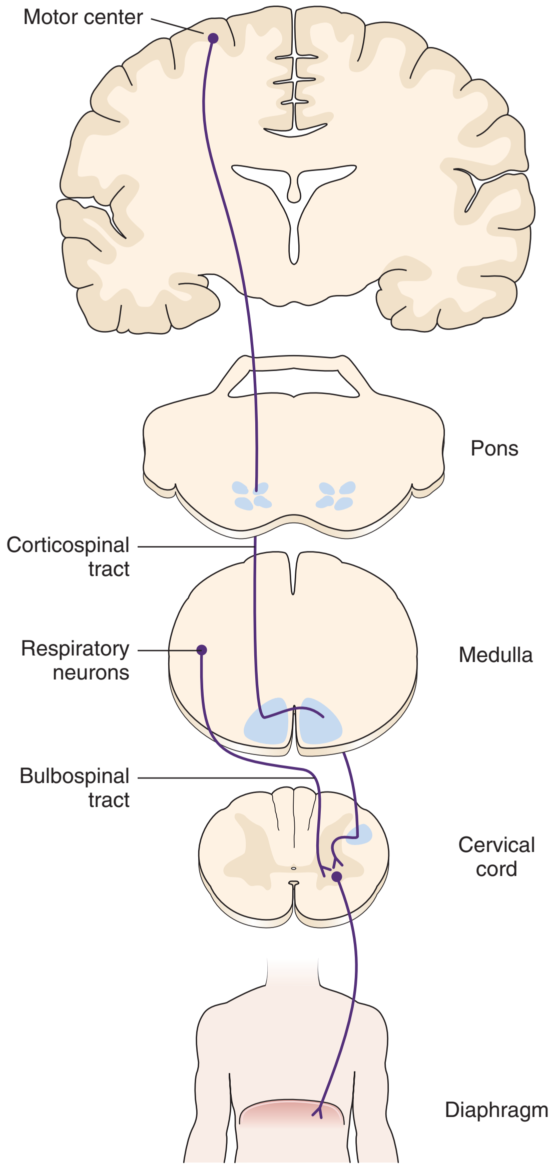

Figure 64-6 Neuromuscular pathway from the motor cortex to the diaphragm.

Spinal Cord Injury

Spinal cord injury (SCI) commonly is a complication of trauma occurring predominantly in young adults, but it also may result from spinal artery infarction or tumor compression. The average age at insult is 34 years, and males are four times more likely to be affected. The extent of any neuromuscular weakness will be dependent on the site of injury, with higher cervical injuries resulting in more profound impairment. SCI at the level of C1 to C3 results in profound respiratory failure secondary to respiratory muscle denervation. Both voluntary and involuntary muscle control are lost. Unless neurologic recovery occurs, the patient will remain tracheostomy ventilator–dependent. SCI at the level of C3 to C6 results in a variable degree of diaphragmatic weakness, with more caudal lesions conferring a better prognosis. Patients may not have long-term ventilator dependence, and some improvement in respiratory muscle function often occurs over time as a consequence of reduction in inflammation and recruitment of other accessory muscles. SCI affecting the lower cervical and upper thoracic spinal cord carries a significantly better prognosis. The intercostal muscles and the abdominal muscles are affected, but the diaphragm is spared. Patients therefore rarely require long-term mechanical ventilation.

Custom-made corsets that are designed to provide both truncal stability and abdominal support are helpful in such patients. These garments reduce the sensation of respiratory effort by optimizing the operating lung volumes and decreasing abdominal compliance, which in turn enhances diaphragm performance. These patients are susceptible to respiratory tract infections, however, as with other neuromuscular disease, due to the impairment of cough function.

Bilateral diaphragmatic pacing can be considered as an alternative method of ventilatory support in a select group of patients who have high SCI and preserved function of the phrenic nerve–diaphragm unit. The most suitable candidates for pacing are considered to be those patients with a preserved response to peripheral phrenic nerve stimulation but lacking a response to transcranial stimulation of the diaphragm motor area.

Tetanus

Tetanus toxin is produced by the anaerobic bacillus *Clostridium tetani*, which commonly resides in soil. The bacillus enters the human through a wound in the skin, and the toxin travels along peripheral nerves to the central nervous system. Hypertonicity and generalized severe muscular spasms develop when the tetanus toxin blocks the release of inhibitory neurotransmitters at the neuromuscular junction. These spasms often are protracted and can cause death by means of severe resistant laryngospasm and respiratory muscle failure. Potential treatments include wound débridement, penicillin, tetanus antitoxin, neuromuscular blocking agents, sedatives, tracheostomy, intubation, and mechanical ventilation. Preventive vaccination is now common, so this has become a rare condition for which the astute physician needs to maintain an awareness.

Drugs

Opiates, benzodiazepines, and anesthetic agents affect neural drive to the respiratory muscle and, consequently, the tone and coordination of the upper airway, diaphragm, and chest wall muscular contraction. These drugs should be used with caution in patients with underlying respiratory muscle weakness to avoid precipitating life-threatening respiratory failure.

CHRONIC DISORDERS AFFECTING THE CENTRAL NERVOUS SYSTEM

Multiple Sclerosis

Multiple sclerosis is an inflammatory demyelinating condition that can affect any part of the central nervous system. Respiratory manifestations of this condition vary with the anatomic location of the demyelinating lesions. The most common finding is a difficulty performing voluntary tests, but because the central control of breathing depends on connections from the brain stem, respiratory failure is uncommon. More usual practical problems include difficulty with voluntary cough secondary to lesions causing paraplegia and complications such as obstructive sleep apnea arising from the weight gain that results from enforced reduction in physical activity and steroid therapy.

Arnold-Chiari Malformation

Arnold-Chiari malformation is a congenital condition characterized by caudal herniation of the cerebellum and medulla

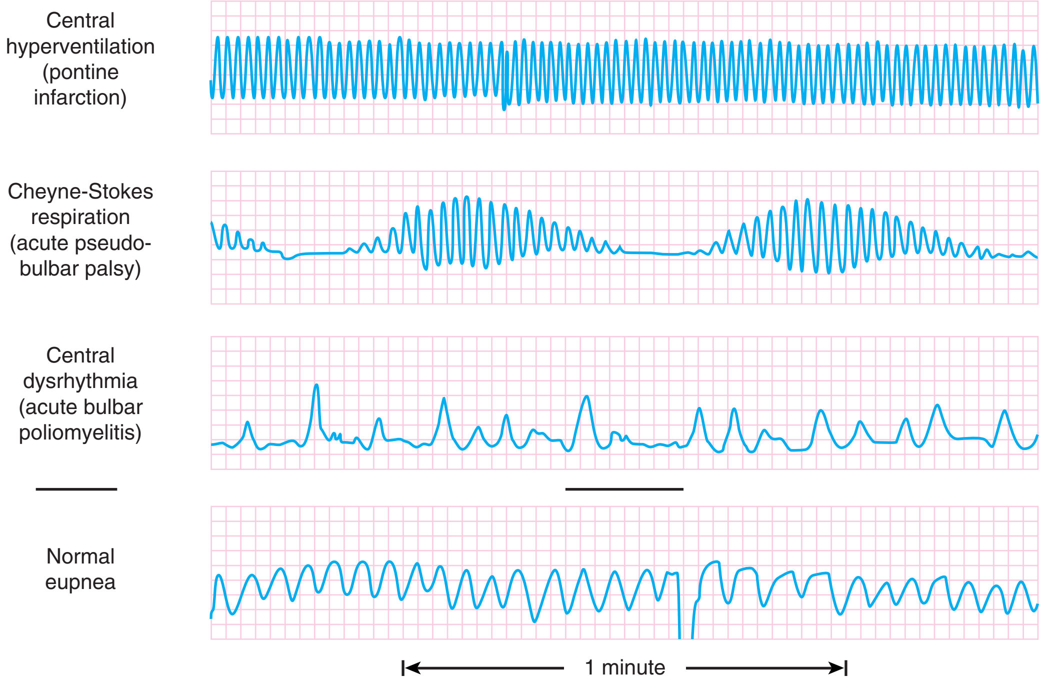

Figure 64-7 Breathing patterns in central nervous system diseases. *(Modified from Plum F, Swanson AG: Central neurogenic hyperventilation in man,* AMA Arch Neurol Psychiatry *81:535–549, 1959.)*

through the foramen magnum. The malformation commonly blocks the flow of cerebrospinal fluid out of the posterior fossa, leading to hydrocephalus. It also may be associated with a syringomyelia where it can often interrupt ventilatory control to cause both apnea and apneustic breathing patterns. Whether deterioration can be prevented to some extent by surgical decompression has not yet been established.

Parkinson Disease

Parkinson disease is the most common movement disorder observed in developed countries and frequently is associated with fatal respiratory complications related to infection. Inspiratory muscle weakness occurs late in the progression of the disease, when maximal inspiratory pressures can fall to approximately 30% predicted. Expiratory muscle weakness also is seen; patients are unable to generate a rapid rise in peak expiratory flow. This impairment is akin to the generalized hypokinesia that is a common feature in Parkinson disease and has a deleterious effect on cough function.

Patients with this disease have significant difficulty in coordinating succinct respiratory muscle recruitment, which may partly explain the breathlessness associated with many of the dystonias. Of interest, early in the course of the disease, when no respiratory muscle weakness is evident from objective lung function parameters, the patients are still less able to perform repetitive respiratory muscle contractions than healthy age-matched control subjects. L-Dopa and apomorphine therapy have been shown to reverse these phenomena, suggesting that the defect is one of a central control and coordination of the respiratory muscles.

Patients with Parkinson disease commonly exhibit involuntary movements affecting the upper airways. A saw-tooth flutter wave often is present on the flow-volume loop trace (Figure 64-8); this aberration results from repetitive adduction of the vocal cords, occurring at the same frequency as a tremor of 4 to 8 Hz. It can cause significant difficulties if tracheal intubation is required. Obstructive sleep apnea is observed more frequently in patients with Parkinson disease, although patients also may experience sleep fragmentation because of pain or dystonias. Finally, the related condition of multisystem atrophy is characterized by features of Parkinson disease and autonomic failure. It has been associated with irregular breathing patterns and life-threatening upper airway obstruction related to glottis and vocal cord dysfunction narrowing during sleep.

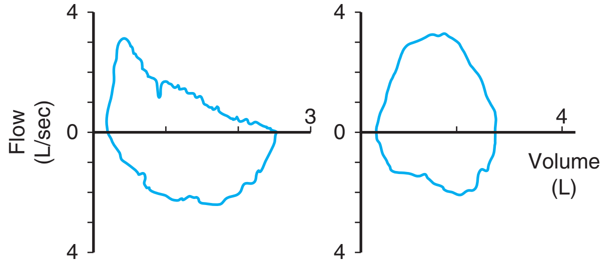

Figure 64-8 Characteristic flow-volume loop in Parkinson disease (*left*) compared with a normal flow-volume loop (*right*). *(From Laghi F, Tobin MJ: Disorders of the respiratory muscles,* Am J Respir Crit Care Med *168:10–48, 2003.)*

ACUTE DISORDERS AFFECTING THE ANTERIOR HORN CELLS

Rabies

Rabies is a ribonucleic acid viral disease that has one of the highest fatality rates worldwide. It is transmitted through an infected mammalian bite, primarily from dogs. When the spinal cord is involved an ascending paralysis with clinical features similar to those of Guillain-Barré syndrome is seen, which can ultimately paralyze the respiratory muscles. The condition is now preventable with the rabies vaccination, and rarely seen in industrialized nations.

Poliomyelitis

Poliomyelitis is a rare condition in the Western world consequent to the introduction of the “polio vaccine,” which is routinely administered during childhood, although the disease occasionally can occur as a result of the live attenuated vaccine itself. For this reason, since 2000 only the inactive polio vaccine has been used in the United States. In the epidemics in the early 20th century, however, it was the commonest neuromuscular cause of respiratory failure. In fact, the high incidence of acute neuromuscular respiratory failure was directly responsible for the development of and advances in invasive mechanical ventilation and critical care as a specialty. In developed countries, physicians continue to encounter a diminishing number of patients who present with late respiratory failure after having suffered poliomyelitis in youth. This phenomenon is more common in those who received mechanical ventilation, usually in an “iron lung,” at the time of the acute illness and in those in whom scoliosis developed subsequently. These so-called postpolio patients respond well to treatment of their chronic respiratory failure with home noninvasive ventilation.

CHRONIC DISORDERS AFFECTING THE ANTERIOR HORN CELLS

Motor Neuron Disease

Motor neuron disease (MND), also known as amyotrophic lateral sclerosis (ALS), has a European annual incidence of approximately 2 to 3 cases per 100,000 population. Only 1% to 3% of MND cases manifest with respiratory muscle weakness and acute respiratory failure. It is uncommon for patients to describe the classical signs of respiratory muscle weakness (see Table 64-1) as a presenting complaint, but respiratory physicians should consider this diagnosis in patients with coexisting muscle wasting and weakness. A more common presentation is one of exertional and positional dyspnea, ineffective cough, and low speech volume in a patient who has already received the diagnosis. Bulbar features, notably aspiration, are common in advanced disease. When muscle weakness is severe, the patient may report disrupted sleep and excessive fatigue, morning headaches and confusion. Physical findings may include tachypnea at rest, inability to complete full sentences, use of accessory muscles, and abdominal inspiratory paradox.

Respiratory muscle weakness may be present in the context of other generalized muscle involvement without chronic respiratory failure. Early detection of respiratory muscle involvement may facilitate appropriate timing of ventilatory support to prevent respiratory crises. Studies have shown that Pn_{sn} is easier to obtain in patients with MND and can be used to predict prognosis. Routine monitoring of Pn_{sn} has been recommended; if the Pn_{sn} is less than 40 cm H_2O, referral for home noninvasive ventilation should be considered. The median survival is 3 to 5 years from onset of symptoms; home noninvasive ventilation has been shown to prolong survival in non-bulbar MND and to enhance health-related quality of life in bulbar MND.

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) includes a group of genetic autosomal recessive disorders. These disorders are characterized by degeneration of the anterior horn cells and the motor nuclei in the brain stem. Patients with SMA exhibit a progressive symmetric proximal muscular weakness.

The SMAs are classified clinically as types 1 to 4, depending on the age at onset and the progression of symptoms. SMA type 1 is the most aggressive form with rapidly progressive muscular weakness; infants usually develop severe respiratory failure and do not survive longer than a year. SMA type 4 is more indolent and may manifest in the second to third decades of life. The mainstay of treatment is supportive therapy, with a focus on nutritional needs and ventilatory support as symptoms arise.

ACUTE DISORDERS AFFECTING THE PERIPHERAL NERVES

Guillain-Barré Syndrome

Guillain-Barré syndrome is an acute inflammatory demyelinating motor polyneuropathy. Patients characteristically present with a symmetric ascending motor weakness with associated depressed reflexes. Symptoms usually progress over a 2-week period, with 90% of patients reaching the peak of the disease course within 4 weeks. Severe respiratory weakness is a common associated feature, and ventilatory support is required at some point in approximately 10% to 30% of cases. Despite many effective immunomodulatory treatments, the mortality rate for Guillain-Barré syndrome requiring intubation is around 5%.

Inflammatory demyelination starts at the nerve root and progresses in a patchy fashion along the nerve sheath, resulting in weakness and paralysis of the distal muscles. This is confirmed by nerve conduction tests whereby conduction velocity of the signal is slowed or absent. A reduction in the amplitude of the action potential obtained through diaphragm needle electromyelography in response to phrenic nerve stimulation has been correlated with the requirement for invasive ventilation. In view of the risk of respiratory failure, it is essential that respiratory muscle strength is monitored in patients with confirmed or suspected Guillain-Barré syndrome. Predictive indicators for requirement of invasive ventilation are cranial nerve involvement, infection in the preceding 8 days, time from onset of weakness to admission less than 7 days, inability to stand, inability to lift elbow above head, inability to lift head off the pillow, and ineffective cough. Respiratory muscle strength commonly is assessed by serial VC and mouth pressure measurements, for which a declining trend is indicative of impending ventilator failure.

The “20-30-40” rule often is applied in clinical practice, with the combination of a VC less than 20 mL/kg, a maximum inspiratory pressure above −30 cm H_2O, and maximum expiratory pressure below +40 cm H_2O indicating the onset of respiratory failure. A clinical challenge is in maintaining an adequate mouth seal in patients with bulbar involvement, and a full face mask can be attached to the spirometer or pressure monitor to ensure optimal delivery of ventilatory support. A minority of patients, mainly those in their seventh and eighth decade of life with significant bulbar involvement, fail to wean from invasive mechanical ventilation, and these patients will require long-term tracheostomy ventilation.

IATROGENIC DISEASE

Critical Illness Neuromyopathy

Diaphragm weakness is observed in animals exposed to prolonged mechanical ventilation with concomitant use of neuromuscular blocking agents, and a similar observation has been reported in humans, albeit with complete denervation as a result of brain stem death. The importance of ventilator-induced diaphragm dysfunction more generally in critically ill patients remains unclear, although most studies have observed that the nonvolitional twitch transdiaphragmatic pressures are low compared with those obtained in healthy normal subjects.

Although no direct correlation has been found between twitch transdiaphragmatic pressure and duration of mechanical ventilation, previous studies have shown that weaning failure was observed in patients who undergo changes in pulmonary mechanics during a weaning trial such that the respiratory muscle load exceeds the capacity.

Peripheral skeletal muscle weakness associated with critical illness, or intensive care unit–acquired weakness, is beyond the scope of this chapter, but an increasingly abundant literature is accumulating in this important clinical area.

Phrenic Nerve Injury

Anatomically, the phrenic nerve is a long nerve measuring 30 to 40 cm and follows a tortuous path from the cervical spine to the diaphragm, predisposing the nerve to injury. In clinical practice, the most common cause of injury is cardiac surgery, particularly when iced slush has been used for cardioplegia. Other causes of phrenic nerve injury must be considered in patients who have undergone anterior cervical surgery (e.g., thymectomy), internal jugular line central venous access cannulation, and cervical radiotherapy.

CHRONIC DISORDERS AFFECTING THE PERIPHERAL NERVES

Neuralgic Amyotrophy

Neuralgic amyotrophy is a syndrome that classically manifests with a relatively sudden onset of muscle weakness and wasting, which may involve the upper limbs or the diaphragm, or both. In addition to the symptoms of dyspnea on exertion, dyspnea on leaning forward, dyspnea on immersion in water, and orthopnea, there can be associated pain in the appropriate dermatome—in particular, shoulder tip or shoulder blade pain. Previous data have shown that one third of patients with diaphragm paralysis will recover completely, one third will have a partial recovery, and one third will have no recovery at all. This recovery can take between 2 and 5 years. A rare familial syndrome exists, and the clinician should consider this as a cause as well as the rare presentation of a more generalized neurologic condition, such as motor neuron disease, or phrenic nerve palsy due to mediastinal compression from some other cause, such as lymphadenopathy.

Hereditary Motor and Sensory Neuropathy (Charcot-Marie-Tooth Disease)

Hereditary motor and sensory neuropathy (i.e., Charcot-Marie-Tooth disease) is a spectrum of disorders resulting from a genetic mutation in one of many myelin genes. The condition is inherited in an autosomal dominant or recessive pattern, depending on the disorder. It is a chronic degenerative process of the peripheral nerves that results in distal weakness. Phrenic nerve involvement with consequent respiratory failure is a recognized complication but is relatively infrequent.

ACUTE NEUROMUSCULAR JUNCTION DISORDERS

Botulism

Botulism is caused by the neurotoxin produced by the gram-positive anaerobic bacteria, *Clostridium botulinum*. The toxin is absorbed after ingestion, through infantile colonization of the gastrointestinal tract, or through a skin wound, commonly in association with intravenous or subcutaneous drug abuse. The toxin results in an acute presynaptic blockade of the cholinergic neuromuscular junction, leading to a life-threatening generalized paralysis. Mortality is reduced with rapid initiation of invasive ventilatory support, which may be prolonged over many months. Most patients achieve a full recovery, but the respiratory muscles can be slow to recover, and mild respiratory muscle weakness may persist indefinitely.

CHRONIC NEUROMUSCULAR JUNCTION DISORDERS

Myasthenia Gravis

Myasthenia gravis is the most common condition associated with interruption of neuromuscular signaling, but the disorder remains rare, with a prevalence of approximate 15 to 20 cases per 100,000 population. It is caused by antibodies against the acetylcholine receptor in the post synaptic nerve terminal. Patients typically present with a fluctuating muscular weakness that progresses with fatigue of the muscles, which classically is described as most pronounced toward the end of the day. Ocular and bulbar symptoms are the most common manifestations, but respiratory weakness also can occur and occasionally may be a presenting symptom of the condition. Acute respiratory failure can occur in a myasthenic crisis that may be precipitated by factors such as infection and surgery.

The mainstay of treatment is immunosuppression and use of cholinesterase inhibitors, although care must be taken to achieve an optimal balance, because excessive cholinergic blockade can result in issues with increased bronchial secretions or frank cholinergic block of the respiratory muscles. Despite appropriate treatment, a proportion of patients exhibit nocturnal hypoventilation, which will be exacerbated by steroid-induced weight gain.

Thymoma commonly is associated with the myasthenic syndrome, and clinicians must be aware that after thymectomy, acute respiratory failure may occur. Diagnostic considerations in this setting include both postoperative myasthenic syndrome, although risk for this syndrome should be much less after surgery, and phrenic nerve damage incurred during the procedure, because the nerve can be embedded in the tumor, with consequent intentional or unintentional resection.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome is a rare condition that affects the release of acetylcholine and reduces neuromuscular signaling at the neuromuscular junction. The disease is caused by antibodies directed against voltage-gated calcium channels. These channels regulate the flow of calcium required for the release of acetylcholine in the presynaptic nerve terminals. The condition is suggested by the presence of proximal muscular weakness, reduced or absent reflexes, and autonomic signs and symptoms such as a dry mouth. A unique feature is the recovery of reflexes and muscle strength with maximal isometric muscular activity and an increase in muscle action potential amplitude observed on repetitive nerve stimulation. Respiratory muscle weakness is uncommon as a presenting feature; more frequently, it occurs late in the disease process. The condition has a strong association with malignancy—in particular, small cell lung cancer, which coexists in up to 50% of cases.

ACUTE MUSCLE DISORDERS

Corticosteroid-Induced Respiratory Myopathy

Corticosteroid-induced myopathy involving the quadriceps is relatively commonly encountered as a consequence of extensive use of corticosteroid treatment for any of various inflammatory and autoimmune conditions. Current available evidence, however, suggests that this is rarely a problem with the respiratory muscles.

Rarer Causes of Acute Myopathy

Myopathy may be associated with many different endocrine and biochemical abnormalities. Commonly, severe hypokalemia causes a rapidly progressive myopathy predominantly affecting proximal muscles. Malabsorption of essential vitamins, such as vitamin D and vitamin E, also may result in a milder generalized myopathy. Hypothyroidism and hyperthyroidism, adrenal insufficiency, and Cushing disease also are associated with myopathy. This can occur at any point in the disease course but occasionally are the presenting manifestation, although such disorders generally are identified in the context of other systemic features. These myopathies rarely involve the respiratory muscles, but if ventilatory failure does occur, their management is supportive while the underlying abnormality is corrected.

CHRONIC MUSCLE DISORDERS

Duchenne Muscular Dystrophy

DMD is an X-linked inherited condition arising from a mutation in the dystrophin gene. It affects males from early childhood, with an incidence of 1 in 3000 births. The decline in function in DMD manifests as a proximal to distal limb muscle weakness, leading to wheelchair dependency by the early teenage years and to respiratory muscle weakness with progression. Respiratory failure is the major cause of death in this group of patients, although mortality also may be associated with the dilated cardiomyopathy that can occur in the absence of respiratory muscle weakness.

As with other progressive neuromuscular conditions, respiratory muscle weakness progresses gradually. The deterioration in respiratory function within these groups manifests initially as nocturnal hypoventilation in REM sleep and progresses to hypoventilation in REM and non-REM sleep and finally to daytime hypercapnia and chronic respiratory failure. This progression in chronic respiratory failure is associated with increasing sleep disturbance, frequency of chest infections, hospital admissions, and deteriorating quality of life. The monitoring of respiratory muscle strength and VC in these patients is a key clinical assessment. VC decreases from the age of 10 years, and a VC of less than 1 L confers a poor prognosis, with mean survival of approximately 2 years without ventilatory support. The presence of scoliosis in these patients may accelerate this process. Mean survival with the onset of chronic respiratory failure is 9.7 months if home nocturnal noninvasive ventilation is not initiated. Although the prophylactic use of home nocturnal noninvasive ventilation before the onset of chronic respiratory failure is controversial, most authorities support the view that noninvasive ventilation brings improvements in gas exchange, normalization of sleep patterns, enhanced quality of life, and prolonged survival. A more recent study indicates that nocturnal ventilatory support should be considered when patients develop nocturnal hypoventilation, and without home noninvasive ventilation, progression to chronic diurnal hypercapnic respiratory failure occurs within 18 months.

Respiratory support also will include secretion clearance, specifically during any episode of pneumonia, with the introduction of a mechanical insufflation-exsufflation device to enhance cough function and secretion management (see earlier under "Cough Peak Flow"). As bulbar function declines, in addition to a reduction in effective cough, patients will be at increased risk for aspiration, and these swallowing problems reduce nutritional intake, resulting in weight loss. Early gastrostomy feeding tube insertion, accomplished with endoscopic or radiologic guidance, is recommended, although evidence supporting this practice is limited. It is possible, with appropriate expertise, to do such procedures with sedation using noninvasive ventilation alone in patients with established respiratory failure.

Other Muscular Dystrophies

Becker muscular dystrophy follows a clinical course similar to that for DMD but typically is of much later onset, with much milder clinical effects. Patients remain ambulatory until the late teenage years, and the degree of respiratory muscle involvement is less. Toward the later stages of the disease, in the fourth decade of life, respiratory failure can develop, and noninvasive ventilation may be required. Facioscapulohumeral muscular dystrophy also is a slowly progressive condition of autosomal dominant inheritance that affects muscles of the face, arms, and shoulders. In approximately 20% of the patients, chest wall and diaphragm involvement may result in respiratory decline necessitating ventilatory support.

Myotonic Dystrophy

Myotonic dystrophy is inherited as an autosomal dominant trait that exhibits generational anticipation. It is a multisystem disorder characterized by features of myotonia (delayed muscle relaxation), progressive skeletal muscle weakness, cardiac conduction deficits and cardiomyopathy, cataracts, frontal baldness, ptosis, testicular failure, hypogammaglobulinemia, and diabetes mellitus. Sleep-disordered breathing is common, with nocturnal hypoventilation and progressive hypercapnia resulting from respiratory muscle weakness and impaired neural respiratory drive. Central and obstructive sleep apnea also may occur as a consequence of upper airway muscular weakness and myotonia. Ventilatory support should be offered on the basis of patient symptoms and arterial carbon dioxide levels. Unfortunately, patients frequently find it difficult to use nocturnal ventilatory support, in part because only a limited symptomatic response is obtained, with persisting daytime somnolence as a consequence of the primary hypersomnolence that accompanies this condition.

Other Rarer Myopathies

Congenital myopathies are a group of inherited disorders of muscle that typically manifest with generalized muscle weakness in infancy. A muscle biopsy is required to characterize the type of myopathy. All patients present with hypotonia and a predominant proximal muscular weakness. The severity of the muscle impairment depends on the individual genetic mutation. A majority of the patients require mechanical ventilation from early life and do not survive childhood.

Metabolic myopathies constitute a heterogenous group of disorders that are related to a deficit in the metabolic pathways of the muscle. Among such disorders, the most common are the glycogen storage diseases. From a respiratory perspective, the most important metabolic myopathy is acid maltase deficiency, because respiratory muscle weakness can be the primary presentation of the condition in the adult-onset form. Treatment is supportive, as with the other myopathic conditions, although enzyme replacement therapy may have a role in slowing the onset of chronic respiratory failure.

Mitochondrial myopathies result from dysfunction of mitochondrial ability to release energy form adenosine triphosphate

(ATP). The clinical manifestations are highly variable but can include respiratory failure.

Idiopathic inflammatory myopathies, including dermatomyositis and polymyositis, manifest with muscular weakness due to inflammatory destructive processes directly affecting the muscle fibers and their blood supply. Dermatomyositis is characterized by typical skin manifestations such as Gottron's papules on the hands and feet and a heliotropic rash over the eyelids and can be associated with malignancy. The muscular weakness may rarely result in respiratory failure. These inflammatory myopathies are associated with interstitial parenchymal lung disease in approximately 20% of cases. Such disease can be rapidly progressive and frequently is fatal.

THORACIC DISORDERS

Chest wall deformities, such as kyphosis, scoliosis, and kyphoscoliosis, and obesity hypoventilation syndrome are described in detail in Chapters 63 and 62, respectively. Obesity itself also has clinical consequences for pulmonary function, and an overview of this issue is presented next, with specific emphasis on pulmonary function tests, pulmonary mechanics, hypercapnic ventilatory response, and respiratory muscle strength.

OBESITY

Clinical Consequences of Obesity

Within the Western world, a well-recognized major public health problem is the growing epidemic of obesity. Although the definition of obesity includes a requirement for a body mass index (BMI) greater than 30 kg/m^2, clinicians are now encountering increasing numbers of patients who are *morbidly obese* (i.e., with a BMI greater than 40 kg/m^2), and more recently, the term *superobese* (BMI greater than 50 kg/m^2) has been adopted to further characterize this patient group. In the United Kingdom, an estimated 25% of the population is obese, with superobesity increasing dramatically over the past decade. By current estimates, superobesity affects 1 in 230 adults in the United States.

With this obesity epidemic, patients are presenting more frequently to respiratory medicine departments and chest clinics with exercise-induced dyspnea, obstructive sleep apnea, and nocturnal hypoventilation necessitating ventilatory support. Observational data on hospitalized obese patients indicate that up to one third of those with a BMI greater than 35 kg/m^2 have hypercapnic respiratory failure.

Respiratory Muscle Pump in Obese Patients

It is hypothesized that breathlessness and alveolar hypoventilation in obese patients result from an imbalance between respiratory muscle load and/or capacity and neural respiratory drive, although the exact pathophysiologic details are yet to be determined. Respiratory muscle capacity, albeit estimated using volitional PImax and PEmax measurements, was found to be reduced in hypercapnic obese patients compared with eucapnic obese patients. However, direct measurement of diaphragm strength, using Pdi$_{max}$, demonstrated no difference between eucapnic and hypercapnic obese patients, indicating that diaphragm weakness does not contribute to the development of ventilatory failure in obese patients. By contrast, a difference is seen in respiratory muscle load between hypercapnic obese patients and eucapnic obese subjects with greater upper airway resistance in both sitting and supine positions and reduced respiratory system compliance. This increasing load on the respiratory muscles results in a reduction in lung volumes, with a reduction in FEV$_1$ and FVC and an elevated FEV$_1$/FVC ratio confirming a restrictive defect. In addition, TLC, expiratory reserve volume (ERV), and FRC are all reduced. Of interest, these reductions are more marked in obese patients with hypercapnic respiratory failure than in eucapnic obese subjects with a matched BMI. It is appreciated that in addition to absolute fat load, the distribution of the fat is important in determining the severity of lung restriction.

The obese patient breathes at a lower lung volume, which reduces chest wall and lung compliance. Breathing at a lower lung volume also results in closure of the small airways during early expiration, causing expiratory airflow limitation and development of intrinsic positive end-expiratory pressure (PEEPi). This phenomenon is exacerbated by adoption of a supine position, such as occurs during sleep. It has been shown that in obese patients, moving from a sitting to supine posture is associated with an increase in neural respiratory drive, as measured by the diaphragm electromyogram, with a corresponding increase in diaphragm pressure generation, as measured from transdiaphragmatic pressure swings, but without a corresponding increase in tidal volume. Furthermore, these patients develop PEEPi on change in position, indicating expiratory flow limitation, although it is difficult to separate whether this is a consequence of early airway closure during expiration or upper airway obstruction, or a combination of both mechanisms. More studies in this area are required to confirm the previous data demonstrating changes in hypercapnic ventilatory response in obese hypercapnic patients. These previous studies have shown that obese hypercapnic patients, compared with eucapnic obese subjects, have reduced hypercapnic ventilatory response as a consequence of an inadequate ability to increase tidal volume, resulting in dead space ventilation. Such research will allow investigators to define the pathophysiologic cause of alveolar hypoventilation in obese patients.

CONTROVERSIES AND PITFALLS

Respiratory muscle weakness is a common complication in many neuromuscular and chest wall conditions, and although it may occasionally be a presenting feature of the underlying disorder, it generally is a complication of an already established diagnosis. In view of the impact of chronic respiratory failure on health-related quality of life and the potential life-threatening consequences of respiratory muscle weakness, respiratory muscle function should be monitored at regular intervals with noninvasive respiratory muscle tests in patients with progressive neuromuscular disease. Furthermore, patients with neuromuscular disease or chest wall disease, or both, who present with unexplained dyspnea should be referred for formal respiratory assessment. This evaluation will include a detailed history and clinical examination with a focus on symptoms suggestive of significant muscle weakness, sleep-disordered breathing, and associated complications such as bulbar symptoms. Other components of the evaluation will include a basic lung volume measurement, noninvasive respiratory muscle testing, and, in special circumstances, invasive respiratory muscle testing. It is well to be mindful, however, of the limitations of performing a single measure of respiratory muscle strength in attempting to diagnose respiratory muscle weakness. Previous data have demonstrated that isolated sniff inspiratory nasal pressure often overdiagnosed the severity of weakness in patients with severe restrictive ventilator deficits from neuromuscular disease. Accordingly, for an accurate assessment of respiratory muscle strength, performing an array of noninvasive tests of respiratory muscle function, such as Pn_{sn}, PImax, and PEmax, is recommended.

With these clinical data, the timing of initiation of noninvasive ventilation can be planned. In patients with neuromuscular and chest wall disease, recent data suggest that chronic respiratory failure will occur 18 to 24 months after the onset of nocturnal hypoventilation. This will be the time to consider the introduction of noninvasive ventilation, and for those patients who are relatively asymptomatic at this stage and are reluctant to pursue noninvasive ventilation, close monitoring of clinical status is indicated. In addition to ventilatory strategies, clinicians must consider other respiratory adjunctive measures, such as physiotherapy techniques and the use of devices including mechanical insufflation-exsufflation devices for patients with neuromuscular disease in whom poor cough function has been documented.

Finally, clinicians need to be cognizant of the rising trend in obesity and of its negative effects on respiratory function. Thus far, no prospective randomized controlled trials have been conducted to determine an optimal ventilation strategy for treating obesity hypoventilation syndrome. A single-center randomized controlled trial of selected patients with obesity hypoventilation showed equivalence between continuous positive airway pressure and noninvasive ventilation, leading consensus opinion to advocate noninvasive ventilation in patients for whom continuous positive airway pressure has not achieved symptom control. With the increasing incidence of superobesity, it is clear that further research in this area is urgently required.

LUNG TUMORS

Chapter 65
Lung Cancer: Epidemiology, Surgical Pathology, and Molecular Biology

Arnold M. Schwartz • M. Katayoon Rezaei

EPIDEMIOLOGY

INCIDENCE AND SURVIVAL

Lung cancer currently is the highest cause of cancer mortality in the United States and even surpasses the sum of the next four cancer types in both men and women. In terms of incidence, (the number of new cases of cancer in a given year), lung cancer is second only to breast cancer in women and prostate cancer in men. In the United States, estimates of new cases of lung cancer for 2010 were approximately 116,000 in men and 105,000 in women, with approximately 160,000 deaths. Lung cancer deaths accounted for 31% and 27% of overall cancer deaths in men and women, respectively, and are more numerous than deaths due to breast, prostate, and colon cancers combined. In terms of overall causes of death in men, lung cancer is the second most common cause of death, after vascular disease, with deaths due to heart attacks and stroke. The overall 5-year lung cancer survival rate is between 15% and 20% as a consequence of its late stage at onset of symptoms and relatively aggressive clinical behavior. Like other malignancies, lung cancer is a disease of aging, with increasing rates in persons older than 50 years of age, and rarely is diagnosed in those younger than 40 years. Graphing lung cancer incidence according to chronologic age of diagnosis on a logarithmic scale demonstrates a straight line for both men and women, indicating that the carcinogenic pathways probably are similar for both genders and that steroid hormones (estrogen and androgens) do not play a major role in carcinogenesis.

Lung cancer more typically is present in men than in women, and in African Americans than in white Americans; these disparities in incidence probably are due to smoking patterns. The disparity extends to younger persons as well; young African American men and women have significantly higher lung cancer rates than their white counterparts. The incidence of lung cancer in adult African American and in white American male adults in 2008 was 101 and 69 per 100,000, respectively. Both African American and white American women had similar cancer incidences of approximately 55 cases per 100,000. Other ethnic and racial groups, such as Hispanic persons, Native Americans, and Asian or South Pacific Americans have a lower incidence than that for white Americans.

Lung cancer incidence is highest in the developed nations of North America (United States and Canada), the European Union, and countries of the former Soviet Union, where cigarette availability and smoking rates are highest. In 2008, lung cancer was diagnosed worldwide in approximately 1.6 million people and led to cancer deaths in 1.4 million, and a majority of new cases are reported from China and less developed countries. Since the 1970s, lung cancer incidence has been decreasing in the United States, Canada, United Kingdom, and Australia but has been increasing in Japan and India. Unfortunately, during this same time, lung cancer incidence has been increasing among women in the United States, Canada, Denmark, Norway, and Sweden. Worldwide, lung cancer incidence is more than double for men relative to women, and the relative risk is even higher in Western Asia, Central and Southern America, and Southern Africa.

Although lung cancer is increasing in large developing nations, such as China and India, the socioeconomic demographic features are important in appreciating lung cancer incidence. The risk of lung cancer is inversely associated with education and income and appears to be more closely linked to smoking than risk of disease from occupational or environmental exposures. Data from developing nations are not as robust and accurate as those from Western countries, and analysis of the socioeconomic setting of smoking also involves confounding variables, such as local diet and environmental carcinogens and inhalant exposures.

When the mortality rates (deaths due to disease within a calendar year) for lung cancer in women and men are plotted against the calendar years for the last 50 years, one notes a marked difference in the pattern of the curves (**Figure 65-1**). The incidence rates for men show a marked rise from the early 1950s to the beginning of the 1990s, whereas rates for women lag by about a quarter of a century and then show an identical rise, essentially parallel to those for men, and continuing into the 21st century. By the 1950s, death due to lung cancer far exceeded prostate and colon cancer deaths among men, and by 1990, lung cancer deaths among women exceeded breast and gynecologic cancer deaths. Usually cancer mortality follows cancer incidence; however, in the case of lung cancer, owing to the very high cancer fatality rate (mortality from cancer for persons given a diagnosis of cancer), lung cancer mortality exceeds the most common cancers in both men and women. As a result of the Surgeon General's 1964 report on smoking, men began to stop smoking in the succeeding 20 to 30 years; the incidence and mortality of lung cancer began to decline from a peak in the early 1990s to a level that approximates the mortality rate of the 1970s. The phenomenon of social smoking among women lagged behind that for men; subsequently, both the incidence of lung cancer in women and its associated mortality continue to rise into the present day.

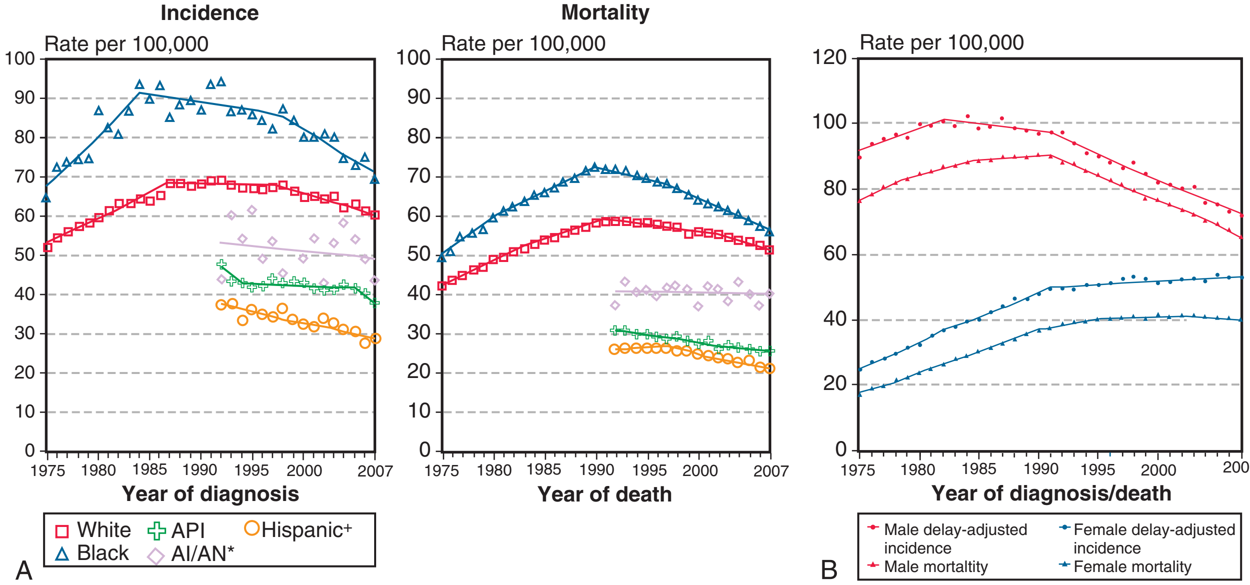

Figure 65-1 **A,** SEER incidence and U.S. death rates for cancer of the lung and bronchus (men and women). Joinpoint Regression analyses for whites and blacks from 1975 to 2007 and for Asian/Pacific Islanders, American Indians/Alaska Natives, and Hispanics from 1992 to 2007. *API*, Asian Pacific Islander; *AI/AN*, American Indian/Alaska Native. **B,** SEER-delay adjusted rates for cancer of the lung and bronchus mortality differences among men and women of all races in the United States (1975-2007). *SEER*, Surveillance, Epidemiology, and End Results [Program]. *(A, Incidence data for whites and blacks are from the SEER nine areas—San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, Atlanta. Incidence data for Asian/Pacific Islanders, American Indians/Alaska Natives, and Hispanics are from the SEER thirteen areas—the SEER nine areas plus San Jose-Monterey, Los Angeles, Alaska/Native Registry, and Rural Georgia. Mortality data are from U.S. mortality files, National Center for Health Statistics, Centers for Disease Control and Prevention [CDC]. Rates are age-adjusted to the 2000 U.S. standard population [19 age groups, Census P25-1103]. Regression lines are calculated using the Joinpoint Regression program Version 3.4.3, April 2010, National Cancer Institute. Joinpoint analyses for whites and blacks during the 1975-2007 period allow a maximum of 4 joinpoints. Analyses for other ethnic groups during the period 1992 to 2007 allow a maximum of 2 joinpoints. *Rates for American Indians/Alaska Natives are based on the contract health service delivery area [CHSDA] counties.* †Hispanic *is not mutually exclusive of whites, blacks, Asians/Pacific Islanders, and American Indians/Alaska Natives. Incidence data for Hispanics are based on the NHIA [North American Association of Central Cancer Registries/NAACCR Hispanic Identification Algorithm] and exclude cases from the Alaska Native Registry. Mortality data for Hispanics exclude cases from Connecticut, the District of Columbia, Maine, Maryland, Minnesota, New Hampshire, New York, North Dakota, Oklahoma, and Vermont. B, Data from SEER nine areas and U.S. mortality files [National Center for Health Statistics, CDC]. Rates are age-adjusted to the 2000 U.S. standard population [19 age groups, Census P25-1103]. Regression lines are calculated using the Joinpoint Regression Program Version 3.4.3, April 2010, National Cancer Institute [http://seer.cancer.gov/statfacts/html/lungb.html].*

Although *lung cancer* typically refers to the malignant bronchogenic epithelial tumors of the lung, namely, squamous cell carcinoma, adenocarcinoma, large cell carcinoma, and small cell (neuroendocrine) carcinoma, the relative incidence, distribution, and frequency of these tumors over time are characterized by marked differences. In the 1970s, squamous cell carcinoma predominated in incidence over the other bronchogenic carcinomas. Of interest, the age-adjusted incidence rate of adenocarcinoma, among both men and women, continued to rise, so that beginning in the late 1990s and continuing into the early 2000s, adenocarcinomas have become the most frequently encountered lung cancers. The two histologic subgroups of lung cancer most strongly associated with smoking, squamous cell carcinoma and small cell carcinoma, have shown a decrease in their overall incidence, reflecting the trend of decreased cigarette smoking among men. The relative percentages of the major lung cancer histologic types are adenocarcinoma 38%, squamous cell carcinoma 20%, small cell (neuroendocrine) carcinoma 13%, and large cell carcinoma 5%. The remainder are composed of variant carcinomas, sarcomatoid (spindle cell) carcinomas, salivary-type carcinomas, neuroendocrine-carcinoid carcinomas, and others.

The histologic sequence eventuating in squamous cell carcinoma begins with smoking-induced replacement of respiratory epithelium with bronchial squamous metaplasia. Additional cellular and molecular events lead to squamous dysplasia, in situ carcinoma, and ultimately, invasive squamous cell carcinoma. Small cell carcinoma does not have a clearly defined precursor lesion, although it is presumed to be the Kulchitsky cell; however, small cell carcinomas often arise in a setting of squamous metaplasia and dysplasia, indicative of the effects of the smoking environment. Adenocarcinoma, a histologic subtype characterized by formation of malignant-appearing glands, papillae, and intracytoplasmic mucin, also arises in the context of cigarette smoking, yet approximately 25% of lung cancer cases are not attributable to direct smoking. These tumors typically are located peripherally and may be associated with scars that in some cases may be preexisting but also may represent a host desmoplastic response to the tumor. As a histologic subtype, adenocarcinomas of the lung continue to increase in incidence among both men and women.

ETIOLOGY AND RISK FACTORS

The major risk factor associated with lung cancer in a majority of cases is cigarette smoking. The probability that a diagnosis of lung cancer will be made in a nonsmoker is less than 15%. The case for cigarette smoking as a major cause of lung cancer is made by strong epidemiologic evidence and by significant results of animal studies. Both case-control and cohort studies have demonstrated the strong association of smoking with lung cancer and have shown that the association is dose-dependent and linked to current versus past smoking behavior. Initial case-control studies investigating retrospective reviews of smoking behavior in groups with and without lung cancer calculated odds ratios of approximately 10 : 1 for smoking associated lung cancers. Later, longitudinal cohort studies demonstrated mortality ratios averaging 10 : 1 for lung cancer deaths in the group of smokers relative to nonsmokers. Moreover, the annual incidence of lung cancer showed a logarithmic relationship with age and duration of smoking. Mortality ratios also demonstrated a dose-response relationship with the number of cigarettes smoked per day. In general, smokers have a 70% increase in mortality relative to nonsmokers.

Cigarette smoking is associated with all the histologic types of bronchogenic carcinoma, however, as discussed above, adenocarcinoma, a smoking related cancer, is also the most common type among nonsmokers. Although a history of many pack-years of cigarette smoking is strongly linked to lung cancer, only a minority of smokers develop lung cancer, suggesting that host biologic and genetic factors may modulate carcinogenic pathways in the development of lung cancer. The clinical history of current or past cigarette smoking also affects the probability of developing lung cancer, with the incidence of lung cancer in heavy smokers more than twice that in light smokers, and more than five-fold that in ex-smokers. Not only is cigarette smoking a risk factor for the development of lung cancer; it is also a predictor of disease recurrence after lung cancer resection in early stage disease. The 5-year overall survival rate for smokers relative to nonsmokers with stage I lung cancer is, respectively, 76% and 92%. There is a modest but real effect of lung cancer attributable to passive or environmental tobacco smoke, based on an update of the Surgeon General's report. Nonsmokers married to smokers incur an approximate 25% relative increase over nonexposed nonsmokers for the induction of lung cancer but of course significantly less than that for active smokers.

In addition to the dominant effect of cigarette smoking, other occupational and environmental conditions are associated with an increased risk of lung cancer. The most well-accepted industrial agents associated with lung cancer are asbestos, hexavalent chromium(VI), arsenic, nickel, and polycyclic aromatic hydrocarbons. Ionizing radiation exposure, as experienced after the atom bomb explosion in Japan (1945), in uranium mining, and with radon encountered in industrial and home settings, also shows hazard rates for lung cancer similar to those for environmental or second-hand cigarette smoke. In persons exposed to industrial chemicals and who also smoke, a synergistic effect may be operative in the development of lung cancer.
